In the section on diseases of the liver and gall bladder it is somewhat surprising to find that while the author mentions pneumonia as a cause of disordered hepatic function—although he admits that this rarely amounts to more than "transient functional disturbance of the cells"—no reference is made to the much more serious effects of eclampsia, hyperemesis gravidarum, actinomycosis, abscess formation secondary to appendicitis or gastric ulcer, or even Banti's disease—none of which are very uncommon conditions. No criticism can be levelled at the non-inclusion in this connection of *Entamoeba histolytica* infections, malaria, kala-azar or yellow fever, as the book is not intended for workers in tropical zones.

The investigation of the cerebro-spinal fluid finds no place in that portion of the book devoted to examination of the central nervous system. In the reviewer's opinion, such an examination is as important in certain neurological conditions, as is the investigation of the Van den Bergh reactions in jaundice—a subject to which the author allots roughly two pages. In this

connection also it may be noted that while tabes dorsalis is described in fairly considerable detail, general paralysis of the insane is not even mentioned.

It is a relief to find that Dr. Carmalt Jones classifies chronic nephritis in the only rational manner—viz., into chronic "azotæmic" nephritis in which nitrogen retention is the main feature while salt excretion is little if at all affected, and chronic "hydræmic" nephritis in which the converse, generally speaking, holds true. The lot of the unfortunate student who even now has to make his way painfully through a maze of "large white kidneys," "small white kidneys," "small red kidneys," "granular contracted" and "arterio-sclerotic kidneys" is only one degree less miserable than that of the unfortunate possessors of these faulty organs of excretion.

Finally, the question of a few more diagrams might be considered in future editions. In the section dealing with the nervous system, for example, it is difficult, for the beginner at least, to visualize the course of the more important sensory and motor tracts without some such aid. No doubt the type of reader for whom this book is intended should not have forgotten entirely his anatomy and physiology—but then, man is a weak vessel.

The success of this book seems assured; it will prove of considerable value to the student starting hospital work, for it bridges admirably that gap which at first sight appears to exist between the principles taught in the physiological laboratory and the application of these principles to clinical conditions met with at the bedside and in the outpatient department.

Printing and finish of the volume are of the standard of excellence that we have come to associate with the well-known publishing house responsible for its production.

J. M. H.

AIDS TO MEDICINE.—By James L. Livingstone, M.D. (Lond.), M.R.C.P. (Lond.). 4th edition. London: Baillière, Tindall & Cox. 1929. Pp. X plus 414, with 3 figures in the text. Price 5s. net.

THE amount of useful, and in the main, up-to-date and accurate information that the author of this small book has succeeded in compressing into the narrow compass of 414 pages, each measuring only 6½ inches by 4½ inches, is indeed remarkable.

True it is that the sharp staccato style has at times an effect on the nerves roughly comparable to a sudden burst of machine-gun fire at close range, but the reader is presumed to have been broken-in by a previous sustained bombardment from some of the more recondite "heavies."

The only section with which the reviewer has any fault to find—and it is one that is common even in large textbooks of medicine—is that dealing with tropical diseases. For example, the information regarding leprosy and leishmaniasis is out of date: no mention is made of the diagnostic methods employed in either disease, and the treatment of kala-azar has not proceeded beyond the tartar emetic epoch. There is no reference to plasmochin in the treatment of malaria and in the same connection Fig. 1 entitled "Scheme of the Cycle of Evolution of the *Plasmodium malariae*" is poor.

To those working outside the tropics the book should prove of considerable value as a handy and reliable work of ready reference: the very reasonable price brings it within the reach of all practitioners.

J. M. H.

THE SENSORY AND MOTOR DISORDERS OF THE HEART: THEIR NATURE AND TREATMENT.—By Alexander Blackhall-Morison, M.D., F.R.C.P. 2nd edition. London: Baillière, Tindall and Cox. 1928. Pp. 362, with 113 figures in the text. Price 18s. net.

In this volume the late Dr. Alexander Blackhall-Morison has recorded his observations, which will be of interest not only to the cardiologist and physiologist

but also to the general practitioner who wants to thoroughly understand the subject. In the preliminary chapters the author deals with the development and minute anatomy of the heart and in the next two parts the sensory and motor disorders of the heart are fully described. The pathology of the cardiac pain is carefully considered, and this section is of great help in clearly understanding the clinical history of the pain, whilst the discussion as to the seat of the pain in conditions like angina pectoris is also helpful. All this enables one to comprehend and appreciate the line of treatment to be followed. The recent advances in surgery in combating such conditions as angina pectoris are also very fully considered.

The motor disorders of the heart are classified in a simple manner and considered in detail; the physiological facts and clinical observations are correlated and put lucidly before the reader. The histories of cases given to illustrate the points the author wants to bring home to the reader are very instructive. The chapters on treatment give most of the methods that are at present employed in the treatment of motor disorders of the heart. The book is thoroughly practical and will be of great interest to those who are called upon to treat patients suffering from cardiac disease and also to those experimental physiologists who want to understand the symptoms of a patient in the light of their laboratory findings.

R. N. C.

ON NEPHRITIS.—By A. Cecil Alport, M.D. (Edin.), M.R.C.P. (Lond.). London: William Heinemann (Medical Books) Ltd. 1929. Pp. XVI plus 175. Price 7s. 6d. net.

DURING recent years one of the developments in medical literature has been the production of small books which attempt to give the reader a concise and comprehensive review of a particular subject or disease.

In this book Dr. Alport has succeeded admirably in describing all the important aspects of a very difficult subject.

All medical students find a peculiar difficulty in understanding the various pathological conditions and clinical symptoms which they are told are caused by one or other of the forms of nephritis. The popular medical textbooks do not seem to be able to help them to obtain a clear view of the subject. Such problems as the causation of œdema and the pathology of uræmia are only understood with great difficulty by the average student. The application of the modern renal efficiency tests and the interpretation of the results obtained have added a great deal to our knowledge, but have made the diseases still more complicated from the student's point of view.

Dr. Alport has reviewed the whole subject in 150 pages. Starting with a historical summary, he then gives us a classification of the types of nephritis. There have been many classifications, and much heated argument between the pathologists and the clinicians in the past. The classification given here may not satisfy all, but it is based on our most recent knowledge and is as simple as possible. The pathology, symptoms and treatment of each type are then described clearly, and the importance of the renal efficiency tests is emphasised.

The subject of uræmia receives a chapter to itself, and there is also a very excellent chapter on the ophthalmology of nephritis. The technique of the various tests is described, and a salt concentration test, as carried out by the author, receives special attention.

There is a very useful pharmacopœia, a full bibliography, and a complete index.

This book cannot fail to be of great use to the medical student, and to the practitioner who at present feels that he does not grasp the details of this difficult subject.

H. H.

BLOOD AND URINE CHEMISTRY.—By R. B. H. Gradwohl, M.D., and Ida E. Gradwohl, A.B. St. Louis: The C. V. Mosby Company. 1928. Pp. 542, with 117 illustrations and 4 colour plates. Price \$10.0 net.

This book which is well got up and excellently printed is stated to be a textbook for laboratory workers and practitioners of medicine. It is further illustrated with four colour plates and one hundred and seventeen illustrations. The contents of the volume are divided into four parts. Part I deals with the technique of blood chemical examinations and extends over sixteen chapters. This part we consider is over-illustrated and makes rather dull reading, though undoubtedly the detailed descriptions of various methods of analysis is of value to the pure laboratory worker, but it is not so likely to appeal to the general practitioner. Part II is devoted to the chemistry of the urine and here we consider that there is a great improvement in the presentation of the subject-matter, which is not only up to date but also of great interest to both laboratory worker and practitioner alike. At the end of this section a chapter is devoted to the bacteriological examination of the urine, a subject that appears rather out of place in a book dealing with chemistry. Part III deals with the interpretation of blood chemical findings. This part of the book is of great interest and well worthy of study; the accounts are full and dealt with practically, and should be read by every practitioner interested in modern methods of laboratory practice, dealing as it does with diabetes, nephritis, gout, etc. The consulting physician, surgeon and gynaecologist will also find much in this section of value. The last section of the book deals with basal metabolism. Undoubtedly this book will appeal to the laboratory worker and should prove of value and help to the general practitioner in working out the various problems with which he is daily confronted.

T. C. B.

MEDICAL ADVENTURE: SOME EXPERIENCES OF A GENERAL PRACTITIONER.—By Dr. Ernest Ward, M.D., F.R.C.S. London: John Bale, Sons and Danielsson, Ltd. 1929. Pp. XII, 291. Price 8/6 net.

HITHERTO the general practitioner has taken too literally the admonition of Sir Thomas Browne—"Think not Silence the Wisdom of Fools, but, if rightly timed, the honour of wise men.... Such Silence may be Eloquence and speak thy worth above the power of Words." For while the specialist physician and surgeon, the pathologist and the bacteriologist, the psychologist and the psychiatrist, to name but a few, have vied the one with the other in their torrential literary outpourings, the general practitioner—that flower, such as it is, of our medical civilisation has remained almost irritatingly inarticulate. Within the last few years, however, a welcome change has been made manifest and a small number of excellently written volumes has appeared embodying the experiences of men whose lot has been the arduous one of general practice.

Dr. Ward's book is a welcome addition: to him general practice is not a dull treadmill existence, but a joyous adventure. The author touches on a variety of subjects, ranging from his adventures as an expert witness in the law courts to a subjective study of encephalitis lethargica. He has an effortless and lucid style, a depth of medical lore which peeps out in every other page, and a refreshing sense of humour—the result is a wholly enjoyable book.

J. M. H.

GLEANINGS FROM GENERAL PRACTICE.—By David Tindal, M.D., F.R.F.P.S. (Glasgow). London: Baillière, Tindall and Cox. 1929. Pp. X plus 209, with 3 figures in the text. Price 6s. net.

In this little book, Dr. Tindal has given us the fruits of over fifty years' experience of general practice in a big industrial centre in Great Britain. We

have often felt that a series of informal discussions and demonstrations by a sound general practitioner would be much more welcome to the embryo medical man than an elegant discourse on the acid-base equilibrium of the blood or the vagaries of the gas-forming anaerobes. For after all, probably not less than ninety-five per cent. of medical undergraduates will pass the remainder of their lives surrounded not by smooth-running kymographs, but by ailing humanity.

Dr. Tindal's book deals with a wide range of subjects, from the ethics of professional conduct on the one hand, to cookery and sick-room administration on the other. It is intended primarily for the benefit of the neophyte about to embark on general practice in the United Kingdom, and several of the precepts would have to be modified to suit the climate and social customs of India, but the broad basic principles which the author stresses are applicable anywhere. *Gleanings from General Practice* can be unreservedly recommended: printing and general get-up of the volume are good and the price is very reasonable.

J. M. H.

ELEMENTS OF HUMAN ANATOMY AND PHYSIOLOGY. (In Hindi). Parts I and II.—By T. N. Varma, B.Sc. (Alid.), M.D., B.S. (Punj.), F.R.F.P. & S. (Glas.), D.T.M. (L'pool), L.M. (Dub.), Part I—4th Edition, 1928. Part II—3rd Edition, 1929. Allahabad: The Allahabad Law Journal Press. Pp. 962, with 18 coloured plates and 378 other illustrations. Price Rs. 6-14-0 net. Available in one single volume or in two volumes from Messrs. Butterworth and Co., Calcutta.

THIS is the fourth edition of a book which was first published in 1916, and contains about 34 illustrations and 69 pages more than in the third edition. The difficulty of finding appropriate terms for English equivalents in technical subjects of this nature can well be imagined, and Dr. Varma is to be congratulated on the selection of words which are in most places self-explanatory. The physiology of a system is considered first, followed immediately by the description of its anatomy and this arrangement is convenient from the reader's point of view. The attention paid to physiology is, however, much less than that paid to anatomy. The author has taken some pains to develop the chapter on the dietary by giving tables showing the food values of different articles of diet and gives some illustrations of ideal diets suitable for people following different vocations. He has freely consulted several textbooks on the subjects of anatomy, physiology and allied sciences, and the inclusion of many well printed plates and pictures copied from various books, forms a prominent feature of the volume. The book is too elementary for medical men and too technical for non-medical readers, but considering the scarcity of books in vernaculars of this nature it is a useful publication.

R. N. C.

TUMOURS ARISING FROM THE BLOOD-VESSELS OF THE BRAIN.—By Harvey Cushing and Percival Bailey. London: Baillière, Tindall & Cox. 1928. Pp. X plus 219, with 159 figures in the text. Price 34s. net.

PROFESSOR H. CUSHING and DR. P. BAILEY are to be congratulated on this book, which is really an extension of their previous work on "A classification of the tumours of the glioma group on a histogenic basis, with a correlated study of prognosis," published by Messrs. Lippincott. They admit that hæmangiomas are rare in proportion to other intracranial tumours, being only two in every hundred, but they have cleared up the obscurities of this group, which indirectly sheds a light on the whole subject of intracranial growths. The blood-vessel tumours are divided into two groups (i) angiomatous malformations, capillary, venous and arterio-venous; (ii) the angioblastomas which are almost exclusive cerebellar in origin, and

arise from near the posterior end of the fourth ventricle. These angioblastomas may be cystic or solid and when properly stained can be distinguished from the meningiomas by the network of reticulum. Some of these tumours are associated with angiomas of the retina, a syndrome known as Lindau's disease. We congratulate these authors on these two books on cranial tumours: they are beautifully illustrated by microphotographs, x-ray photographs, and clinical illustrations. Both books should be in possession of ophthalmologists, surgeons and pathologists. The work of the authors has cleared up much of the obscurity and confusion that existed in the pathological diagnosis of these intracranial growths.

H. W. A.

GNOCOCCAL URETHRITIS IN THE MALE: FOR PRACTITIONERS.—By P. S. Pelonze, M.D. Philadelphia and London: W. S. Saunders Company Ltd. 1928. Pp. 357. Illustrated. Price 24s. net.

SEVERAL works dealing with gonorrhoea have been reviewed in these columns lately, in regard to which it has seemed to the reviewer necessary to draw attention to the tendency of the authors to regard the subject too much from the clinician's view point to the neglect of the pathological aspect. No such charge can be made against the author of this book. He starts with the consideration of the morphological and cultural characteristics of the gonococcus and then, after a brief but accurate review of the normal anatomy and histology of the urethra and its adnexa, discusses the pathological histology of the lesions met with and their bearing upon the defensive processes by which the body combats the disease. Upon this basis he builds his system of treatment, and of course it is the only rational basis and leads to condemnation of the methods at present advocated by many books. As the author says: "they had the facts—too many of them—but these were so arranged that, try as one might, it was almost impossible to co-ordinate them and when it came to the question of treatment, the vast array of good things to do was so dazzling as to afford puzzling confusion rather than real guidance. With so many good plans of treatment suggested any choice seemed a good one in the effort to cure the disease more quickly than anyone should expect." Quite so, and it is this sort of teaching which is responsible for the multiplicity of strong chemical injections, large doses of powerful vaccines and meddlesome instrumentation, which do so much damage and lead to long drawn out complications in cases which are very simple if properly handled at the outset. The author rightly lays great stress on the importance of chronic follicular prostatitis in keeping up chronic gleet and deprecates the needless trauma often inflicted on the urethra by topical applications through the endoscope to the urethral follicles for the treatment of lesions which are not there. This is the first book in which we have seen clear and definite instructions to massage the prostate in cases of supposed anterior urethritis at the termination of treatment, to make sure that symptomless involvement of the posterior urethra has not occurred, a fertile source of chronicity, and on the other hand warnings of the dangers of too early or too vigorous massage. The whole of the treatment advocated is based on the pathology of the disease and is good and sound. There are no short cuts to success in this disease and the attempt to find them exposes the patient to grave risk, a matter in which students and practitioners often fall into error through the confused teaching in many books. The author is unsparing in his condemnation of the claims made for the use of diathermy, but he seems to go rather too far; its utility as a means of applying rectal heat in acute prostatitis is undoubted and it is far superior to the water heated applicator which he advocates, nor do we think that the risk of causing atrophy of the testis is great enough to justify the withholding from the patient of the rapid relief it gives in acute epididymitis. Part II of the

book gives a number of case histories showing the mischief which may be wrought by too energetic treatment, the common mistakes which are made and other cognate matters. The whole work can be strongly recommended to practitioners and students.

W. L. H.

BRANCHIAL CYSTS.—By Hamilton Bailey, F.R.C.S. (Eng). London: H. K. Lewis and Co., Ltd. 1929. Pp. VIII plus 86, with 50 illustrations. Price 5s. net.

THIS small book is sub-divided into ten chapters. In the first two chapters the author deals with the clinical aspect of the branchial cysts and has lucidly presented the differential diagnosis, especially from breaking down tubercular glands for which they are often mistaken. Chapter III contains a detailed description of the removal of branchial cysts. In chapter IV, branchial cysts and fistulae have been contrasted. Chapter V deals with the clinical aspect of thyroglossal cysts and the author gives his explanation of the formation of such cysts which will be read with interest. In chapters VI and VII, the author describes thyroglossal fistulae and in chapter VIII the surgical treatment of both cysts and fistulae is described in detail. Chapter IX deals with submaxillary salivary calculus with special reference to its clinical aspect, differential diagnosis and surgical treatment. In the last chapter the author describes ligature of the angular vein as a preventive measure in facial carbuncle against thrombo-phlebitis of the cavernous sinus. It is suggested that another chapter devoted to the development of the branchial clefts and pouches and of the thyroid gland would be useful to the reader for ready reference. The book will be extremely useful to surgeons, as its study will remind them of these embryological remnants when dealing with swellings in the cervical region. The get-up of the book is excellent and the illustrations add very greatly to its usefulness.

N. P.

HYGIENE AND PUBLIC HEALTH. (Parkes and Kenwood). 8th edition, revised by Henry R. Kenwood, C.M.G., M.B., F.R.S. (Edin.), D.P.H. (Lond.) and Harold Kerr, O.B.E., M.A., M.D., D.P.H. London: H. K. Lewis & Co., Ltd. 1929. Pp. VII plus 823, with 91 illustrations. Price 21s. net.

THIS well-known manual still preserves its reputation as being one of the most readable books on hygiene and public health. Written in an easy style, it nevertheless conveys an immense amount of information. Chapter after chapter of well-written detail bear testimony to the care with which the authors have for many years collected material for the next edition. The book is up to date in most respects, there is a fairly good description of the activated sludge process, chlorination of water is well described, and the modern views on ventilation incorporated. The book possesses some of the defects of its qualities. The desire for wealth of detail has still preserved much that could now be dispensed with. No one now we suppose believes now that acute poliomyelitis is carried by the *Stomoxys calcitrans* or that cholera is air-borne. On page 431 it is stated that the ordinary flea *Pulex irritans* may convey epidemic plague, on page 567 that it plays no part in the transmission of plague. We missed any reference to encephalitis as a complication of vaccination. Again the easy narrative style does not lend itself to enthusiasm. Perhaps in the next edition the authors may let themselves "go" a bit and give an introductory chapter dealing with preventive medicine as a real entity in modern progress and civilisation, something of its origin and development and its future. Throughout the book there are hints that actual clinical cases of disease are but a small fraction of affected individuals, but the fundamental nature of the work on epidemics initiated by Topley and Webster and Dudley and later by Gill and others might be commented on more definitely in the earlier part of

The following statement shows the number and percentage of registered deaths from smallpox in children and adults:—

Age.	NUMBER OF DEATHS.	
	From smallpox.	Per-centage.
Under 1 year 3,427	44.1
Between 1 and 10 years 2,426	31.2
Above 10 years 1,928	24.7
	100.0

Since 75 per cent. of the deaths for the year are amongst children under ten years of age, there is still much scope for improvement in this branch of preventive work.

Plague.

The total number of deaths from plague during the year under report is 2,457 against 2,143 in 1926. These figures represent death-rates of 0.1, as compared with the quinquennial average of 0.2 per mille.

The districts of Ganjam, Godavari East, Nellore and Chingleput have been free from plague for the past five years. Chittoor and Guntur record only one case each in 1927. Of the six districts which were infected, Bellary (1,298) and Madura (828) record more than 85 per cent. of the total mortality.

The decrease in incidence which occurred during 1926 continued during the first six months of 1927; but, owing to the outbreak of a severe epidemic in Bellary during August, the mortality recorded in the third quarter of the year was considerably higher than during that part of any of the three previous years. This increase in incidence continued to the end of the year under review, and it seems probable that, unless active preventive steps are taken, plague in 1928 will appear in more virulent form.

Only six municipal towns were infected, 181 deaths being registered, as against 162 deaths in 12 towns during 1926. These figures give a death-rate of 0.1 per mille for both years. Hospet continues to maintain its unenviable reputation of being the worst plague-spot in the Presidency, the quinquennial death-rate being 0.5 per mille. Bodinayakkanur (1.7) and Coonoor (1.5) recorded high death-rates; Bellary had only two cases and Ootacamund only one.

Seven rural towns registered 440 deaths during the year against 12 towns with 643 deaths in 1926. These figures yield death-rates of 0.2 and 0.3 per mille, respectively. The highest death-rates from this cause were registered in Kottur, Bellary district (25.4), Cumbum (11.4), Harpanahalli (7.4), Uttamapalayam (2.0) and Chinnamerangi (1.2).

Deaths from plague were reported from 270 towns and villages against 189 in 1926.

Fevers.

The number of registered deaths under this head was 321,995 compared with 337,945 in 1926, the rates per mille of population being 7.9 and 8.3, respectively, against a quinquennial average of 7.9. The total once more amounts to 32.5 per cent. of all deaths registered during the year, but the group represents an *omnium gatherum* of diseases, with fever as a prominent symptom, which cannot be separated without patient and prolonged investigation.

Rates above 10 per mille were recorded in the districts of Ganjam (20.4), Vizagapatam (18.1), Kurnool (15.8), Cuddapah (13.5), the Nilgiris (12.1), Godavari East (11.2), Nellore (10.8), Guntur (10.7), Godavari West (10.5) and South Kanara (10.3). The lowest rate was registered in Tanjore (2.4).

The total deaths registered under this head number 81,277 as compared with 85,602 in 1926, these figures giving rates of 2.0 and 2.1, respectively, the quinquennial average being 1.6. The highest rates were recorded in Madras (13.2), the Nilgiris (5.0), Godavari West (4.3), Kistna (3.6) and in Kurnool (3.2).

If the statistics are to be believed, those districts seem to suffer constantly from respiratory diseases, as they all recorded the highest rates in 1926 and their quinquennial averages are also the highest in the Presidency.

Ankylostomiasis Campaign.

As in past years, this campaign was carried on during the year with the assistance of the Rockefeller Foundation, Dr. J. F. Kendrick being in charge of the work. The Assistant Director spent the whole of his time at Usilampatti in Madura district where he conducted a successful demonstration in soil sanitation, and carried through an effective programme of treatment, education and sanitation in schools. The proposal to organize anti-hookworm measures on tea and coffee estates was accepted by Government, and the staff was strengthened by the addition of a First-class Health Officer, designated the Health Officer, Planters' District, with headquarters at Ootacamund. He commenced work on the 26th July with a staff of one Sub-Assistant Surgeon, two compounders and one peon. Attention was devoted to educational work, treatment and examination, prevention of soil pollution, whilst investigation in the Madras Penitentiary was continued.

Rabies and Hydrophobia.

Deaths registered as being due to hydrophobia increased from 488 in 1926 to 636 in the year under report. Five hundred and sixty of these were registered in rural areas and seventy-six in municipal and rural towns. The five districts of Tinnevely (74), Tanjore (68), Bellary (65), Kistna (63), and Salem (52) recorded over 50 per cent. of the total, whilst in Madura, Madras and the Nilgiris districts not a single death from this cause was registered.

Injuries.

The number of deaths registered under this head was 11,753 against 11,770 in 1926. About 20 per cent. of these were due to suicides, and 55 per cent. to wounds and accidents.

All Other Causes.

The deaths registered in this great group number 456,536 as against 476,805 in 1926. These figures represent death-rates of 11.1 and 11.6 per mille respectively.

Correspondence.

THE YELLOW FEVER DANGER.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—It is comforting to know that the Public Health Commissioner with the Government of India, the Government of India and the Secretary of State are all fully alive to the danger of importing yellow fever to India and the Far East by air. It appears that international regulations are being framed to meet this "yellow peril." The new situation which has arisen in consequence of the rapid development of air travel needs very careful watching and any measures which are adopted ought to err on the side of excessive caution rather than of laxity in view of the great danger that exists.

The following points must be borne in mind:—

- (1) Hindle has proved that the Indian *Stegomyia* (*Aedes aegypti*) sent from Karnal in the Punjab is capable of conveying yellow fever.
- (2) Hindle has also shown that an attack of yellow fever may be unrecognizable clinically, as it may be so mild as to be mistaken for influenza or febricula.
- (3) It is quite possible for a person who has been infected in West Africa to reach the Indian zone by

air before the infective stage of the disease has been reached.

(4) If such a person were to be introduced to a place where suitable mosquito vectors exist, it is unlikely that any ordinary precautions could prevent the introduction and spread of the infection.

Dengue is known to spread like wildfire when infection is introduced in a susceptible population, and as yellow fever is spread in exactly the same manner it is reasonable to believe that the infection once introduced would be incapable of control. Under these circumstances we have to choose between the slight inconvenience which would be caused by interference with air traffic between West Africa and the Eastern countries, as compared with the appalling results which might follow from the introduction of yellow fever to India and the Far East. The simplest and surest procedure would be to prohibit air communication with all areas which are known or even suspected of being infected. If further knowledge of yellow fever should show that these fears are unfounded it will be time enough to relax the restrictions, meantime it is better to be "sure than sorry."—Yours, etc.,

J. W. D. MEGAW,
Major-General, I.M.S.,

Surgeon-General with the Government
of Madras.

CAMP OOTACAMUND,
10th April, 1929.

PREVENTIVE SURGERY.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—An invitation to me to address the recently held Provincial Hygiene Conference of the United Provinces on some aspect of preventive medicine has led me to write to you the following lines with reference to a

Plea for a Scheme of Preventive Surgery.

We are living in an age when surgery has triumphed as an art. With the introduction of asepsis and anaesthesia, patients have come to submit willingly to surgical operations, and the bad old days are over. The spectacular mutilations of olden days have been replaced by sound procedures based on sound physiological and anatomical knowledge. The growth of our knowledge has led to the establishment of public health departments in many lands, who maintain a service for the prevention of disease and for the immediate control of epidemic disease whenever and wherever it appears.

Bernard Shaw, (1) the eminent dramatist, has indeed suggested that we are going too far ahead. He writes: that "a modern person looks forward to a precise and convenient regulation of health, and desires by a nicely calculated diet of thyroid extract, adrenalin, thymin, pituitrin, and insulin, with pick-me-ups of hormone stimulants—the blood having first been carefully fortified with antibodies against all possible infections by inoculations of bacteria and sera from infected animals, and against old age by surgical extirpation of the reproductive ducts or weekly doses of monkey gland—to achieve a healthy old age." With all due respect to so eminent a non-medical authority, this sounds satirical. A scheme of life pushed to such an extreme would not be worth living.

Let us consider in what ways preventive surgery can benefit the general public. And here we have first to consider *Veneral Diseases*.

Experience both in peace and war has shown us what a tremendous toll these diseases take of the man-power of a nation. The natural tendency of infected persons to hide such diseases ever tends towards their further dissemination. Inefficient treatment further helps to spread infection. Moral lectures achieve but little, and preaching will not convert the unconvertible. The closing down of brothels tends but to increase the more secret dissemination of venereal disease. The real line of advance against such

diseases is popular education, especially with regard to the dangers of venereal diseases, and the prophylactic measures to be employed against them—whether by the individual or by disinfection by attendants specially trained for the purpose. Provision should be made by municipalities in this country for disinfection centres, since it has been shown (2) that 96 per cent. of those who apply to such centres within eight hours of exposure to infection can be sterilised of any possible infection; 86 per cent. of those who apply within 8 to 24 hours; and 60 per cent. of those who come later.

In place of such prophylactic and treatment centres, what have we to-day in India? The bazaars every evening resound with the gratuitous harangues of dignified quacks leading their credulous listeners to ruin through the administration of either harmful drugs, or of drugs in harmful doses.

Tumours.—We know but little to-day about the origin of tumours. Yet one fact is very clear in the practice of surgery in India to-day; that the greater majority of such cases reach us at a much later stage than do corresponding patients in Europe. In fact many of them have been for long in the hands of the quack and the unqualified before they reach the hands of the modern surgeon—often only too late.

Abdominal and allied conditions.—Here again the case is identical; our patients reach us only when exhausted by prolonged and inefficient treatment, and what would at first have been a simple surgical procedure turns into a grave surgical risk. Kocher rightly said "in an abdominal trouble, the surgeon should be the first to be consulted."

Removal of the tonsils or adenoids in time may stop pus-discharging ears, and prevent the onset of irremediable deafness or other serious complications. Oral and dental sepsis, if neglected, may pave the way to serious abdominal lesions. Tuberculosis of the glands, bones, and joints is very common in India, and the great majority of such cases only reach us when secondary sepsis has set in. Cannot such a condition of affairs be remedied by the issue of leaflets in the vernaculars of the province concerned in order to educate the people?

Deformities and diseases of Children.—These receive but little attention in India. Rodman (3) states that artificial modes of living are responsible in a large measure among the civilised races for the deformities of children. It is a calamity to see otherwise healthy and sturdy people limping along with neglected congenital talipes, the physical deformity marring their wage-earning capacity. A little attention in childhood would have made a world of difference in their subsequent careers.

In such matters well co-ordinated action is necessary, to educate the public to a knowledge of what modern surgery can do in its preventive aspects. incessant propaganda, lectures, posters, placards, etc., could achieve a tremendous saving of man power. One cannot do better than sum up the matter in the words of one of the greatest living surgeons of to-day, Sir Berkeley Moynihan, (4) as follows:—"We eagerly await the day when disease shall not be required to be checked in high career, but shall be blighted at its origin, or even denied existence, when our weapons shall be laid aside."—Yours, etc.,

MENTAL HYGIENE IN INDIA.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—It is extremely gratifying to learn that a mental hygiene movement is gradually gaining ground in India at last, but it must be an uncomfortable thought for the medical profession that for the second time in the history of this movement laymen should be the first in the field to lead us the way.

The vast organisation in America owes its being to the untiring energies of Mr. Clifford W. Beers. The Indian Association for Mental Hygiene was founded towards the end of 1928 by Captain Stedman, M.C. These outstanding examples should be a sufficient incentive to us to respond in equal fashion, to further the study of psychology and psychopathology.

In England, as in America, the modern opinion is that mental diseases just like any other physical diseases should be treated in the earliest stages, and so to-day there are in almost every large mental and general hospital clinics, both in and out-patients, for the early treatment of the psychoses and psychoneuroses. To be better acquainted with these complex states, students and practitioners are freely admitted to these clinics for instruction.

No words of mine can sufficiently emphasise how great is the necessity to disseminate wider knowledge of the subject, to arrive at better results than now obtain in India, than an account of the following cases:—

The wife of a European was recently admitted to the Ranchi European Mental Hospital and after examination was diagnosed as a case of dementia paranoides. She has been married for 12 years, and is without issue simply because the husband is impotent, as he suffered from ejaculatio præcox, i.e., emission without intromission. This is the *fons et origo mali*. There is no history of insanity, epilepsy or amentia in the family, and except for two occasions when the patient had what is termed "nervous breakdown," she has been quite healthy. There can be no doubt that in the 12 years of unconsummated married life her libido must have been stored up under pressure only to burst through now, as a psychotic volcano. Had one of the many practitioners—some of them eminent in their own line—through whose hands she passed, taken the trouble to enquire into her sexual life at the very beginning much pain, misery, and money must have been saved both husband and wife. Instead her treatment varied from a cervical dilatation down to a dose of burgundy at night!

A case of acute spasmodic torticollis was admitted to this hospital two years ago. He consulted several doctors who advised electro-therapy, x-rays, resection of the spinal accessory nerve and even a metal collar. He came to us as a last resort when he was contemplating suicide. The case was simply a hysterical manifestation of a psychic conflict which was unearthed when the sexual life history was gone into. There was marital unhappiness, and psychologically "he was turning his head away" from his wife.

After a short course of psychotherapy he left and is now well and back at his work.

How many cases of gastric crises and hysteria with abdominal symptoms have laparotomy done?

Obvious cases of early dementia præcox are frequently passed off under the cloak of neurasthenia and "nervous breakdown."

A lady who is now acutely maniacal and who had what I presume were hysterical fits was recently thought to have had cerebral hæmorrhage. It is not surprising that many such cases of mistaken diagnosis come our way, considering how little interest general practitioners take in the psychic side of their patients' ailments. In the field of neurology, too, errors in diagnosis are frequent. One cannot emphasise too strongly how necessary a thorough routine examination of the nervous system is, to avoid such errors. The great problem of *encephalitis lethargica* which has been extensively studied in Europe is little known in

this country, and yet some of these cases which develop the Parkinsonian syndrome are admitted for dementia præcox, etc.

Such pitfalls—and there are many in neurology and psychopathology—can be best avoided by studying these conditions with greater attention in special clinics in every general hospital in this country on the same lines as in England and on the continent.—Yours, etc.,

THE TREATMENT OF NIGHT BLINDNESS.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I shall feel obliged if you will kindly publish the following note in the *Indian Medical Gazette*.

Four years ago I used to treat cases of night blindness by subconjunctival injections of 1:4000 bichloride of mercury. Night blindness was cured in every case that I treated. One injection was enough. During the past 18 months I have substituted 10 per cent. saline for mercury. The technique is as follows:—

The eye is cocaineised as for cataract operation. With the usual aseptic precautions $\frac{1}{2}$ c.c. of sterile 10 per cent. salt solution is injected subconjunctivally on each side. Puncture of the conjunctival vessels is avoided. The eyes are bandaged. The bandage is removed at night, when to the satisfaction of both the doctor and the patient night blindness will be found to have disappeared. There is pain after injection but it soon disappears or becomes bearable. Oedema passes off in a day or two.

The liver treatment is certainly more expensive and less speedy.—Yours, etc.,

MELÆNA AND HÆMATEMESIS IN THE NEW BORN.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I beg the hospitality of your columns to comment on the case of melæna and hæmatemesis in the new born described in your issue for January 1929 by Dr. Sen Gupta.

He writes as follows:—"The child since the onset of this trouble showed marked paleness, though the pulse was comparatively fair," and concludes "I have never previously come across such a case, nor have I heard of one. I think the child must have swallowed some of the mother's blood at the time of birth and that blood came out as melæna and hæmatemesis."

Here I would like to draw the attention of your contributor to the fact that newly born babies sometimes suffer from a peculiar hæmorrhagic disease of obscure causation; and that the hæmorrhage may be of the intracranial, intra-abdominal, subcutaneous, or gastro-intestinal type. Robert Hutchison writes as follows:—"The disease usually first manifests itself about the second day and very rarely after the twelfth. As a rule, the first thing to be noticed is hæmorrhage from the alimentary canal" (*Lecturers on the Diseases of Children*, p. 26).

Sir James Goodhart in his *Diseases of Children* describes this mysterious malady (pp. 25 to 30) under the heading "spontaneous hæmorrhage of the new born." "The disease is of rare occurrence, having a proportion of 0.6 to 1.8 per cent. in countries with a white population. Many theories as to the causation of the disease have been put forward—one of them being that some kind of poison or toxin perhaps acts

as a solvent of the endothelium of blood vessels and so causes hæmorrhage. These spontaneous hæmorrhages bear no relationship to hæmophilia, for infants who recover show no special tendency to bleed subsequently. Prognosis is usually grave. In some cases collapse is so rapid that there is little opportunity for treatment. Gelatine given by the mouth seems to have a definite value in arresting the hæmorrhage (Fruwald):—

Gelatin alb. (Merck)	..	gr. xxx
Sodii chloridi	..	gr. ii
Aqua distillata	..	oz. iii

One drachm of this solution every hour. Fresh blood serum from man, horse, or rabbit, injected subcutaneously—10 c.c. at a time, repeated twice or thrice, has been found valuable."

According to Dr. Herbert French, the serum from the father's blood is very efficacious in the treatment of melæna neonatorum. From this fact he conjectures that the cause of the malady—in certain cases at any rate—is some intrinsic abnormality in the infant's hæmopoietic system.

Adrenalin chloride, 1:1000 solution; one or two minims by the mouth with a little water every hour, two or three doses, is sometimes useful. Calcium chloride in doses of gr. ii, dissolved in water, every two hours is strongly recommended. Two drachms of alum, boiled in a pint of milk and sweetened, may be used—a teaspoonful frequently.

Food should consist of plain barley water to albumin water or whey. Milk should not be given. Rest and warmth are of great importance.

Conclusion.—The sudden onset of the hæmorrhage on the third day of the infant's life without any apparent cause, and the "marked paleness" which was noticed during the hæmorrhagic period—make me conclude that the case was probably one of spontaneous hæmorrhagic disease of the new born, as described by several of our leading teachers of medicine.

Dr. Sen Gupta is to be congratulated on having published so interesting a case, and on its successful termination.—Yours, etc.,

A. SAHA, L.M.F.,

ASCARIS INFECTION SIMULATING BRIGHT'S DISEASE.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—I have read with interest Dr. Jagdish Chandra Butta's case of Ascaris infection simulating Bright's disease on p. 330 of your issue for June, 1928. I had an almost exactly similar case just previously, of which the details are as follows:—

I was called in to see a lady aged 50, suffering from swelling of the abdomen and feet. On examination the heart was sound, but she suffered from asthma. The urine showed a slight trace of albumin. I prescribed a saline mixture, with diuretics and purgatives. There was no change in the swelling, however, and the patient complained of abdominal pain. I then thought of santonin, and prescribed it. The next morning the patient passed a number of roundworms, and there was immediate relief. The day after further roundworms were passed, and her symptoms now cleared up entirely. A month later similar symptoms again recurred, and were again completely relieved by santonin.—Yours, etc.,

A CROCHET NEEDLE AS AN EMERGENCY SURGICAL INSTRUMENT.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—A small Hindu boy was brought to me by his father with the history of having introduced a black pepper seed into his ear some days previously. On examination I found the seed embedded well down the meatus, and all attempts to remove it with ordinary surgical instruments failed. A crochet needle was suggested by the father, and one was borrowed from an adjacent shop, sterilised, and used. The removal of the foreign body was so easy with this emergency instrument that I am convinced that its use is indicated in such cases, where—often—removal of the foreign body is not at all easy. The crochet needle is an instrument which may be of some interest to practising surgeons.—Yours, etc.,

NEOSALVARSAN.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—We would thank you to publish the following lines as a warning to the medical profession in India.

Certain unscrupulous importers are at present flooding the market with cheap Neosalvarsan. These spurious stocks, originally manufactured in the M.L.B. plant in Hoechst, are coming from various European countries where they were recognised as unfit on account of their old age and discarded by order of legal authorities. We were in a position to trace the source of some of them and found:—

(i) all packings bearing the number G-81754 were seized during the French occupation of Hoechst in November, 1923; these packings are at least 6 years old and unfit;

(ii) all packings bearing the number H-31782 were sold in 1925 to London and there lost sight of;

(iii) all packings bearing the numbers H-94333 and 94334 were sold several years back in bulk and lost sight of; and

(iv) all packings bearing the number 81369 without a capital letter in front are at least 10 years old.

All these stocks were imported by unlicensed traders who were not in a position to dispose of them in other countries. They were ordered to be destroyed as their use is dangerous for the patient.

Our firm are the legal importers of the genuine Neosalvarsan and Myosalvarsan, which are especially packed for the tropics and we take full guarantee for every packing bearing the slip:

"Specially manufactured for the Tropics and packed for British India, Burma and Ceylon and imported by Havero Trading Co., Ltd."

On the other hand the responsibility for any regrettable incident, resulting from the use of the above mentioned packings rests entirely with the unscrupulous importers and the customer.—Yours, etc.,

HAVERO TRADING CO., LTD.,
Pharmaceutical Department,
"Bayer-Meister Lucius."

Service Notes.

APPOINTMENTS AND TRANSFERS.

LIEUT.-COL. F. P. Mackie, O.B.E., M.D., F.R.C.P., F.R.C.S., V.H.S., I.M.S., is appointed Honorary Surgeon to The King and promoted Bt.-Col. in succession to Col. H. Ainsworth, M.B., F.R.S., I.M.S., retired 28th September, 1928.

Lieut.-Col. A. G. Tresidder, C.I.E., M.D., I.M.S., is appointed as officiating Civil Surgeon and Superintendent, Medical School and Mental Hospital, Hyderabad, Sind, *vice* Lieut.-Col. J. L. Lunham, M.B., B.Ch., (R. U. I.), F.R.C.S.I., D.T.M. (Cantab.), I.M.S., proceeding on leave.

Lieut.-Col. T. G. F. Patterson, D.S.O., M.B., I.M.S., is appointed Honorary Physician to The King and promoted Bt.-Col. in succession to Major-General H. J. K. Bamfield, C.B., D.S.O., K.H.P., I.M.S., retired, 24th September, 1928.

Lieut.-Col. A. F. Hamilton, M.B. (Lond.), F.R.C.S. (Eng.), I.M.S., J.P., to officiate as Superintendent, J. J. Hospital, Bombay, in addition to his own duties.

Lieut.-Col. C. H. Smith, O.B.E., I.M.S., an Agency Surgeon, is posted as Legation Surgeon, Nepal, and *ex-officio* Assistant to the British Envoy of Nepal, with effect from the 1st April, 1929.

Lieut.-Col. H. A. Williams, D.S.O., M.B., I.M.S., Civil Surgeon, Moulmein, is appointed to officiate as Inspector-General of Civil Hospitals, Burma, during the absence on leave of Colonel W. H. C. Forster, I.M.S.

Lieut.-Col. W. J. Simpson, I.M.S., Agency Surgeon, Bhopal, is appointed to officiate as Political Agent in Bhopal, in addition to his own duties with effect from the 12th March, 1929 and until further orders.

The services of Major L. A. P. Anderson, I.M.S., Assistant Director, Central Research Institute, Kasauli, are placed temporarily at the disposal of the Government of Bombay for appointment as acting Director, Haffkine Institute, Bombay, with effect from the date on which he assumes charge of his duties.

Major W. J. Webster, M.C., I.M.S., an officer of the Medical Research Department, is attached as a supernumerary officer to the Haffkine Institute, Bombay, with effect from the 31st January, 1929.

The services of Major H. H. Elliot, M.B.E., M.C., M.B., F.R.C.S.E., I.M.S., are placed at the disposal of the Chief Commissioner, Delhi, for appointment as Civil Surgeon, New Delhi, with effect from the date on which he assumes charge of his duties.

The services of Major J. P. Huban, O.B.E., M.B., I.M.S., Civil Surgeon, New Delhi, are replaced at the disposal of the Government of India in the Foreign and Political Department with effect from the date on which he relinquishes charge of his present duties.

The services of Major A. N. Bose, M.B.E., I.M.S., and Major R. M. R. Porter, M.C., M.B., F.R.C.S.E., I.M.S., are placed permanently at the disposal of the Government of Bihar and Orissa, with effect from the 1st April, 1926 and the 7th February, 1927 respectively.

Major J. Rodger, M.C., I.M.S., an officiating Agency Surgeon and Residency Surgeon, Mewar, is appointed to officiate as Civil Surgeon, Ajmer and Chief Medical Officer in Rajputana, in addition to his own duties with effect from the 22nd March, 1929.

Major A. J. D'Souza, I.M.S., is appointed to be Senior Medical Officer, Port Blair, with effect from the date on which he assumes charge of the appointment.

Major H. E. Shortt, M.B., I.M.S., an officer of the Medical Research Department, is placed on foreign service under the Indian Research Fund Association with effect from the forenoon of the 4th March, 1929.

Lieut. M. L. Ahuja, M.B., I.M.S., a temporary officer of the Medical Research Department, is appointed to officiate as Assistant Director, Central Research Institute, Kasauli, with effect from 1st April, 1929.

LEAVE.

Colonel W. H. C. Forster, M.B., I.M.S., Inspector-General of Civil Hospitals, Burma, is granted leave on average pay for six months with effect from the 9th April, 1929 or the date on which he avails himself of the leave.

Colonel W. S. Willmore, M.D., M.R.C.P., I.M.S., Inspector-General of Civil Hospitals, Bihar and Orissa, is granted leave on average pay for eight months

with effect from the 20th May, 1929, preparatory to retirement.

Lieut.-Col. D. P. Gail, I.M.S., Civil Surgeon, Howrah, is granted leave on average pay for two months with effect from the 15th April, 1929, or from the date on which he avails himself of the leave.

Lieut.-Col. J. Anderson, I.M.S., an Agency Surgeon, is granted leave on average pay for 8 months combined with leave on half average pay for 20 months, under the Fundamental Rules with effect from the 14th March, 1929.

Lieut.-Col. J. W. Watson, C.I.E., I.M.S., an Agency Surgeon, is granted leave on average pay for 24 days combined with leave on half average pay for 6 months and 24 days under the Fundamental Rules with effect from the 22nd March, 1929.

Lieut.-Col. R. B. Seymour Sewell, I.M.S., Director, Zoological Survey of India, is granted leave on average pay for 5 months with effect from the 23rd March, 1929.

Lieut.-Col. A. G. Tresidder, C.I.E., M.D. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., has been granted by the High Commissioner for India an extension of leave on half average pay for four days (not due).

Lieut.-Col. J. H. Murray, C.I.E., M.D., I.M.S., Inspector-General of Prisons, Bombay Presidency, is granted leave on average pay for six months with effect from the 14th March, 1929 and is permitted to retire from the post of Inspector-General of Prisons, Bombay Presidency, on the expiry of the leave.

PROMOTIONS.

Lieut.-Colonel to be Colonel.

Walter Valentine Coppinger, D.S.O., M.D., F.R.C.S.I., I.M.S. Dated 30th March, 1929, *vice* Colonel John Norman Walker, superannuated.

Captains to be Majors.

S. C. Alagappan, M.B., F.R.C.S.E., I.M.S. Dated 3rd March, 1929.

A. M. V. Hesterlow, M.B. Dated 14th March, 1929.

RETIREMENTS.

Lieut.-Col. E. B. Munro, O.B.E., M.B., I.M.S., with effect from the 20th February, 1929.

Lieut.-Col. B. B. Paymaster. Dated 22nd January, 1929.

NOTES.

IMMUNOGENS, PARKE, DAVIS & CO.

"IMMUNOGENS" represent a new type of antigen recently introduced by Messrs. Parke, Davis & Co. That an immunising bacterial antigen should be as far as possible free from toxicity is a principle which has long been recognised, but only rarely obtained in actual practice. The research work which has led to the introduction of "Immunogens" was suggested in a paper by Sir Thomas Horder in 1926. Briefly, "Immunogens" represent an attempt to produce a bacterial antigen free from toxin, yet possessing high antigenic value. The mode of production of such antigens has been dealt with by Ferry in a paper in the *Medical Journal and Record*, September 5th, 1928.

The fundamental experiment on which this work rests is that filtrates of the growth of different bacteria of the typhoid-eoli group, the pneumococcus, and other bacteria in broth gave an antigenic power which was quite unsuspected, though they are free from bacteria and from endotoxins. The optimum time for

production of the highest antigenic power in the broth filtrates was growth for from 18 to 24 hours, filtrates from old cultures (contrary to the usual belief) being much less active than those from fresh ones. Presumably the antigenic substance concerned is not an endotoxin, but some substance loosely bound to the bacterial cells from which it can easily be washed free. Further, growths on solid media give a better higher antigenic value when dissolved and filtered than do growths in broth. Results proved to be better with the pneumococcus than with any others of a large range of organisms tested.

As a result of preliminary experiments, it becomes clear that endotoxins, which apparently produce the more severe symptoms when vaccines are used, are within the bodies of the bacteria concerned, but that substances of much higher and much less toxic action are loosely bound to the surface of the bacteria and can easily be washed free from them.

It is on this basis that "Immunogens" rest. Sir Thomas Horder and Dr. N. S. Ferry, M.D. (*British Medical Journal*, 1926, July 31st, p. 177) claim that such washings more nearly approach the ideal antigen than any others which they had come across. This antigen is in aqueous solution, is low in protein content, high in antigenic power, and practically non-toxic. Three doses of "Pneumococcus Immunogen" were found to protect mice against 1,000,000 lethal doses of culture.

In preparation of Immunogens, cultures are first rapidly washed with normal saline. The bacteria are then rapidly removed in order to prevent autolysis of the bacterial bodies (which process is known to cause a development of considerable toxicity in the solution). The final product is "Immunogen." Clinical reports speak highly of the new preparations, especially with reference to streptococcal, pneumococcal, and gonococcal infections.

"Immunogens" are prepared of two different varieties; one from pure strains of the organism concerned; the others, "Immunogen Combined" from cultures of both the primary and secondary invading organisms. The following are available in 5 c.c. bulbs:—Catarrhalis Immunogen (Combined), Gonococcus Immunogen, Gonococcus Immunogen Combined, Pertussis Immunogen, Pertussis Immunogen Combined, Pneumococcus Immunogen, Pneumococcus Immunogen Combined, Staphylococcus Immunogen, Streptococcus Immunogen—prepared from both hemolytic and non-hemolytic strains—and Streptococcus Immunogen, Combined.

Messrs. Parke, Davis & Co., P. O. Box 88, Bombay, will be glad to supply information with regard to these new products.

QUINOXYL, B. W. & CO.

QUINOXYL, a new preparation by Messrs. Burroughs, Wellcome & Co., for the treatment of amœbic dysentery will be of interest to medical men in this country. It is a mixture of iodo-hydroxy-quinoline-sulphonic acid, 80 per cent., with sodium bicarbonate, 20 per cent. This corresponds to the drug introduced by Mühlens and Menk in 1921 for the treatment of amœbiasis. Quinoxyl is an odourless, finely crystalline yellow powder with a sweetish taste, and is issued in 10-gramme and 100-gramme bottles. The sodium salt is also issued as "Tabloid Quinoxyl" in 0.25 gramme and 0.5 gramme "tabloids," and for oral administration, and as "Soloid Quinoxyl" in 5-gramme "soloids" for the preparation of enemas.

It is claimed that the drug keeps well in the tropics if kept dry and in the dark. It should be administered either orally in doses of 0.25 to 1 gramme t.d.s., or by rectal enema—200 c.c. of a 2.5 per cent. solution, after a preliminary lavage of the colon with one pint of a 2 per cent. sodium bicarbonate solution. The combined oral plus rectal course of treatment for ten days is that which is recommended. The drug is rapidly absorbed, and can be detected in the urine

within five or six hours of administration by either route, as it gives a green colour with ferric chloride. Solutions for rectal administration should not be boiled, as boiling causes dissociation of the compound.

This new preparation should be of special interest to those observers who are able to follow up their cases of intestinal amœbiasis by repeated after-examination of the stools.

"SPARKLET" CHLORAMINE.

THE sterilisation of water supplies by chloramine is now a well-established principle, and it is claimed that by this method the objectionable taste of chlorine is eliminated from the treated water. In this connection an interesting apparatus has been put on the market by United Water Softeners, Ltd., Aldwych House, London, W.C.2. This consists of a bottle 19 inches high and 4 inches in diameter, enclosed in a non-corrodible metal covering. In the screwed-in base of the metal cover are a set of chlorine capsules, whilst tablets for the preparation of ammonia are also supplied with the apparatus. In order to sterilise water by this "sparklet" apparatus, the screwed-on cap is removed, the bottle filled up to the 1,250 c.c. mark with water, a chlorine capsule is fitted into the cover and pierced, and the chlorine gas allowed to permeate the water. The cap is then filled up to the 50 c.c. mark with water, two of the ammonia tablets added and dissolved, and this solution added to the water in the flask. This makes chloramine, and when the whole is shaken, the water is sterilised.

The apparatus is most ingenious and will be of interest to medical men and public health officers. The chlorine capsules and ammonia tablets in the base of it suffice for sterilisation of 120 imperial gallons of a highly polluted water supply, or for 480 gallons of a suspicious supply.

PIPERAZINE, MIDY.

THIS is a French preparation for which very high claims are made. As is well known, piperazine has a strong action *in vitro* in dissolving uric acid, piperazine urate being about seven times as soluble as lithium urate, though whether its action *in vivo* is equally efficacious is subject to some doubt. The drug consists of colourless, deliquescent crystals, readily soluble in water, and is usually prescribed in doses of 5 to 15 grains.

The claim made by the manufacturers of this compound is that it will dissolve uric acid in the body, will stimulate hepatic activity, and that it is of value in the treatment and prevention of renal lithiasis and gout. (One knows from practical experience that piperazine is of real value in gouty states.) The drug cannot be administered in wafers or powders owing to its tendency to deliquescence, and Piperazine, Midy is an effervescent granular preparation of the drug, designed to overcome these difficulties. Reports in the French medical journals—especially one in the *Paris Medical*, a journal with an established reputation—speak very highly of the results of prescribing this preparation.

The Indian agents are Messrs. E. Stella & Co., P. O. Box 868, Taj Building, Wallace Street, Bombay, who will be glad to furnish information and copies of reports in reply to any enquiries.

"OTOSCLEROL."

"OTOSCLEROL" is a preparation by the Munchener Pharmaceutische Fabrik, München 25, Plinganserstrasse 90, Bavaria, for the treatment of deafness, buzzing in the ears, and aural oto-sclerosis. It is stated to contain 6.66 per cent. of cimicifugin, 36.3 per cent. of bromides, and 13.52 per cent. of phosphorus. The tablets are of strength 3 grains each, and the dosage advised is one tablet t.d.s., gradually increased to five tablets t.d.s. Several reports by continental workers speak very highly of the result of its administration

in oto-sclerosis, and especially in cases of toxic infection resulting in middle ear trouble.

The British agents are Messrs. Coates and Cooper, 41, Great Tower Street, London, E.C.3.

BOVRIL, LIMITED.

THE Thirty-second Annual General Meeting of Bovril, Limited, was held on 26th February, at River Plate House, Finsbury-Circus, London.

Sir George Lawson Johnston (chairman of the company) said the net profit for the year's trading, at £366,897, is a little more than £6,000 ahead of the previous year.

During the war, the export of Bovril was restricted; for a period it was prohibited. However, with a special effort in 1919, they got their export sales up to pre-war figures. Each year since 1919 had shown an increased export of Bovril over its predecessor; 1928 again showed this continued advance in their exports.

In a competition recently promoted by *The Daily Mail* to encourage amateur advertisers, no fewer than 3,600 entries for Bovril advertisements were sent in. Some of the suggestions they had used in their publicity work, some they had not, although they had given a good deal of private amusement.

They were still keeping up their weekly, or, at any rate, fortnightly, change of slogan, and most of them must have seen a good many examples. Some of them might not have seen a new one now appearing on railway platforms which read: "Before the next (s)train, take Bovril."

During the recent spell of arctic weather, when influenza claimed so many victims, the London General Omnibus Company provided comfort and protection for their drivers and conductors by supplying them liberally with hot Bovril at the various depôts and termini on their system. More than 3,000 Thermos flasks of hot Bovril were sent out daily for this purpose. It would be difficult to say whether the Bus Company's thoughtful action or the Bovril was the more appreciated by the men.

Sir James Crichton-Browne, M.D., F.R.S., said the shareholders must be gratified to note that the sales had maintained a high level through the period of acute industrial depression through which the country was passing. The unemployment figures were depressing, and in the classes above those from which the enumerated unemployed were drawn there had been pinching and an impoverished larder. If the people could be weighed as well as counted, he was sure some national loss of flesh would be disclosed with, perhaps, some deferred effects of an unfavourable kind on the national health, for, as Sir George Newman, the Chief Medical Officer of the Ministry of Health, had just said in his Report—and no higher authority could be quoted—"Nutrition is the one thing needful."

At a time like the present, when incomes had been reduced, and the country was being harried by a disastrous epidemic, it was of the utmost importance that every ounce of food taken should yield its full contribution to nutrition and to body-building, and hence the value of the service that Bovril as a body-builder could render.

THE "EMPIRE" MICROSCOPE.

THAT the price of microscopes is coming down is a most welcome fact, for the medical man in the tropics cannot possibly carry on his work successfully without the aid of a microscope. It is claimed for the "Empire" microscope that it is entirely British made, and that it will give life-long service. This microscope is of the usual pattern, with a square stage and mechanical stage, triple nose-piece, lateral fine adjustment, and an Abbé condenser.

This microscope appears to be a very suitable one for students' needs. For the beginner, the model E 31548, with two oculars and 2½ and 1½ inch

objectives, at Rs. 210 will meet all his requirements for histological work. For the student studying pathology, model E 31547 with three objectives including the usual oil-immersion 1½ inch, at Rs. 285, seems very reasonable. This has no mechanical stage, but model E 31546 at Rs. 365 is fitted with a mechanical stage, and seems in every way suitable for general bacteriological and laboratory work.

The Indian agents for "Empire" microscopes are Messrs. Stephens and Co., 275 Bow Bazar Street, Calcutta.

HAMBLIN'S OPHTHALMIC INSTRUMENTS AND APPARATUS.

THE attention of ophthalmic surgeons may be directed with advantage to the ophthalmic instruments and equipment advertised on p. xxvi of our advertisement column. These are all manufactured by Theodore Hamblin Ltd. of 15, Wigmore Street, London, England, and are of the highest quality both in design and workmanship. Hamblin's instruments are not designed with the idea of producing a cheap article. Nearly every instrument produced by this firm has been designed in collaboration with ophthalmic surgeons who are cognizant of the demands to be made upon it, and who are often unfortunately only too painfully aware of the way in which a badly designed and cheaply manufactured instrument can fail them. Surgeons in India are so situated that they must have no qualms as to the efficiency of any instrument they wish to purchase. It is on account of the care with which Hamblin's instruments are produced and the thought which has been given to the requirements of the surgeon that their claim to the attention of ophthalmic surgeons requiring reliable equipment may be recognised. Theodore Hamblin Ltd. are primarily and principally spectacle makers, and as such it is their desire to retain the goodwill of ophthalmic surgeons. It follows as a natural corollary that they are less concerned with the commercial aspect of the production of the instruments sold to ophthalmic surgeons than that such instruments should be of the best quality possible, and have the high standard of efficiency associated with their name. This is emphasized by the fact that Hamblin's supply instruments only to medical men, and to dealers only on the understanding that they are intended for the use of members of the medical profession.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE Editor, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

DANGEROUS BLOOD DONORS.

By R. B. LLOYD, M.A., M.B., B.Ch. (Camb.),

LIEUTENANT-COLONEL, I.M.S.,
Imperial Serologist,

and

S. N. CHANDRA, M.B.,

Officiating Assistant Serologist.

(Results expressed in the Moss terminology.)

THE object of this short note is to describe the iso-agglutination reactions of three very abnormal cases recently examined. We also report two instances of abnormally high iso-agglutinin titre in group IV donors.

(1) Abnormal reactions.

Case 1.—Patient R., diagnosis corneal ulcer, no other disease, Wassermann reaction negative. There was no question of a blood transfusion in this case. His abnormal blood group was discovered during an examination of his blood from a research point of view. His cells, tested for iso-agglutination against sera of known groups, yielded the following results:—

With group IV serum —
With group II serum +
With group III serum —

These reactions correspond to no known group. This person's serum tested against cells of known groups showed the following reactions:—

With cells I +
With cells II +
With cells III +

His group therefore appears to be IV.

On the supposition that his correct group was IV, in which case group II serum should yield a negative result in the first experiment, the cells of R were tested against four other known group II sera. These yielded a negative reaction in each case. Had the particular group II serum first employed for grouping not been used, this individual R would have been passed as a perfectly normal instance of group IV.

There is therefore some abnormality either in the cells of R or in the agglutinins of the particular group II serum first used. To investigate this further, absorption tests were carried out. The serum of this particular group II person, denoted X group II, was absorbed with the cells of R, and afterwards tested for iso-agglutination as under:—

Serum of X group II (absorbed with cells R) and cells R — (absorption complete).
do. and cells I +
do. and cells II —
do. and cells III +

This X group II serum unabsorbed had been very frequently tested against known group IV cells yielding in every case a negative result.

It is therefore possible that the serum of X group II possesses some abnormal agglutinative power, and that R was a perfectly normal group IV person, or that R was in some way abnormal as regards agglutinogens. The latter is the more likely.

The practical outcome is that R should not be used as a universal donor, for the recipient might be of group II, in which case a dangerous reaction might occur.

Case 2.—Patient P; diagnosis advanced spleno-medullary leukaemia.

The cells of P tested for iso-agglutination reacted as under:—

With group IV serum —
With group II serum —
With group III serum —

Therefore, as judged from his cell reactions, his group is IV. Similarly:—

Serum of P with cells II +
do. with cells III +
do. with cells I +

Therefore, as judged from his serum, his group is IV.

So far he appears to be an entirely normal instance of group IV. The proposed donor was S, wife of the recipient. Her reactions were as under:—

Cells of S with serum IV —
do. with serum II —
do. with serum III —

Therefore, as judged from her cell reactions, her group is IV. Similarly for her serum reactions:—

Serum of S with cells I +
do. with cells II +
do. with cells III +

Therefore, as judged from her serum, her group is IV.

These two persons being thus both of group IV ought to be entirely compatible, but cross-agglutination tests carried out doubly, i.e., serum of P against cells of S, and serum of S against cells of P gave in both cases a strongly positive agglutination reaction. This is a very unusual type of abnormality. Fortunately, abnormal group IV persons are rare. Both the serum of P and the cells of P were perfectly compatible with the cells and serum, respectively, of four other group IV donors. On the other hand, both the serum and cells of P again displayed the same abnormality against one other healthy group IV donor. No further examination was possible in this case, but the conclusion would appear to be that the blood of P is abnormal. This is quite frequently the case in blood diseases, such as leukaemia from which this patient suffered. This case again illustrates the extreme danger of the use of a group IV universal donor,

employed without a cross test, in the transfusion of persons suffering from blood diseases.

Case 3.—Mr. G., a case of neuritis caused by electric discharge, offered himself as a blood donor.

The reactions of his cells were as under:—

Cells G with group IV serum	+	(weak).
Cells G with group II serum	+	(weak).
Cells G with group III serum	—	

Thus from his cell reactions Mr. G. appears to belong to group III. His serum reactions were as under:—

Serum G with cells III	+	(abnormal).
Serum G with cells I	+	
Serum G with cells II	+	

Therefore this person is of abnormal group. His serum behaves as group IV, while his cells behave as group III. As the two positive reactions with his cells were weak, it would seem that Mr. G. was really of group IV, and that there was some abnormality in his cells, which was demonstrated by a weak positive reaction with group II serum and which was necessarily shown by group IV serum also. This is another instance of an abnormal group IV person whom it would not be safe to utilise as a universal donor.

(2) *Instances of abnormally high iso-agglutinin titre in group IV donors.*

Patient T who required a transfusion was grouped and found to be of group II. The only donor available (S. S. G.) was found to be of group IV. This donor might at first sight appear suitable, but direct matching tests showed very strong agglutination between the donor's serum and the recipient's cells. There is necessarily some agglutination in this case, but it was considered to be excessive. The test was accordingly repeated after dilution of the donor's serum to 1 in 10. The agglutination was still very strong. As 1 in 10 is the dilution which the donor's blood ordinarily undergoes during a transfusion this donor was regarded as unsafe.

In another instance of this kind the patient J was of group II. Two donors were available, one of whom was group III (incompatible). The other was H. N. G. who was of group IV, but who was not passed as a safe donor on account of high iso-agglutinin titre detected by cross matching after dilution of the donor's serum.

This brief note is intended to bring out the fact that danger from the use of group IV universal donors may arise in two ways:—(a) abnormal reactions of the recipient caused by disease, and (b) unusually high iso-agglutinin titre in the group IV donor used. The employment of universal donors, without a cross test, should accordingly be limited absolutely to blood transfusions necessitated by surgical emergencies in otherwise healthy persons. The use of group IV universal donors without cross tests for the transfusion of medical cases involves serious risk.

The results in this paper have been expressed in terms of the terminology of Moss, as readers in India are not as yet accustomed to the use of the International Nomenclature.

ENCEPHALITIS LETHARGICA—A BRIEF DESCRIPTION OF THE DISEASE, WITH SHORT NOTES ON THE POST-ENCEPHALITIC LETHARGIC CASES TREATED AT THE RANCHI INDIAN MENTAL HOSPITAL.

By J. E. DHUNJIBHOY,

MAJOR, I.M.S.,

Superintendent, Ranchi Indian Mental Hospital.

CASES resembling epidemic encephalitis or encephalitis lethargica were first reported in India by the military medical authorities at Karachi as early as 1919. On this report, the D.M.S. in India issued a circular letter No. 7T, dated the 27th February, 1920, to all military medical officers in India giving a brief description of the disease with a view to enabling them to detect and treat the cases as early as possible.

Many medical men in charge of large general hospitals and mental hospitals in India also, as well as private practitioners of repute from time to time have observed cases of post-encephalitis lethargica, especially of Parkinsonian type.

The first few cases of this disease seen by me in England were at the Bethlem Royal Hospital in 1923. In 1924 at the Berhampore Mental Hospital in Bengal I saw two suspected cases of this disease, but in the absence of any detailed history from the patients' friends and relations I could not diagnose them as such. Since then I have seen a few undoubted cases of post-encephalitis lethargica of different types at the Ranchi Indian Mental Hospital, as well as in my private practice.

On the 11th June, 1928, I read a paper entitled "Encephalitis lethargica with special stress on its psychological complications" before the Ranchi Medical Society with a clinical demonstration of different types of cases.

All post-encephalitis lethargica types of cases now seen in India, especially among persons who have never gone out of India, prove beyond doubt the prevalence of encephalitis lethargica at some time or another in sporadic form in India.

Moreover, the fact that encephalitis lethargica has been an increasingly important cause of insanity in the West, and that during the past few years this disease has been seen more and more in the new admissions of patients to mental hospitals, and similarly a few such cases having also been detected at the Ranchi Indian Mental Hospital, seems to me a justification for giving a rather more detailed description of the disease than it might appear to deserve. In my description of the disease I have mainly confined myself to the psychological complications as they cover my sphere of work and experience.

History.—Epidemic encephalitis or encephalitis lethargica is now considered to be an acute contagious disease, the virus of which attacks the central nervous system and for the most part its grey matter. It made its first appearance in 1917 in which year Von Economo of Vienna published a description of it and named it "encephalitis lethargica." It began to appear all over Europe in epidemic form in 1917. It was so widely spread in epidemic form that this led to its description and recognition as a definite disease entity. At the present time the physical and mental changes due to the lesions which it causes in the central nervous system are giving rise to great anxieties from the medico-legal as well as from the medical aspect. Though the disease was first introduced in the West in epidemic form, most of the cases on the continent and in England which the physicians now encounter are sporadic.

Mode of Infection.—Although histological findings suggest an invasion by some micro-organism, none has so far been demonstrated. The disease is contagious and appears to be spread by carriers who are resistant to it, infecting those who are not resistant. Instances in which direct infection can be traced from one case to another have occurred, but are rare. Recently in the Whittingham County Mental Hospital a small outbreak of encephalitis lethargica occurred affecting 6 patients, admitted some considerable time previously to the hospital and limited to two adjoining wards. The virus of encephalitis lethargica, besides being found in the brain and cerebro-spinal fluid, is also found in the saliva and naso-pharyngeal secretion, and it seems probable from experience that the route of infection is through the naso-pharyngeal mucous membrane.*

Incubation Period.—This has not yet been definitely determined, though some authorities regard it as from 10 to 24 days.

AGE, SEX AND OCCUPATION INCIDENCE.

Individuals of every rank of life and occupation and of both sexes are equally liable to infection. It affects persons of all ages from infancy onwards, but it is found to be most common between the ages of 2 and 30. Further, the mental after-effects appear to be more marked and very frequent in the younger patients.

Mortality Rate.—It is at present impossible to fix the mortality rate with any degree of accuracy owing to the disease being so often unrecognised. However, some authorities put this down to 18 to 20 per cent.

Pathology.—This may be divided into four headings.

(1) **Macroscopical.**—The body is generally emaciated and lacking in fat. The intracranial membranes are perfectly normal, and the dura and pia mater show no inflammatory reaction. The pia mater strips readily from the surface of the cortex, the colour of which is a dull buff instead of the usual glistening whitish grey. On section slight congestion of the brain substance may be apparent as shown by small bleeding points, generally in the grey matter. These changes are likely to be observed in the parts about the Sylvian aqueduct, the fourth ventricle and the basal ganglia.

(2) **Microscopical.**—The most marked microscopical change is the perivascular round celled infiltration which occurs, especially round the small vessels. Every kind of cell degeneration seems to have been noted in all parts of grey matter, but the cells principally affected are the ganglion cells. Changes have been observed throughout the grey and white matter of the central nervous system and also in the peripheral nerves. Some minute bodies have also been found by different observers within, and outside the nerve cells, but the meaning of these is not yet determined. Another point of interest about these changes in the brain is that they are found to be of different stages, showing that the disease is apparently a progressive one, and that the virus—like that of syphilis—remains active for long periods even if quiescent, producing fresh inflammatory lesions from time to time. It has now been definitely established that post-encephalitic Parkinsonism is due to the destruction of the cells of the substantia nigra and this has been definitely proved on post-mortem examinations.

(3) **Bacteriological.**—Much experiment has been carried out on this disease. Inoculation into rabbits and monkeys often produces typical symptoms of the disease. To sum up our knowledge gained on the subject, one may say that encephalitis lethargica is an infectious disease and is due to an invisible filtrable virus. This keeps virulent for long periods in water and milk and it can be destroyed by carbolic acid. The virus has been found in the brain, cerebro-spinal fluid, saliva and naso-pharyngeal secretion, and experimental work has shown that there are points of similarity between this virus and that of herpes febrilis.

(4) **Biochemical.**—The Wassermann reaction in both the blood and cerebro-spinal fluid is negative, and the cerebro-spinal fluid is clear and colourless and does not escape with increased pressure. The cell count shows no appreciable increase in all the cases. Pandy's and the colloidal gold test reactions as a rule are negative. The sugar content of the cerebro-spinal fluid is slightly increased in encephalitis lethargica, but the chlorides are usually normal. In the blood there is no change except a possible leucocytosis during the febrile stage of the disease.

*The virus of encephalitis lethargica is usually supposed to be a filtrable one. Doerr and Zdansky, Levaditi, Nicolau and Schoen, and Cowdry and Nicholson have observed organisms described as *Encephalitozoon cuniculi* in the brains of rabbits and mice suffering from a similar, or identical, disease. This work, however, still lacks confirmation.—EDITOR, I. M. G.

SYMPTOMATOLOGY.

This disease commonly begins with a febrile illness, and in its milder forms is often mistaken for influenza in the West and possibly malaria and influenza in the East. The temperature runs from 100°F. to 101°F. and apart from headache (sub-occipital) and general malaise and slight stiffness of the neck with a slight lethargy and drowsiness, there is very little general disturbance. In the course of a day or two the nuclei of the third nerve become affected, leading to dimness of vision for near objects, due to paralysis of accommodation; ptosis and weakness of the ciliary muscles are also noted and at this stage complaint is also made of diplopia. The acute attack lasts only a short time and many patients may not be laid up for longer than a week or two. By this time the neuronie disorder will nearly always appear to have cleared up or will be represented by some minor difficulty of co-ordination that gives no definite indication of organic diseases.

The mental symptoms of the early stage of the disease consist of lethargy and delirium.

Lethargy.—In the lethargic type, besides the somnolence, which is so common, the patient when awake is in a state of mental lethargy, a slowness in reaction to mental stimuli of any kind which cannot fail to be noticed. During the waking intervals, the patient is often restless, noisy and excited. Lethargy in this disease often takes the form of inversion of the normal sleep rhythm, that is to say the patient is unable to keep awake or to be kept awake during the day and is unable to sleep during the night. When this occurs the patient is usually restless, noisy and excited at night (*vide* Case 1).

In the *delirious* type, restlessness, mental or physical, or both, takes the place of lethargy or masks it. The mental symptoms tend to abate in time but the lethargy and somnolence very frequently remain for long periods after the acute stage of the disease has passed.

In the more acute form the mental symptoms may be severe, and this form may suggest an acute confusional psychosis. The patient is extremely restless, excited, confused and disorientated. He suffers from vivid hallucinations and in severe attacks he is quite unmanageable and therefore it may be necessary to certify him to get him admitted into a mental hospital.

Sometimes the course of the disease may be extremely prolonged with continued symptoms of general intoxication and the development from time to time of signs of fresh involvement of the nervous system. Such a case may go on for many months and terminate in recovery or death. On the other hand, as stated above, there is a large group of mild or abortive cases in which the symptoms of general infection are present and the cranial and other nerve palsies clear up very rapidly and the patient recovers completely in two or three weeks' time. Since the

symptoms in encephalitis lethargica depend almost entirely upon the localisation of the virus, one must be prepared to find almost any combination of signs and symptoms in the course of an attack. Thus with regard to the onset, in addition to the common type already described there may be instances in which meningeal symptoms predominate from the first (*vide* Case 8), and restlessness, irritability or even a noisy delirium may take the place of the more usual lethargy, or the illness may begin actually with an apoplectic seizure or the picture may be entirely dominated by the presence of muscular twitchings (what is called a myoclonic type). In another group of cases the disease may be ushered by severe neuralgic pain in the peripheral nerves and this may be followed by wasting and weakness of an isolated group of muscles or absence of tendon jerks, and a subjective sensation of numbness in the extremities which may simulate polyneuritis. This account of the symptomatology is by no means exhaustive, for it is extremely varied, and differs in individual cases. In mild cases the signs of involvement of the nervous systems are often fleeting and special enquiries are necessary to elicit the history of transient diplopia and dimness of vision, temporary paralysis of accommodation, pain and stiffness of the back of the neck, and neuralgic pain or muscular twitchings. The extent and duration of pyrexia are also variable. It is high as a rule during the initial stage, but on account of the serious nature of the onset it may have subsided before the case comes under medical observation.

COURSE OF THE DISEASE.

The very acute form is often fatal, especially if the mental excitement is at all severe. In the milder types the patient makes a satisfactory recovery when the fever subsides, except for symptoms of a localised paresis which may show itself in a difficulty of accommodation or may require an exhaustive neurological examination to reveal it. But the greatest importance of the disease lies, however, in its sequelæ which vary in form and which strongly suggest from their capacity of spontaneous variation a progressive and active disease process. The sequelæ may appear after the initial onset at a varying interval from two months to many years, and during this interval the patient as a rule has enjoyed good health and carried on his usual occupation.

The commonest clinical sequelæ of encephalitis lethargica are as follows:—

(1) *The Parkinsonian syndrome in adults.*—This is the most common disability of a general kind resulting from encephalitis lethargica. The early signs of Parkinsonism are found in the upper part of the body and more often in the face than elsewhere. The face is greasy and the expression tends to be fixed, with eyes staring, the mouth often a little open and a trickle of saliva dribbling from it; also the palpebral fissures may be wide or narrow and, when an attempt is made to open or shut the eyes, quivering of

SYMPTOMATOLOGY.

This disease commonly begins with a febrile illness, and in its milder forms is often mistaken for influenza in the West and possibly malaria and influenza in the East. The temperature runs from 100°F. to 101°F. and apart from headache (sub-occipital) and general malaise and slight stiffness of the neck with a slight lethargy and drowsiness, there is very little general disturbance. The extent and duration of pyrexia are also variable. It is high as a rule during the initial stage, but on account of the serious nature of the onset it may have subsided before the case comes under medical observation.

COURSE OF THE DISEASE.

The very acute form is often fatal, especially if the mental excitement is at all severe. In the milder types the patient makes a satisfactory recovery when the fever subsides, except for symptoms of a localised paresis which may show itself in a difficulty of accommodation or may require an exhaustive neurological examination to reveal it. But the greatest importance of the disease lies, however, in its sequelæ which vary in form and which strongly suggest from their capacity of spontaneous variation a progressive and active disease process. The sequelæ may appear after the initial onset at a varying interval from two months to many years, and during this interval the patient as a rule has enjoyed good health and carried on his usual occupation.

The commonest clinical sequelæ of encephalitis lethargica are as follows:—

(1) *The Parkinsonian syndrome in adults.*—This is the most common disability of a general kind resulting from encephalitis lethargica. The early signs of Parkinsonism are found in the upper part of the body and more often in the face than elsewhere. The face is greasy and the expression tends to be fixed, with eyes staring, the mouth often a little open and a trickle of saliva dribbling from it; also the palpebral fissures may be wide or narrow and, when an attempt is made to open or shut the eyes, quivering of

the lids takes place and lacrimation is also visible. Diplopia, squint, nystagmus are less commonly found than in the acute stage of the disease. But the defects in ocular movements and pupillary reactions are *never absent*. The external ocular palsies are supranuclear in origin and consist of defective conjugate movements, especially on convergence. The pupils are not usually altered in size or shape but are often unequal and almost always show some disturbance of reflex action to light or to accommodation or both. Mistiness of vision from defective nerve balance or ciliary paralysis is often complained of and may be a persistent defect.

The characteristic feature of the Parkinsonian stage is the immobility of the affected parts and its rigidity and the typical Parkinsonian mask, gait, salivation and lacrimation.

ILLUSTRATIVE CASES.

Chronic Encephalitis of Parkinsonian Types.

Case 1. (Photograph A).—S. S. D., A Hindu widow, aged 50, was admitted on 19th March, 1927, on the following medical certificate: "A dull stupid looking individuality, morose, habits unclean, face vacant, peculiar stare, gradual progressive weakness of muscles. She has been in this stage for the last six years or so and is gradually getting worse. What she wants must be immediately complied with, otherwise she would make a hell of the whole household by her pitiable cries."

On examination and further observation in the hospital she was diagnosed as a typical case of Parkinsonian type of chronic encephalitis lethargica. She had a fixed gaze, greasy face and mask-like expression. She had a typical stoop with immobility and rigidity of the upper part of the body and the proximal joints. Saliva was dribbling from her open mouth and lacrimation was present. Eyes with fixed gaze and marked quivering of the eyelids on opening and shutting. The right pupil was slightly more dilated than the left. Light and accommodation reflexes were sluggish. No diplopia or nystagmus was present. Had a characteristic monosyllabic slur and slight tremor of the tongue.

Personal history.—To complete the diagnosis her son-in-law was interviewed. He said that in 1920 the patient suffered from a serious illness of febrile type. During this illness she had tremors of the hands and complained of dimness of vision and diplopia. A year after this she exhibited maniacal symptoms with the present Parkinsonian syndrome. She was quite manageable all these years at home but since 1926 became unmanageable as she developed typical disturbance of sleep rhythm, and during the night remained awake and kept the whole household awake by her cries, which gradually led her people to seek admission for her into a mental hospital. No psychopathic or neuropathic history in the family. During her stay in the hospital she suffered from disturbance of sleep rhythm for a month. To further confirm the diagnosis, a few injections of hyoscine hydrobromide were given and a marked temporary improvement took place in her case. Her salivation and lacrimation after a few injections disappeared and some expression began to appear on her face. She began to take more interest in life and attended the amusement hall and gardens. She was then placed on a six months' continuous treatment with hyoscine hydrobromide, but no further improvement was noticed. For the first week 1/100 gr. was given and later 1/50 gr. throughout the remaining period. Once a week pilocarpine nitras 1/10th of a gram was injected to counteract the uncomfortable symptoms of hyoscine. As she did not show any mental symptoms and was quite well-behaved during her stay of nearly two years in the hospital, she was discharged on 27th February, 1929, to the care of her son-in-law, who was

very pleased to take her back as she had improved very much. Instructions were given to him to put her immediately on hyoscine injections if she got worse.

Case 2. (Photograph B).—S. K. B., a male Hindu student, aged 24, was admitted on 12th November, 1925, on the following medical certificate: "Has a vacant look, stupid appearance, incoherent talk, restlessness, foolish speech and generally depressed."

On admission he was diagnosed as a case of catatonic type of dementia præcox. He was also so diagnosed in the Berhampore Mental Hospital where he had been previously admitted for treatment on 15th December, 1924, and discharged as cured on 29th August, 1925. On further examination and observation, he was diagnosed as a case of Parkinsonian type of chronic encephalitis. He had lacrimation, salivation, fixed gaze, immobility and rigidity of the upper part of the body and proximal joints, and the characteristic gait and mask. Had fine tremors of the hands. The eyes showed marked quivering, pupils unequal, light and accommodation reflexes sluggish. To complete the diagnosis, his guardians were written to. They informed us that the patient had suffered from an acute attack of fever in 1922, he recovered from this illness and 18 months later developed maniacal symptoms for which he was sent to the Berhampore Mental Hospital on 15th December, 1924. On his discharge from the mental hospital on 29th August, 1925, he was quite well mentally, but was reported to be highly lethargic and did nothing but sat at home and gazed at the inmates of the house. On 24th November, 1925, he again developed maniacal symptoms for which he was sent here for treatment. The history shows that he had the first acute attack in 1922 but recovered and the Parkinsonian syndrome developed in 1924. He is still highly lethargic, though on hyoscine treatment for six months a little improvement took place in his condition. His salivation and lacrimation disappeared, and a little expression returned to his face. He began to take a little interest in his life but he did not improve beyond this. He occasionally tries to run away from the wards.

Case 3. (Photograph C).—M. K., a male Mahommedan cultivator, aged 50, was admitted on 10th September, 1927, on the following medical certificate: "Listless, depressed, slurred speech, mutters to himself, apathetic, attacks other people." On admission he was diagnosed as a Parkinsonian case with typical mask, gait, immobility and rigidity of the affected parts and salivation and lacrimation.

Eyes quivering, sluggish reflexes to both light and accommodation, pupils equal, defective conjugate movements, especially on convergence, and had tremor of lower jaw and "tombone" (antero-posterior) movements of the tongue. Speech, typical monosyllabic slur of the Parkinsonian. As he was picked up from the road by the police nothing is known about his previous history. But this was a typical case of Parkinsonian syndrome and the tremor of the jaw which is the only tremor of its kind lends further support to the diagnosis. The diagnosis was further confirmed by hyoscine treatment. He showed slight improvement on hyoscine therapy. The salivation and lacrimation disappeared, a little expression returned to his face and the tremor of the jaw much improved. He did not show any further improvement than this.

Case 4.—R. D., a Hindu woman, aged 30, was admitted on 19th August, 1926, on the following medical certificate: "Morose, apathetic to her surroundings, attitudinistic, negativistic, refuses to eat, does not wear clothes." On admission she was diagnosed as a case of catatonic type of dementia præcox. On further observation and examination she was found to be suffering from the Parkinsonian syndrome with typical gait, mask-like face, lacrimation, salivation, rigidity and immobility of the affected parts. She never spoke a word after her admission and refused to eat any food and was occasionally nasal-fed and throughout spoon-fed. The eyes showed no marked quivering, pupils unequal, light reflex normal, but that to accommodation sluggish. She was reported by the police to be a woman of easy virtue

and had no relation from whom we can obtain her previous history. On the clinical diagnosis of the case she was treated with hyoscine hydrobromide and to our great surprise we found a great improvement in her case. After a month of hyoscine treatment she began to talk, bathe and feed herself, and attended the amusement hall where she sang and danced. Her salivation and lacrimation disappeared and complete expression returned to her face. Her treatment was continued for six months and a marvellous improvement took place. Hyoscine has been stopped in her case since then, but no untoward symptoms have yet appeared and she has maintained her improvement. She behaves quite normally now. This case has responded remarkably to hyoscine treatment.

Case 5.—In December 1927 I was consulted in the case of S. J., a Parsee girl student, aged 19, in Bombay. On examination she was found to be a typical case of the Parkinsonian type of post-encephalitis. Her parents gave the history that in 1923 she became completely lethargic and refused to do any work and was even spoon-fed. Before that she was a very social, intelligent and hard-working student. It was further said that the girl had suffered from a serious febrile illness on 8th January, 1922, which was clinically diagnosed as paratyphoid fever. She recovered from this after a month or two and was sent for a change as she was found very weak in health. She suffered from dimness of vision after her illness and had to consult an ophthalmic surgeon who prescribed glasses. On her return from up-country she again attended the school and was quite normal for some time but later was inclined to be lazy and then became completely lethargic and the typical Parkinsonian syndrome developed about a year after her illness. She was treated for hysteria for nearly four years, during which period I was told that she was completely changed physically. An old photograph of her was shown to me which definitely corroborated the statement. She was placed on hyoscine treatment and it proved very successful. She became active and began to take an interest in her life and after six months' treatment she became quite normal. As she is still very weak she is not attending the school but studies at home and is not a source of extreme worry and trouble to her people. During my last visit to Bombay in 1928 I saw the patient again and she has still maintained the improvement since 1927.

CHRONIC ENCEPHALITIS. SECOND TYPE. WITH INVOLUNTARY MOVEMENTS.

Involuntary movements of many kinds are amongst the commonest manifestations of chronic encephalitis lethargica. More than one variety may be seen in the same patient and they may change during the course of the illness. Some are slight and almost insignificant, others are large and arresting and in a severe case the body may be in an almost convulsive riot of movements. (*vide Case 6*). Involuntary movements have, however, rarely occurred as the sole manifestation of the disease. Mental or physical derangements of some sort are always present. They may be so slight as to be easily missed by the casual observer. Emotional instability and restlessness, especially at night, changes in behaviour and oculo-motor defects are perhaps the most frequent slighter accompaniments of involuntary movements.

The involuntary movements of encephalitis lethargica are grouped as follows:—

- (1) *Choreic form.* In this the movements resemble those of chorea (*vide Case 7*).
- (2) *Myoclonic movements.* These are well marked in the acute phase of the disease, but

they appear as late manifestations in any part of the body and proceed for months, accompanied by pain. The pain is often severe and continuous and may last long after the shock-like muscular contractions have disappeared. The contractions are rhythmical at a rate which varies and may go up to 40 a minute, involving part of a muscle, a whole muscle, or a muscle group. Sometimes the upper abdominal wall of the diaphragm is the part most affected and in the latter case the objective manifestation is recurring hiccup.

Second type—Cases with Involuntary movements.

Case 6.—K. N., a Mahomedan male labourer, aged 23, was admitted on 29th March, 1927, on the following medical certificate: "Dull, stupid, does not answer all questions, noisy, abusive, indecent, and has some ataxy of the lower limbs." On admission he was found to be excited, but after a month he became quite normal and began to answer all questions coherently. His speech was slow but distinct, comprehension good. He was found to be suffering from involuntary tremor of the upper and lower extremities, more marked in the legs. The tremors on the left side of the body were more marked than of the right. His tremors were such that it appeared that his whole body was almost in a convulsion of movements. The tremors increased when the patient got excited or a little flurried, and decreased when resting in bed. Habits clean. He was slightly emotional, due to the physical defect of which he was quite aware. The eyes showed marked quivering, pupils unequal, light reflex normal, accommodation sluggish, conjugate movements of the eyeballs defective. The patient later became quite intelligent and gave a clear history of the first attack. He said that he was seriously ill about eight years ago with a febrile illness for which he was treated by a village doctor. He recovered from this serious illness which lasted for over four months. He further said that during his illness he suffered from tremors, diplopia and dimness of vision and he still suffers from defective eye-sight. On recovery from this serious illness he continued to work as a labourer but later on suddenly felt no inclination for work and about two years after his illness the present condition of tremors appeared which deprived him of his livelihood, and he lived by begging, for the last four years. He said that in the year 1927 he was practically starving as he had no money and it is natural that he developed exhaustion psychosis. Within a month of his admission to hospital his mental symptoms disappeared owing to good food and good hygienic conditions and during his stay of 19 months in the hospital he never showed any mental symptoms, except that at times he was highly emotional on account of his physical disability. He was placed on hyoscine therapy and a marked improvement took place in his tremors. He slept well and his tremors improved so much on hyoscine that he thought that he would go out and earn his living again by some light work. He was discharged on 5th October, 1928, with the advice to continue the hyoscine treatment in case the tremors increased again. This case also responded admirably to six months' hyoscine treatment.

Case 7.—T. P., a Mahomedan cultivator, aged 22, was admitted on the 15th July, 1927, on the following medical certificate: "Goes about naked, restless, noisy, dirty in his habits."

On admission, he was irrelevant, incoherent, and excited; after about a month he was quite normal except that he was a little restless and used often to run away from the wards. Occasionally he used to shout at night (disturbance of sleep rhythm). He had marked choreiform movements of the right upper and lower extremities and face.

The eyes showed marked quivering, the right pupil more dilated than the left. Reflexes to both light and accommodation were sluggish. He complained of

dimness of vision in the right eye. Later he improved very much and gave the history that he had suffered from serious febrile illness for three months about four years before, and since then he developed these tremors. In his descriptive roll by the police it was stated that he had had a similar mental attack at home some few years before, so the present attack was a relapse, showing that the disease is still active in him. He was also placed on hyoscine therapy and in his case also it worked wonders. His tremors improved so much on hyoscine treatment that he begged for his discharge and as his mental condition was much improved he was discharged on the 30th July, 1928.

A letter was also given to him to continue the treatment outside in case his tremors become worse again.

Tremors.—Tremors of different parts of the body also occur. In addition to affecting the limbs they are found elsewhere, giving rise for example to shaking of the head to and fro, movements of the tongue, and rhythmical sucking of the lips. All involuntary movements are aggravated by emotional disturbance and fatigue, and disappear during sleep. This was particularly noted in all my patients with involuntary movements.

Respiratory disease type.—The following three chief respiratory types of disorder have been observed:—(1) disorder of respiratory rate, (2) disorder of rhythm, and (3) respiratory tics.

With some of the more severe respiratory cases delusions and violence may develop, necessitating the patient's removal to a mental hospital.

(1) *In disorders of respiratory rates.*—Tachypnoea and bradypnoea are usually paroxysmal. These vary in duration from a few months to several hours. In tachypnoea the rate may be 60 to 100 a minute, and the breathing is shallow. It may be followed by a period of either bradypnoea or apnoea. In bradypnoea the respiratory rate may fall as low as 6 per minute and the breathing is deep and often noisy and panting.

(2) *The disorder of rhythm* includes such abnormalities as sighing and breath-holding. Breath-holding is a most dramatic performance which may be often repeated, especially towards the evening and occur during sleep. After a few deep breaths the chest is held in full inspiration for as long as half a minute.

(3) *Respiratory tic*, such as hiccup, yawning, hard cough without expectoration, sniffing, sneezing are all classed under this heading. These cases are most often met with in young people of school age, who in addition show a change in character and are subject to nocturnal excitement. I have not yet seen a case of respiratory disorder type of encephalitis lethargica in India.

MENTAL SYMPTOMS IN LATER STAGES.

Between the appearance of these later symptoms and the early stage of the disease there is frequently an interval during which the patient is moderately well, and this interval may be quite long—three or more years.

Dementia præcox is often simulated in the frequent cases of mild Parkinsonism with catatonia. Also manic depressive psychosis and paranoia are simulated. Mental changes of every kind have been reported, and changes in the emotional make-up are very common, probably from lesions in the thalamus and basal ganglion. But the most striking mental changes which occur, especially in children and young people, are the sudden and complete alterations of character and temperament now known as the "apache" type. These changes are not at all rare, and manifest themselves either suddenly or insidiously at varying intervals after the onset of the disease. The patient, who before the illness, was hard working, full of interest, good tempered and happy, becomes idle, mischievous, lacking in interest, irritable, impulsive, malicious and a source of grave anxiety to parents and guardians. The complete change in morality is often dramatic in its suddenness. Lying, thieving and sexual immorality, and even inclination to homicidal acts appear in young people of the most respectable and respected families whose upbringing and education have been of the best, and in whose family history generally no psychopathic or neuropathic tendency can be discovered and whose previous moral character and disposition were good. There is generally, though not always, found some change on the intellectual side as well. Cases showing such changes in the character are attending the out-patient departments of all the hospitals in the West in increasing numbers, and a few of them are also now detected at the Ranchi Indian Mental Hospital (*vide* Cases 8 to 12). Children or young men who had hitherto being good tempered, trustworthy, and a help in the home are now untruthful, dishonest, have lost all regard for right or wrong, are irritable, have attacked people with a knife or other weapon, and cannot be left without constant supervision. When seen, these children or young men may be found to be intelligent, with nothing to indicate any such accusation and nothing on which to base any certificate of mental deficiency or insanity. The domestic disturbance caused by these patients is often enough to reduce the peaceful household to a state of chaos. These patients present a problem both to their parents and to the State, and are now potential recruits to the criminal population of mental hospitals. I wonder whether some day such a past attack of encephalitis lethargica will be urged as a defence on a criminal charge.

The term "apache" has now been used universally in the description of cases of post-encephalitis lethargica whose chief characteristics are delinquency and bad conduct, and the apache syndrome is here meant to include all behaviour irregularities from mischievousness to serious crime, such as murder. The condition appears to depend partly on a heightened irritability and diminished power of control, and partly on a lack of reasoned judgment and self-criticism. In

any case, the result is a more or less complete disintegration of those psychological sentiments which contribute to the social and moral senses. Motor restlessness is a striking feature in these patients and may be responsible for the numerous cases of "wandering" as well as for their pugnacity.

Apache type—Or cases with changed conduct and temper.

Case 8.—S. K. M., a Bengali Brahmin student, aged 18, was admitted on 2nd August, 1927, as a criminal patient charged with theft on the following medical certificate: "He goes into fits of temper and shows symptoms of excitement and is very violent to others. He takes away all his clothes and goes about naked: he has a violent temper."

On admission his speech was irrelevant, he was quarrelsome, excited, orientation in time and space was good, and slightly delusional. After about a month his speech was relevant but he showed a most quarrelsome temperament. He simply could not get on with the staff and other patients. Later he became very abusive and was kept in a separate room for some time under the strictest institutional discipline. This had the desired effect on him and he improved a little, but he went on telling lies and began to steal other patients' properties. He showed aimless activity with occasional irritability and quarrelsomeness. Occasionally he showed outbursts of acute excitement which lasted for three or four days. He was reported to have attempted suicide at home and also ran away from home many times. In the hospital he also tried to run away and threatened to commit suicide.

Eyes.—The patient complained of dimness of vision and said that he had suffered from diplopia and dimness of vision ever since his last illness, and that he had had to go to an eye specialist for glasses. He had marked quivering of the eyelids. His right pupil was more dilated than the left. Accommodation reflex sluggish, light reflex normal. He had also fine tremors of the hands. He had definite conjugate movements on convergence.

Previous history.—The patient had a severe attack of meningitis and he recovered from this illness after four months. A few months after his illness he became abnormal in his conduct and temperament. He jumped into the Ganges with a view to committing suicide but swam across to the other bank when he saw people attempting to rescue him. He often ran away from the house. Before the illness he was reported to be of good conduct and behaviour; he passed his matriculation examination in the first division. This history was given to me by his father who is also an educated man and was agreed to by the patient himself, and further corroborated by the descriptive roll from the police. His was a typical case of post-encephalitic "apache" type. In his case meningitis was simulated. He was attacked with the so-called meningitis in 1923, and a few months later he began to show abnormal changes of conduct and temperament. He was kept at home all these years, but he committed so many petty offences such as pulling the alarm chain of a train while in motion, travelling without a ticket, going round in taxis and gharries without payment of hire, assaulting people on the slightest provocation, committing petty thefts of articles from friends and relatives; that his people got tired of his sudden change of character, and took protection from the police and had him admitted to the Mental Hospital. The typical symptoms of apache encephalitis were markedly present in his case, such as lying, thieving, quarrelling, wandering, threatening to commit suicide, aggressiveness and in spite of this his intelligence was quite good and his degree of intelligence was always higher than that of his conduct.

Treatment.—Hyoscine has no effect on such cases, but under strictest institutional discipline some cases improve, and he showed much improvement later and was discharged on 28th February, 1929, to the care of his

father who was quite pleased to take him home as he found much improvement in him. In such cases the prognosis is a great problem.

Case 9.—J. N. B., a Hindu Brahmin student, aged 20, was admitted on the following medical certificate: "Talks nonsense, violent at times, abuses, suffers from insomnia, refuses food, remains naked." On admission he was found to be quiet, answered all questions coherently and admitted his abnormal conduct and had an insight into his disease. From the date of his admission on 24th December, 1927, to the date of his discharge on 10th June, 1928, he showed no symptoms of excitement but he was extremely quarrelsome, abusive, and a liar.

Eyes.—Slight quivering, defective conjugate movements on convergence, right pupil more dilated than the left. Complained of dimness of vision and wanted glasses for his eyes. Very fine tremors of fingers of both the hands were noticed.

Previous history.—His father informed me that in 1923 the patient suffered from a severe attack of influenza. A month after the illness he showed slight mental excitement with tremors of the hands. He was treated by a homœopath and was quite cured of his illness. After his recovery he again joined the school and passed his matriculation in the first division and then joined the college for his I.Sc. examination. Two and half years after the previous illness he began showing symptoms of lethargy. He shirked his work and refused to go to college, and he was found to be abnormal in his conduct and temper. No psychopathic and neuro-pathic history in the family. Several times he jumped into a tank adjoining his house but always came up on being entreated by his relatives. He often ran away from his house; he bit the ear of one of his relatives on the slightest provocation. He once very nearly choked his mother. He stopped the Bombay Mail by pulling the alarm cord for which he was sentenced to confinement till the rising of the Court. In 1927 he again pulled the alarm cord of the train at Midnapore and the Sub-divisional Officer of that place released him on the surety of his father. He had often travelled without tickets in buses, trams and trains. He had committed petty thefts from his friends and relatives. He was reported to be very clever, social and a well-behaved boy before the serious illness—so-called influenza—in 1923. The supposed illness was nothing else than the first attack of encephalitis lethargica which resulted in a post-encephalitic character of apache type later. His was a case of ungovernable naughty child throughout. As he showed no mental symptoms during his stay in this hospital and improved in his habits under institutional discipline, he was discharged in care of his father who was willing to take him back as he found him much improved. This case also showed typical symptoms of apache character, namely, lying, thieving, assaulting, attempting suicide, wandering spirit, etc.

Prognosis is again a problem in this case. His intelligence ratio was far superior to his behaviour.

Case 10.—A Mahomedan student, aged 16, was admitted on 15th January, 1927, on the following medical certificate: "Violent antipathy against mother, ungovernable temper, irresistible thieving propensities, refused food, sometimes remained naked, throws anything that is handy at others." On admission he showed all the symptoms of a naughty child. He was abusive, extremely quarrelsome, told many lies and used to steal other patients' property and food. In fact he was unmanageable for some time and was most troublesome and pugnacious. He often ran away from the wards.

Eyes.—Quivering was present, light reflex normal, but accommodation sluggish. He had slight tremor of the hands and when he was excited his tremors were well marked.

Previous history.—His father, who is a professor, informed me that he was quite normal from the date of his birth up to the date of his abnormal conduct and temper. He was very cordial, fond of society, and was a great favourite in the school. He took a great interest in life. He was a very clever student and was reported to be good and obedient before his illness. He further stated that 10 to 12 months before the first attack in his

present illness he suffered from a kind of fever which was then diagnosed clinically as dengue in 1923. He recovered from the illness and was quite normal until 1924, when he developed abnormal conduct and temper and became very lazy, shirked his work and remained at home. But in December 1926 he became absolutely unmanageable and his people were simply forced to put him in a mental hospital. He improved very much under strict institutional discipline and was discharged to the care of his father on 12th May, 1928. I am still in touch with his father by correspondence and his last report shows that he is still well-behaved. He was a typical case of post-encephalitis of apache type. He was very intelligent in proportion to his conduct. He had all the symptoms of the apache type, such as quarrelsomeness, thieving, lying and wandering and pugnacity, but he never attempted suicide, though in his case slight homicidal tendencies were shown against his mother.

Case 11.—G. M. alias K, a Mahommedan B.A. class student, aged 25 years, admitted on 8th May, 1928, by the police as an unknown insane person. On admission he was restless, garrulous, abusive, quarrelsome, and refused to wear clothes and to eat his food and was filthy. Later he became quite euphoric and was quite normal within a month. He then gave us his proper name and address and told us that he was a student of the B.A. class.

Eyes.—Marked quivering and during the excitement stage he used to roll his eyeballs and a mild nystagmus was present. He had slight tremor of the fingers.

Personal history.—On his recovery we wrote to his people, and his uncle, a cultured man who was very anxious about his whereabouts, came immediately to see him and he gave me the following typical history. He said that the patient had had an attack of severe fever and he suffered from it for nearly two months. He was under the treatment of a hakim. During his illness he showed some tremors, complained of dimness of vision and diplopia. This happened in 1922. On recovery he was quite normal and prosecuted his studies and had a brilliant career in the school and college. In 1926 he appeared to be queer and showed some symptoms of mental excitement, for which he was again treated by a hakim. A few months after this he began to shirk his work and did not attend the college. He often used to run away from home and college and began to show abnormal conduct and temper. He became restless, quarrelsome, and told many lies and began to steal articles belonging to other persons. In 1928 he ran away from the house and they lost all trace of him until they heard from me. He was reported to be very social, intelligent and well-behaved before his serious illness in 1922. He improved very much under strict institutional discipline and was discharged on 1st December, 1928, to the care of his uncle. He was a typical apache type. Recently I was informed by his uncle that he is still well-behaved and is prosecuting his studies.

Case 12.—In 1927 I was consulted in Bombay in the case of a share broker, aged 32. It was said that four months before the appearance of the mental symptoms the patient was attacked by some fever which was diagnosed as rheumatic fever. He had suffered from diplopia and dimness of vision. On recovery from the serious illness he developed tremors of the hands and tic all over his face, which he never had before. He was sent to the hills for change of air, and on his return he attended his business as usual. A year after the illness they found in him a gradual alteration of character and temper. The patient who, before his illness, was hard working, full of interest, good natured, happy and fond of his wife and family life, was reported to have become idle, mischievous, quarrelsome, irritable, a liar and a thief. He also had hallucinations of hearing, especially of a persecutory type, and had attempted suicide more than once. A typical case of apache, and the so-called rheumatic fever was the first attack of encephalitis. No psychopathic or neuropathic history in the family.

Eyes.—Showed quivering and he complained of dimness of vision in both eyes in spite of glasses. He had ptosis of the left eye and the conjugate movements of the eyeballs were defective.

As he was unmanageable at home and a rich person he was sent up-country in care of a person who could manage him with discipline. The latter report shows that he is improving under strict discipline.

There are still half a dozen more suspected cases of apache type in the hospital, but as neither previous history nor any marked physical signs have been elicited in their cases, I have not diagnosed them as such. However I am in correspondence with their friends and relatives with a view to eliciting the previous history.

DIAGNOSIS.

In cases of the common type, beginning insidiously with drowsiness and low fever and ocular palsies, diagnosis is easy, but it may be a matter of extreme difficulty when the incidence of the infection is much more widespread. The diagnosis may be complicated by large cerebral abscess and the ears should be examined for signs of suppurating otitis. Cerebral tumours may simulate symptoms of encephalitis lethargica, but the examination of the optic discs may clear up the diagnosis, as papilloedema is always present in cerebral tumours and never in encephalitis lethargica.

Encephalitis lethargica starting with meningeal symptoms may simulate meningitis, but the stiffness of the neck is not so marked in encephalitis lethargica, and later the examination of cerebrospinal fluid will clear the diagnosis.

DIFFERENTIAL DIAGNOSIS OF MENTAL SYMPTOMS IN ENCEPHALITIS LETHARGICA.

In the later stages various mental diseases may be closely simulated and again the central nervous system as well as the history should be closely investigated. The presence of extrapyramidal lesions and the destruction of the rhythm of contraction and reflex movements are common signs. There may be signs of Parkinsonism, alterations of rhythm, loss of association movements, salivation, ocular palsies, or a history of diplopia and fever, all of which are always suspicious symptoms of encephalitis lethargica. Some cases may be confused with epilepsy, from the history of fits which may simulate the convulsions of that disease, but the fits when observed closely will be found not to be true epileptic fits.

The catatonic stupor of dementia præcox and the early stages of dementia præcox closely resemble encephalitis Parkinsonism, but there is a profound difference in mentality. The catatonic patient is indifferent and at times extremely inaccessible and his ideas are certainly irrational. He will change his gait at a sharp command and he is usually negativistic, whereas the monotonous slut of the Parkinsonian is characteristic. If the encephalitic is roused he is always accessible, answers rationally and he will not express any of the delusional ideas so common to the catatonic. Even in his periods of excitement the encephalitic rarely voices the bizarre delusions and hallucinations so common in the catatonic and he

certainly does not do so in his quiescent state. The Parkinsonian struggles against his disability, whereas the catatonic seems to be wrapped in a paralysis of volition. A few hypodermic injections of hyoscine hydrobromide may be a valuable aid to diagnosis, as they frequently lead to some immediate improvement in Parkinsonism, but have no effects on catatonic cases (*vide* Cases 2 and 4).

Manic depressive psychosis is also simulated in its depressed phase, but the commonest type of encephalitis depression is relative and largely dependent upon the disability. As a rule there should be no difficulty in differentiating it from the depressed phase of manic depressive psychosis, as in the latter alteration with elation is common, and there is usually a past history of similar attacks and usually a psychopathic history in the family.

The paranoial type of encephalitis cannot be distinguished with any certainty from other paranoid psychoses in the absence of definite physical signs, or of a conclusive history of an acute attack of the disease.

The apache type must be distinguished from mental deficiency. The apache syndrome appearing in a normal child or in a normal young adult of hitherto normal behaviour and normal intelligence are strongly suggestive of encephalitis, even in the absence of other evidence of the disease. However, the diagnosis between a mental defective and an apache is rendered very difficult when encephalitis attacks those who come from an insane stock or who have been feeble minded from an early age. There may be only a vague history of an acute attack or perhaps none at all. However, it is a known fact that encephalitics are most troublesome and pugnacious patients. Their delinquencies are more wanton, more bizarre, more constant and more intractable, and yet they are very sociable and liked by all. They are seldom cowards, they are often ingenious and show some sense of humour. These characteristics are due in part to the increased motor and psychic activities which are a more constant feature in the encephalitic than in the mentally defective. The encephalitic is almost invariably intellectually superior to his conduct, whereas the intelligence and behaviour ratio in a mental defective are approximately equal.

The acute excitement in an apache may simulate mania, but the cardinal symptoms of mania are a flight of ideas, elation, and increased motor activity. The apache undoubtedly shows motor activity and some are always on the move, but their restlessness is quite different from the incessant activity of the maniac. Besides, loss of concentration and easy distractibility of the apache differ greatly from the flight of ideas of the maniac. The restless apache after a few minutes' conversation will return to the same subject, whereas passing rapidly from one subject to another is a characteristic of a maniac.

The maniac covers a large field of ideational material, whereas the apache hovers round a small field. In an apache the true euphoria of the maniac is absent.

PROGNOSIS.

Questions as to prognosis are very difficult to answer. The difficulty arises from two causes. Firstly because the disease has not been under observation for a long enough time to be certain to what extent recovery holds good. And secondly, because fresh foci of the disease may occur at any time and produce fresh mental or neurological symptoms. The death-rate appears to be about 20 per cent., not taking into consideration the abortive cases. The great majority of deaths occur within the first three weeks of the illness, and after this period the prognosis as regards life is good. *Signs of ill omen* are rising temperature, deepening of stupor into coma, or noisy delirium with extreme muscular twitchings (myoclonic form). In cases which are not fatal improvement is almost always slow, extending over three to four months, but in the majority of cases recovery is complete. The cranial nerve palsies as a rule clear up relatively soon, leaving perhaps slight inequality of pupils with reaction to accommodation sluggish, but lethargy, weakness and slowness of movement persist for a considerable time. It must not be forgotten that involuntary movements may appear after a latent period of apparently normal life. Symptoms which are likely to persist for a long time—perhaps indefinitely—are mental deterioration, rigidity and tremors of the paralysis agitans type.

TREATMENT.

There is no specific treatment for the disease. The patient should be made as physiologically healthy as possible, as no line of treatment has yet been found which will seriously affect the course of disorder once established. Spontaneous recovery may occur, but generally the disease progresses slowly and surely towards a state of physical and mental helplessness. However, relentless medical men have tried numerous drugs for the treatment of encephalitis lethargica. Von Economo of Vienna has tried urotropine for the treatment of this malady with good results. He gave urotropine in large doses, 60 to 120 grains at a time, intravenously for 4 to 5 days and subsequently by the mouth in the usual small doses. Piticanin of Roumania treated three cases of myoclonic type of encephalitis lethargica and of paralysis agitans type with good results by intravenous injections of the patient's own cerebrospinal fluid, the injection being given in doses of 10 c.c. for 5 to 7 days; 8 to 10 such injections are necessary. Shortly after the first injection a considerable improvement was observed and the symptoms subsequently disappeared. Rossmere on the other hand treated a group of 8 cases with intraspinal injections of their own blood serum. The average amount of serum injected after

withdrawal of a corresponding volume of cerebro-spinal fluid was 30 c.c. The injections were repeated at an interval of 4 to 20 days, depending on the effect reached after each case. Recently injections of hyoscine hydrobromide were tried in the cases of encephalitic Parkinsonian at the West Park Mental Hospital and at Maudsley. It was found from clinical experiments that hyoscine is of the nature of a specific in the treatment of encephalitic Parkinsonism. In some cases the effects of hyoscine were very good, but in practically every case given the correct dose some improvement was shown. On the physical side there is diminution of the general muscular rigidity, lessening of the tremors of the face and extremities and the disappearance of excessive salivation and lacrimation, which are such frequent and distressing features of this condition. The patient becomes more alert and will occupy himself with light tasks, his gait is much freer, some expression creeps into his mask-like countenance, and he begins to exhibit an interest in things outside himself. His slurring and hesitant speech becomes more free. The question of dose is of importance. It is best to commence with small doses and increase gradually until the required effects are obtained. Hyoscine may be given subcutaneously or by the mouth. If given hypodermically, a start can be made with 1/100 grain once a day, and if necessary increase up to as much as 1/50 grain. It is seldom that a larger dose than this is found to be necessary. When administered by the mouth large doses may have to be given—even up to 1/10th of grain 3 times a day. But 1/50 grain, even by the mouth is not as a rule exceeded. It should be given just after meals, since if taken before food the dryness of the mouth and throat makes mastication and deglutition somewhat difficult. To combat some of the unpleasant symptoms of hyoscine therapy, such as paralysis of accommodation and the dryness of the mouth, occasionally pilocarpine nitras 1/10th of a grain is useful. It is noteworthy that such treatment has been administered for a period of two years and no deleterious effect whatever has resulted from the drug and that no tolerance to it has developed.

Recently tryparsamide and argotropin have been tried. Tryparsamide has been lately largely experimented with in cases of general paralysis and it is proved that it is the only arsenical preparation which seem to gain access to the central nervous system in a way which no other preparation has yet done, and therefore it opens a new chapter in the treatment of neuro-syphilis and also encephalitis lethargica. Cases of encephalitis lethargica experimented on with this drug have shown no further progress of the disease since receiving this drug. It is given in a course of eight weekly intramuscular injections of 2 to 3 grammes.

Argotropin was first recommended by Dr. Wimmer of Copenhagen. It is a combination of 1 per cent. of colloidal silver and 20 per cent. hexamethylene tetramine. It is administered

intravenously, one ampoule of 5 c.c. being given every day. A course consists of 8 to 10 injections. Time forbids more than the mere mentioning all other methods of treatment. Pyorrhoea and other septic troubles are extremely common and correcting of them is absolutely necessary.

In conclusion I may say that hyoscine is of undoubted value in the Parkinsonism of chronic encephalitis. Its action is a specific one, but it is important to remember that its action is temporary and its prolonged use does not lead to intolerance or to deleterious effects. Though in the majority of cases the full benefit of hyoscine can only be obtained by hypodermic injections, yet there is no doubt that in many cases considerable benefit follows its oral administration. I tried hyoscine hydrobromide injections in all my encephalitis lethargica cases of Parkinsonian and tremor types and met with good success in some and some improvements in others.

I injected 1/100 grain of hyoscine hydrobromide daily for the first week, and for the remaining period 1/50th of a grain. Once or twice a week according to the circumstances of the case pilocarpine nitras 1/10th of a grain was given to combat the uncomfortable symptoms due to hyoscine. Injections were stopped after a six months' course in all cases, whether improved or otherwise. In the case of the apache type, the treatment is purely symptomatic, but I have often found that a good talking to and strict disciplinary measures are the soundest treatment when an apache becomes unmanageable and shows symptoms of lying, thieving, quarrelsomeness and pugnacity. When such behaviour is reported to me I immediately send for the patient to my office and give him a good talking to on the subject, shut him up for a week or more in a single room, and if necessary put him on half diet, cut all his cigarettes, stop all his parole, and admission to the amusement hall and games. The treatment goes home to him and he tries to improve his abnormal conduct and temper. In England they experimented by sending the apache type to juvenile jails instead of to mental hospitals. The results were good. Had my Case 8 (Apache type) not improved by the ordinary seclusion treatment, I determined to send him to a juvenile jail as an experiment. It is possible to improve early cases of the apache type by such disciplinary measures, mixed with suggestions and kindness.

THE SPECIES DISTRIBUTION OF HOOKWORMS IN INDIA.

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
(From the Hookworm Research Laboratory, School of
Tropical Medicine, Calcutta. Supported by the Indian
Jute Mills Association).

SINCE it has become recognised that the *Ancylostoma duodenale*, is much more injurious to its

host than is *Necator americanus*, it is obviously of more practical importance rather than that of mere academic interest to know the relative distribution of the two species in any country. There are a few records of this nature referring to India, and, although the general conclusion to be drawn from these papers is that *N. americanus* is the commoner worm, they are by no means unanimous in this respect. It is true that many of the records are based on a very small number of cases, and so they are perhaps not a true index.

The following figures have been obtained from in-patients treated in the Carmichael Hospital for Tropical Diseases, Calcutta. Only a few of the patients were admitted for hookworm treatment especially; the majority of them were suffering from other diseases with hookworm infection as an added factor. They have been divided into three classes, viz., (1) Cured, (2) Not cured, (3) Doubtful cures.

(1) *Cured*.—This means that subsequent stool examinations were uniformly negative for hookworm eggs.

(2) *Not cured*.—Hookworm eggs were still present after one or more treatments. The number of uncured cases appears fairly high, but this is because in many instances the infection was reduced to negligible proportions, and the patients were discharged as the primary condition for which they had been admitted to hospital was cured. An interesting fact that has emerged in the course of this inquiry is that Lane's centrifuge was introduced about half-way in the series, as a means of establishing a cure. Before the use of the centrifuge 68 per cent. of cases were returned as cured, and after the centrifuge was used the cure rate fell to 47 per cent., there being no other change in treatment or diagnosis whatever.

(3) *Doubtful cures*.—Patients who had to be discharged for other reasons before it could be ascertained with certainty whether they had ceased to pass eggs.

Table I has been compiled by recording the species of worms recovered from all the cases, following treatment, and Table II, gives the actual number of worms passed.

TABLE I.

Class of case.	Necator only.	Ancylostoma only.	Mixed infections.	Total.
Cured ..	240	30	54	324
Not cured ..	138	38	55	231
Doubtful ..	48	22	21	91
TOTAL ...	426	90	130	646

TABLE II.

Class of case.	WORMS RECOVERED.			
	NECATOR.		ANCYLOSTOMA.	
	Males.	Females.	Males.	Females.
Cured ..	2,577	2,781	374	538
Not cured ..	2,780	3,392	1,410	1,772
Doubtful ..	928	1,025	429	628
TOTAL ..	6,285	7,198	2,213	2,938
	13,483		5,151	

Most of the cases from whom these figures have been obtained came from Calcutta and its environs, so they may be taken as an indication of the species distribution of hookworms in Southern Bengal. *A. duodenale* is present in 34 per cent. of cases, and 14 per cent. of these are pure infections; *N. americanus* is present in 86 per cent. of cases, and 66 per cent. of these are pure infections. Tomb (1922) in the Asansol district found that 70 per cent. of the worms recovered after thymol treatment were Necators, and that 30 per cent. were Ancylostomes among the miners, and that 64 per cent. were Necators and 36 per cent. were Ancylostomes among the villagers, and he found that Ancylostomes were never present as a pure infection, but were always accompanied by Necators. The *Report of the Rockefeller Foundation* (1922) also found that in Southern India, Necator was the commoner, and that when Ancylostomes were present they were only in small numbers and were invariably mixed infections with Necators. This report also states that coolies in Madras who had come from Bengal, the United Provinces, and the Central Provinces were almost always infected with Ancylostomes, and that Necators were often present but only in small numbers. The worms obtained from an unknown number of coolies on a tea estate at Sibesar were examined, and of 384 worms only 3 were Ancylostomes.

In the Berhampore Gaol, Lane (1913) examined the worms obtained from 150 prisoners, and he found that 60.7 per cent. were infected with Ancylostomes, and 64.6 per cent. were infected with Necators; the actual numbers of worms obtained were 1,322 Ancylostomes and 1,283 Necators. He also found that 9.3 per cent. harboured *Ancylostoma braziliense*, but the fourteen cases that showed this infection only had 20 worms between them. Lane does not say whether he found pure infections with any species.

In Bihar and Orissa, Korke (1926) published two papers on ancylostomiasis in these districts,

and he found that out of 685 cases in Bihar the predominant species was *A. duodenale*, but he gives no figures. He also says that there is apparently a line of demarcation between the distribution of the two species in Bihar. In the camps Duia and Maclellan he found, "..... almost without exception the parasites were identified as Necator."

In the Madras Presidency, Mhaskar (1919) says that Necator is much the commoner species, being nearly 100 per cent. in most areas, but that Ancylostoma varies from 80 per cent. in Tangore to 10 per cent. in Madura.

A. braziliense does not appear to be a very frequent human parasite in India, for the only other reference to it in this capacity, in addition to the one by Lane, quoted above, is the record of its presence in Burma. In this connection Chandler (1927) quotes Jolly who found that 2.5 per cent. of the worms recovered in that country were of this species, and that 5.6 per cent. were *A. duodenale*, the remainder being Necator. Chandler examined six post-mortem cases in Rangoon and found that all the cases harboured *A. duodenale*, five of them had one or more *A. braziliense*, and there were no Necators. He also examined many hundreds of worms obtained after treatment in Calcutta and never found a single *A. braziliense*, despite the fact that nearly all the dogs and cats in Calcutta harbour this species. He suggests that there are certain conditions in Burma and perhaps in Berhampore which are suitable for the propagation of this worm as a human parasite, and that the same conditions are absent from Calcutta.

Although the general indications from the present investigation and from those to which reference has been made are that Necator is much commoner than Ancylostoma, it seems probable that fuller inquiry along these lines would reveal certain foci where *A. duodenale* is the predominant species and that it is therefore of greater importance in India than is generally recognised.

THE VALUATION OF CHARAS.

By D. N. CHATTERJI, B.A., B.Sc., A.I.C.,

Chemical Examiner
and

M. B. ROY, B.Sc.,

Assistant Chemical Examiner to the Governments of
U. P. and C. P., Agra, United Provinces.

THE distribution and sale of charas on importation into India are controlled by excise regulations, and its assay is of importance to Government. During the course of our work a large number of samples were received by us for examination. We were at times in difficulty for want of a speedy and reliable method of assay to get through the work quickly when we had pressure of other work. The most dependable method available up to the present is the physiological one, which consists in the administration of the drug usually to a dog. This method has several well-recognised drawbacks, its chief limitation being that dogs vary considerably in their susceptibility towards the drug. Difficulty is also experienced in administering the drug to the animals, as they often instinctively refuse to take it beyond a certain dose, however much the attempt may be made to conceal its presence in the food with which it is administered. Moreover, the dogs must be given sufficient rest after each experiment. Several workers have from time to time attempted to devise a method of standardising Indian hemp or its preparations by the chemical properties of the drug. Hooper (*Pharmaceutical Journal*, 1908, 81, 347) amongst them claimed that the determination of the iodine value could be used for the standardisation of charas, but Marshall and Wigner (*British Medical Journal*, 1, 1911, 1176) did not find the iodine number of "certain value" and in their opinion it could not be used as a substitute for physiological standardisation.

We thought, however, that the iodine number was capable of indicating the physiological strength of charas, hence we considered it desirable to re-examine Hooper's method, along with certain other chemical tests, some of which were tried in the past, and to correlate them with the results obtained by physiological tests.

In the determination of the iodine number, instead of strictly adhering to Hooper's procedure, we adopted the following method. Two grammes of charas were extracted with rectified spirit and the tincture made up to 100 c.c. with alcohol. Ten c.c.s. of this were evaporated down, Hubl's iodine solution added and the iodine number of the extractive matter was determined in the usual way. We adopted this procedure to avoid the weighing of the alcoholic extract as we found that the latter did not dry to a constant weight at 100°C., but continually diminished in weight.

For the determination of the extractive matter our method was to distil off on a water bath the alcohol from a definite volume of the tincture as

obtained/above, and then to take a single weight after drying the residue for a further period of 5 minutes at 100°C. in an air oven.

For the physiological tests we used the same dog in all our experiments in order to eliminate the error due to idiosyncrasy in different animals. The dog, in our experiment, maintained a practical uniformity of the minimum effective dose towards the drug. The physiological number expressed by us represents the number of milligrams of extractive matter capable of visibly affecting the dog. The following results were obtained on examination of pharmacologically active samples of charas, the results being calculated on the weight of samples after drying at 100°C. for 2 hours.

CONCLUSIONS.

A comparison of the acetyl numbers of good and bad samples, as noted above, confirms the view of Marshall and Wood (*British Medical Journal*, 1, 1912, 1234) that it cannot be used as a substitute for physiological standardisation. The percentage of extractive matter and acid value too are of no significance.

The iodine number on the other hand is found to be a fair index of the pharmacological quality of charas. If this number exceeds 220 a sample may be considered pharmacologically good, but if it be below 200 the sample may be condemned as deteriorated. For a value lying between these figures we would propose to carry out a physiological test. The advantage gained by determin-

TABLE I.

RADIOLOGICAL EXAMINATION OF THE LIVER IN CASES OF SUSPECTED AMŒBIC ABSCESS.

By J. H. BARRETT, D.R.M.E.,

CAPTAIN, I.M.S.,

Quetta.

A PERUSAL of the more recent textbooks which deal with tropical diseases reveals the fact that the radiographic diagnosis of amœbic abscess has scarcely been considered at all. To me this omission seems a great pity. There are certainly many cases where the x-ray method, carefully carried out, may afford the greatest help. These may be conveniently classified as follows:—

(i) *The obscure case without well-marked symptoms.*—A patient comes to hospital complaining of vague subcostal pain, slight temperature, headache, furred tongue. There may or may not be a history of dysentery. Laboratory examination of the stools may reveal nothing abnormal. Perhaps the blood picture is inconclusive and the total leucocyte count may be about 12,000 to 14,000 per c.mm. The blood is often negative to malarial parasites. Clinically there may be sufficient signs to warrant a diagnosis of either (a) hepatitis, (b) diaphragmatic pleurisy, (c) gall-stones, or possibly of simple intercostal neuralgia, or again of a small liver abscess. What then can radiology do? The clinician has little to fear from either hepatitis or a simple diaphragmatic pleurisy. He is more concerned with the exclusion of gall-stones, cysts, liver abscess, local pleurisy with small effusion, or possibly malignant disease. In those cases surgery may have to be employed, and it is in such a case that x-rays will usually afford him the greatest help. Radiology will often decide for him whether the case is a surgical one or not. It may be pointed out at once that the x-ray findings are only contributory links and must be taken into consideration with the rest of the chain of evidence. The x-ray link may be the most powerful of all.

(ii) *Cases which have been diagnosed as hepatitis.*—The physician has made a diagnosis of hepatitis, yet for some reason progress, in spite of emetine, is slow. He wants to know whether there is some other condition present as well, to explain the lack of reaction to treatment. The radiologist may be able to give valuable assistance in this way. Suppose he finds both domes of the diaphragm of normal contour, and elevation, and moving actively with respiration and with perfectly clear lung-fields above, then he is justified in stating that there is no x-ray evidence of either pleurisy with effusion, basal pneumonia, or liver abscess affecting the diaphragmatic surface. The exclusion of such conditions is valuable in giving a prognosis on the case. If on the other hand the radiologist finds a high dome, displacement of the heart, local bulge and dome fixation and definite obscuring of the basal lung fields or possibly a costo-phrenic or cardio-phrenic fluid

line, then it becomes at once apparent that the case is something more than a simple hepatitis, and the question of employing the exploratory needle for either liver or pleura will have to be decided. The x-ray findings will help in this decision, as it is usually difficult to mistake free fluid or pus in the pleura for anything else.

After radiological examination of a number of cases of liver abscess, I have come to the conclusion that a fair sized abscess of the liver, adjacent to the right dome of the diaphragm, always produces a basal œdema of the lung. With a soft x-ray tube and an electric current of 3-4 m.a. this can usually be demonstrated on the fluoroscopic screen, provided the other lung is normal and lights up well to enable a comparison to be made.

(iii) *Cases in which a doubtful diagnosis of liver abscess has been made.*—These are the cases which have been diagnosed clinically and the surgeon seeks radiological confirmation before operating. Also he wishes to exclude possible complications, especially with regard to the adjacent lungs and pleuræ. These radiological examinations are important, and may reveal the unexpected. One case in my experience had a quiescent tubercular focus in the left lung apex. Another had a whole rifle bullet behind the heart. Another had a small metal screw (inhaled) near the diaphragm. Another had a calcified hydatid in the lung, and yet another had an un-resolved pneumonic patch at the lung base. These are cases which may give rise to no symptoms, therefore it is well to have an x-ray investigation before operation.

THE RADIOLOGICAL EXAMINATION.

Posture.—The patient is first x-rayed on the couch lying face downwards. The tube target is centred over the 5th dorsal vertebra. Two photographs are taken, one in inspiration and one in expiration. The patient holds his breath during the exposure, which should be as short as possible. A further photograph is taken with the patient lying on his back. Centering is effected over the centre of sternum opposite the fourth costo-chondral junction. This photograph is taken in inspiration.

Next, if the patient is not too ill, he is examined in the upright position (fluoroscopic) for about three minutes, and a rapid inspection made of the region of the domes of the diaphragm. If the patient is too ill this examination may be made in the sitting position. In routine examination I do not think stereography or teleo-röntgenography are necessary.

Although cases vary considerably, I think if the investigator will look for the signs tabulated, he will be able frequently to give useful information to the clinician.

Cases examined radiologically.—Forty-two cases were examined radiologically during the period 1st May 1925 to 1st May 1928. Out of these cases five were reported as liver abscess

and three of these were subsequently proved to be such at operation. Twenty-three cases were definitely reported negative to liver abscess. Of the remaining fourteen cases eight were suspected clinically of having gall-stones; these eight were negative radiographically to liver abscess or gall-stones and they got well subsequently without operation. Out of the remaining six cases examined the *x*-ray signs were indefinite in five, and one case was diagnosed hydatid of the liver, and the cyst was demonstrated on the *x*-ray film.

Radiological findings in the Routine Examination of cases suspected of Amoebic Abscess of the Liver.

Normal.	Hepatitis.	Liver abscess.
(1) Lung fields clear.	Lung fields may or may not be clear.	Lung fields usually obscured at the right base.
(2) Diaphragm silhouette clear.	Diaphragm silhouette may or may not be clear.	Diaphragm silhouette (right) usually obscured.
(3) Diaphragm movement range may reach 2 inches.	Diaphragm movement range rarely more than 1 inch.	Diaphragm movement range (right) practically always under 1 inch and commonly practically immobile.
(4) Diaphragm, no local bulge.	Diaphragm, local bulge.	Diaphragm often local bulge on right dome.
(5) Palpation, no subcostal pain.	Palpation, subcostal pain usual.	Palpation, subcostal pain may be considerable.
(6) Diaphragm silhouette always seen.	Diaphragm silhouette always seen.	Diaphragm silhouette may be completely obscured.
(7) Heart and lungs no displacement.	Heart and lungs no displacement.	Heart and lungs may be displaced.
(8) See-saw movement never present.	See-saw movement not usual.	See-saw movement (right dome up and left dome down) may be present.
(9) No lung complications present.	Lung complications rare.	Lung complications (pleurisy, etc.) are not uncommon.
(10) Diaphragm position normal.	Diaphragm position normal usually.	Diaphragm often abnormally high.

REMARKS.

1. The diaphragm range is measured on the screen with a compass.
2. The trunk-vertical position is the best.
3. The fluoroscopic part of the examination need not take more than a few minutes.
4. An opinion cannot be given on fluoroscopy alone. Skiagrams are essential.
5. In fluoroscopy use an electric current of 3 m.a. I found that larger currents are unnecessary; besides they may give rise to screen-lag.

CONCLUSIONS.

In cases suspected of liver abscess the *x*-ray method of examination affords valuable information in the following manner:—

(a) A doubtful diagnosis of amoebic abscess made on the clinical signs may be cleared up.

(b) The presence or absence of lung complications may be indicated.

(c) Cases negative to amoebic abscess, radiographically usually yield to non-operative measures, i.e., emetine, etc.

(d) The *x*-ray examination aids prognosis, e.g., lung complications add to the gravity of the disease and clear lung fields are indicative of more favourable prognosis.

(e) Within my experience no case where the *x*-ray evidence was wholly negative has subsequently been proved to have been a case of amoebic abscess.

PARIS GREEN AS AN ANOPHELINE LARVICIDE.

By S. N. SUR, M.B., D.P.H. (Lond.), D.T.M. (Liverpool),
Assistant Director of Public Health,
Malaria Research, Bengal,

and

HARIPADA SARKAR, L.M.S., D.P.H. (Cal.),
Assistant to the Assistant Director of Public Health,
Malaria Research, Bengal.

THIS paper has been written mainly for the information of practical malariologists and in it the observations on Paris green of Drs. Gosio, Missiroli, Chalam, Hacket, Dalal and others as well as of our own have been put together. The merits and demerits of this remedy and its probable cost of operation in Bengal have been discussed, which may be of interest to the field workers.

Paris green or Schweinfurt's green is a chemical compound of arsenic, copper and acetic acid. Its chemical name is copper aceto-arsenite, its formula being $3 \text{ Cu H As O}_3 + \text{Cu} (\text{C}_2 \text{ H}_3 \text{ O}_2)_2$. It is therefore a double salt of copper arsenite and acetate. It is a microcrystalline powder of emerald green colour. It is practically insoluble in water. It is perfectly soluble in ammonia and concentrated acids. In the pure state it contains 58.6 per cent. of arsenious anhydride ($\text{As}_2 \text{ O}_3$). Paris green is often adulterated. The percentage content of arsenious anhydride should therefore be ascertained from the dealer when ordering it for larvicidal purposes. Some manufacturers guarantee it to contain 55 to 58 per cent. of arsenious anhydride.

It has been used with great success as an anopheline larvicide in America and Southern Europe. It has also been used with success by Dr. Chalam, Dr. Dalal and others in India.

For use Paris green is diluted with some inert dust in the proportion of 1 part of Paris green to 99 parts of road dust by weight. In the

absence of road dust, clay dust, sawdust, powdered French chalk, or soap stone powder may be substituted. Soap stone or steatite can be had locally in India and is known as *ramkhalli*. The mixture must be perfectly dry before use, otherwise the presence of the least moisture will cause the mixed dust to sink soon. It will also not spread over the surface of the water to form a film of the powder. As the season for anti-malarial operations in Bengal is just the one when one gets frequent showers of rain, it is very important that the road dust should be collected in the dry season and stored for use in the wet season. It is better sieved before putting into bags. If this precaution is not taken there will be great difficulty in securing dry dust at the time when it is greatly needed. In such cases French chalk powders may be used as diluent but will greatly enhance the cost of operation, although the price of Paris green itself may be insignificant.

Experiments with Paris green were carried out in a tank near the Central Jail at Krishnagar in the months of November and December, 1928. The diluent used was dry road dust and the mixture was applied by means of a hand blower devised by Dr. Hacket. The tank was full of such aquatic vegetation as *Vallisneria*, *Utricularia* and *Hydrilla*. In our experiments, Paris green was mixed with dry road dust in the proportion of 1 in 100 by weight. It was found very effective in killing anopheline larvæ as will be evident from the experiments detailed below. In our experiments the same pan of 10 in. diameter was used for collection of larvæ. In each case 15 dips were made to compare the number of living larvæ and the same place was tested.

EXPERIMENTS.

<i>A. fuliginosus</i>	72%	nil	71%	nil	89%	88%	83%	61%	nil

* They could not be identified as the larvæ seemed to have just emerged from the egg-shells during the course of the day. They were very tiny.

It is therefore seen that total eradication of larvæ cannot be expected within 2 hours of the

application of the powder. A total eradication may be expected within 24 hours. It also becomes apparent from the experiment II that it has no action on the eggs which hatched out during the course of the day into small tiny larvæ. From experiment III it seems that *A. fuliginosus* larvæ are more vulnerable than *A. rossi* larvæ. Experiments were also carried out in dishes on the life of Culicine larvæ and Anopheline pupæ. It was found that the mixture had no effect on them.

The alimentary tracts of dead larvæ were dissected out and the contents were examined under the microscope. These showed the presence of typical granules of Paris green in the different regions of the œsophagus and the gut. It therefore acted as a stomach poison. Under ordinary conditions the dust forms a film on the surface of the water and floats for some time. The anopheline larvæ being surface feeders the minute granules of Paris green are taken automatically by them with the inward current produced by their feeding brushes. Arsenic and copper being powerful stomach poisons they die even when a very minute quantity of Paris green is ingested by them.

The quantity of the mixture required to kill all anopheline larvæ in a water area of 20 square yards was about 3 ounces, containing only 14 grains of Paris green. The cost is therefore insignificant. It may be had at Rs. 88 per 1 cwt., which works out the cost of Paris green as a larvicide to be about one anna per 1,000 square feet of water surface. If the diluent is road dust collected and stored beforehand the expense is inconsiderable. But if the diluent used is French chalk powder or steatite powder, the cost would come to about 6 annas every 1,000 square feet, the price of French chalk powder being about Rs. 4-8 per cwt.

The powder may be used by means of hand bellows as devised by Dr. Hacket or by means of any powder blowers such as found in the market like "Misto" powder blowers. When a breeding-place overgrown with tall grass or water hyacinth is to be treated, it is better to have a special long nozzle attached to the blower to be introduced into the growth before blowing the powder. Otherwise powder blown over the growths will settle on the leaves and the larvæ would not be affected. In big swamps which are full of weeds not only in the edges but also in the mid portion, it is better to apply it over the whole surface. This may be done by the operator sitting on a *bhela*—an improvised float made of *sola* or Indian pith such as fishermen use or made of blocks of plantain trees. The only precaution required is that the operator should always keep himself on the windward side of the dust cloud.

Paris green should be applied at least once every six days. As it has no action on the egg stage and the pupal stage of anophelines, the interval between the two applications must therefore

be shorter than the period which takes just hatched out larvæ to develop into pupæ. As the length of this period varies in different seasons, in summer the time taken being very much shorter than the average, the interval must not therefore be prolonged more than six days.

At present a mixture of pesterine and kerosene or fuel oil and kerosene is being largely used as a larvicide in areas where anti-malarial operations have been undertaken in Bengal. The cost of this mixture is about 5 to 6 annas per 1,000 square feet.

The advantages of the use of Paris green as a larvicide are:—

(1) It is inexpensive in comparison with pesterine or kerosene, etc., the cost being about an anna per 1,000 square feet. But if French chalk powder is used as a diluent, the cost per 1,000 square feet comes up to the same level as that of pesterine or fuel oil.

(2) It has no smell, whereas the odour of pesterine or liquid fuel is very much objected to by the public.

(3) The solubility of Paris green is so negligible and the quantity used is so small for the area treated that there is no fear of toxic effects. It sinks to the bottom of the tank after a certain period, and being practically insoluble it does not materially affect the composition of the water. According to Drs. Gosio, Missiroli and Hacket, even when Paris green comes in solution in minute quantity, there is no accumulation of arsenic in solution in the water, as it is eliminated within 48 hours by natural biological processes through the agency of aquatic vegetation, viz., *Penicillium brevicaulis*, a species of lower fungus which is present in most water collections and absorbs all arsenic in solution. In our experiments we found that the quantity used was not toxic to even small aquatic fauna such as fish, frogs, leeches, water-bugs. Ducks and cattle using the water were not affected.

(4) It is equally effective in weedy water collections as in clean ones; the cost of preliminary expense for the clearance of weeds before spraying with oil is thus saved.

But it has the following disadvantages:—

(1) It cannot kill the eggs and pupæ of anophelines and has no effect on the aquatic stage of culicines. In rural towns where there is some sort of water works without underground drains the mosquito nuisance is so great that the campaign should not only be against anophelines but also against culicines. In such cases Paris green is useless.

(2) A shower of rain or high wind just after the application may vitiate the result. In such cases, it should once again be applied.

(3) It may not be useful in waters with a strong current such as are found in submontane regions.

(4) Although fish and ducks have been found not in the least affected, there is a general apprehension of arsenical poisoning by doctors, as tank

water is very much used by the Indians for drinking purposes. Where there is a piped water supply, its use is safe.

SIMPLE TESTS FOR STOCK SOLUTIONS OF QUININE AND POTASSIUM IODIDE.

By J. W. D. MEGAW,

COLONEL, I.M.S.,

and

HERBERT HAWLEY, M.Sc., F.I.C.,
 Public Analyst, Madras Presidency.

In a note in the *Indian Medical Gazette* of May 1928 the senior writer in collaboration with Professor Sudhamoy Ghosh and Mr. N. R. Chatterjee of the Calcutta School of Tropical Medicine called attention to the great frequency with which stock solutions of quinine in hospitals and dispensaries are seriously under the stated strength. A simple test was given by which inspecting officers could easily check the strength of the solutions.

FIG. I.

- Teakwood rack (drawn approximately to scale).
 A Test tubes of equal calibre.
 B Pipette for quinine test reagent. (Capacity about $\frac{2}{3}$ that of test tubes.)
 C Pipette for iodide test reagent. (Capacity slightly less than $\frac{1}{2}$ that of the test tubes.)
 D Pipette for iodide mixtures. (Capacity about $\frac{1}{3}$ of C.)
 E Pipette for quinine mixtures. (Capacity about $\frac{1}{10}$ that of B.)
 J Lead plate for stability.

 L Wire supports to keep test tubes in place.
 M Wire handle for rack, placed on one side of the cross piece.
 N Wires running between the supports to keep the tubes in position.
 (A perforated tin plate may be used instead of the wires L and N.)

Within the past year a large number of samples were taken by the senior author for examination from head-quarters hospitals and smaller dispensaries in the Punjab and Madras. The mixtures were usually much below the stated strength except in those dispensaries in which the compounders were aware that I was in the habit of checking the solutions.

At my recent inspections most of the mixtures were found to be up to the proper strength, but this was probably because a warning notice had been issued to all District Medical Officers.

In some dispensaries the warning had not been received or had been ignored as can be seen from the following results of accurate analytical tests of stock mixtures made quite recently in the Madras Presidency.

			Stated strength.	Actual strength.
Head-quarters	Dispensary	A	10 grains	1.6 grains.

"	"	L	4 "	2.5 "
"	"	M	4 "	0.6 "
"	"	N	4 "	2.8 "

The iodide of potash mixtures were usually up to strength, in spite of the fact that the compounders did not know that tests were likely to be made, but in some cases serious deficiencies were found, for example one case in which it was less than 3 grains to the ounce instead of 10 grains.

Many of the medical officers were astounded at the results of the tests: some of them were indignant at first that the compounders should be suspected of guile, indeed one experienced District Medical Officer assured me that tests were unnecessary as he had implicit confidence in his compounders.

The test already published is quite satisfactory, but experience has shown that readings can be made more quickly and readily if the stock and control quinine solutions are diluted before adding the reagent. Solutions of 10 grains to the ounce may be diluted up to 6 or 8 times before the reagent is added and solutions of 5 grains up to 3 or 4 times. When this is done it is easier to detect at a

glance any great deficiencies in the stock mixtures, also the precipitate falls more rapidly.

FIG. II.

Arrangement of test case seen from above.

 F One-ounce bottles for quinine control solution.
 G One-ounce bottles for iodide control solution.
 H One-ounce bottles for quinine test reagent.
 I One-ounce bottles for iodide test reagent.

Note.—The mouth of the bottles should be large enough to receive the pipettes. The rubber bulbs of the pipettes will be above test tube rack.

A New Simplified Test for Quinine Solutions.

The junior author has devised a still simpler test which will be found to be very satisfactory; it can be recommended for general use.

The requirements are:—

- I. Quinine Test Reagent made up of—
 Pure phosphotungstic acid, 1 ounce.
 Dilute sulphuric acid (B. P.), 5 ounces.
 Rectified spirit, 12 ounces.

II. Control solutions of sulphate of quinine.

These should be made up accurately to the same formula as the solutions which are to be tested. (Usually 5 or 10 grains to the ounce.)

III. Small test tubes of equal calibre (about $1\frac{1}{3}$ to $2\frac{1}{5}$ inch in diameter and 3 to 4 inches in length) are convenient.

IV. A small pipette holding about $\frac{1}{4}$ c.c. (a pen filler or a narrow glass tube with a mark by which equal quantities can be delivered will serve if a graduated pipette is not available).

The quantity to be delivered need not be $\frac{1}{4}$ c.c., all that is needed is to ensure that exactly similar quantities of the quinine solutions are delivered into each tube and that the volume of the solutions should be about one-tenth the quantity of the reagent when solutions of 10 grains to the ounce are being tested and about one-fifth in the case of solutions of 5 grains to the ounce.

Method.

Add equal quantities of the reagent to two tubes of equal calibre to a depth of about 2 inches. A mark may be made on each of the tubes to facilitate measurement or a special pipette holding about $2\frac{3}{4}$ c.c.s. may be used. To one of the tubes add a measured quantity (usually $\frac{1}{4}$ c.c.) of the control solution of quinine, mix well by inverting the tube several times while keeping it closed by the thumb or by a cork (vigorous shaking must be avoided). To the other tube add an exactly equal quantity of the solution which is being tested and mix it in the same way. Again mix the contents of both tubes simultaneously so that sedimentation may start at the same moment in both tubes. Place the tubes in an upright position; after 10 minutes or so the depth of each precipitate will be roughly proportional to the amount of quinine contained in the mixture. Even after 5 minutes a good idea may be formed of the relative strengths of the two mixtures by comparing the heights of the clear columns of liquid above the precipitates. If the apparent variation is slight, an accurate chemical analysis may be made by sending a sealed sample to a qualified analyst.

If any doubt exists as to the purity or strength of the powder from which the quinine solution was made the compounder should be asked to make up a fresh mixture under personal supervision; some of this should be examined simultaneously with the existing stock solution. It will usually be found that the defect does not lie in the powder but in the preparation of the mixture; at the same time it is desirable to leave the compounder no loophole of escape as he is likely to excuse himself on the plea that the powder supplied has been impure. The test enables anyone to satisfy himself as to two important points, (1) the strength of the stock mixture, (2) the purity of the stock of quinine powder which is in use. It is, of course, essential to keep a vigilant eye on the stock of quinine powder as this also is liable to be tampered with.

The tests carried out by the senior writer in the Punjab and in Madras have disclosed a perfectly appalling state of affairs; they throw a flood of light on the supposed failure of quinine when given by the mouth and on the popularity of intramuscular injections. It is safe to say that cases of "quinine resistant" malaria are usually cases of "compounder resistant" malaria.

Another important point is that the administration of adulterated solutions has given an unfair advantage to the proprietary preparations of the cinchona alkaloids and also to the various substitutes for quinine which have been introduced.

In some local fund dispensaries quinine is handicapped in another surprising way: the yearly allotment for drugs is divided into twelve equal parts and each of these parts has to last for a month. The result of this astonishing procedure is that patients receive much smaller doses of quinine in the malarious season than in the healthy months. It would be incredible that such a practice should exist, were it not that several doctors have frankly admitted that they have followed it for many years.

It is not an exaggeration to assert that if it is possible to ensure that every patient gets the quantity of quinine which is ordered for him by the doctor a revolution will be brought about in the efficiency of our hospitals and dispensaries.

Test for Iodide Mixtures.

Encouraged by the valuable help derived from the rough quantitative test for quinine the senior writer asked Mr. Hawley to work out a similar test for potassium iodide mixtures. This test is carried out on exactly similar lines to the quinine test.

Reagent.

Powdered lead nitrate crystals	..	5 grammes.
Dilute nitric acid (B.P. 1914)	..	100 c.c.
Rectified spirit	..	200 c.c.

Dissolve the lead nitrate in the dilute nitric acid and then add the rectified spirit.

Method.

When dealing with solutions of 10 grains to the ounce proceed as follows:—

To each of two long narrow test tubes of equal calibre add the same quantity of the reagent (2 to 3 c.c.); to

one of the tubes add 1 to 1½ c.c. of a control solution of potassium iodide made up to ten grains to the ounce; to the other add exactly the same quantity of the solution which is being examined. Mix well by slowly

FIG. III.

One form of test case with the contents removed. The bottles hold one ounce. The arrangement shown in Figs. I and II is handier and more compact.

inverting both tubes several times. Compare the volumes of the precipitates after ten minutes. As in the case of the quinine solutions, the exact quantities of the solutions which are used do not matter, provided that the correct proportions are maintained and that the tubes are of equal calibre. In the case of a solution of five grains to the ounce, equal quantities of the mixture and of the reagent should be used and the control solution should be first diluted with an equal quantity of water. The purity of the potassium iodide from which the stock dispensary mixture was made can be controlled in the same way as the strength of the quinine powders. As potassium iodide is a costly drug it is likely to be tampered with in the same way as quinine. These simple tests can easily be carried out by any inspecting officer, they will serve as useful controls on the nefarious activities of certain compounders.

The illustrations show a handy outfit which has been devised by the writers: it is hoped that some manufacturing firms will construct still more convenient test cases and that these will be used by all inspecting medical officers, especially during surprise visits.

MYIASIS IN LEPERS.

By G. R. RAO, D.M.C. (Madras), D.T.M. (Bengal),

Medical Officer, Leper Asylum, Cuttack.

A CASE of nasal myiasis in a leper, with peculiar symptoms, was reported by me in the April 1928 number of the *Indian Medical Gazette*. Since then I have had the opportunity of studying the occurrence of this condition in three more cases. As the study of these cases has brought out some interesting facts regarding the method of infection and as the subject is likely to attract the attention of others who have to deal with a large leper population, especially advanced cases in asylums and segregation colonies, I offer no apology for bringing this short note to the notice of the profession.

Brief clinical histories of the three cases, are given below:—

(i) *Saiti Bchera*, male, age 55, B₂—A₂ case of leprosy suddenly noticed an alarming oedema of his whole face on the morning of the 3rd January, 1929. The previous night he was all right except for a little bleeding from his nose. Guided by the previous case, I diagnosed this case as one of "myiasis of the nasal cavities," and examined his nose. A foul smelling sanious discharge was present. As usual, his nose was irrigated with 1 in 80 carbolic lotion and a few dead maggots were recovered. The irrigation was repeated after 6 hours. Next day, a few living larvæ were brought out by gentle scraping with a small-sized Volkmann's spoon. These larvæ were bred with the greatest difficulty and only one reached the imaginal stage. The adult was found to be *M. domestica*.

It is difficult to say why the larvæ recovered from cases of myiasis do not live long. Most of them die after three or four hours. The use of carbolic lotion was thought to be the cause of the poor longevity of the larvæ. So an attempt was made on the next day with saline, and even then very few of them survived up to the adult stage. Possibly, these larvæ after having fed on human tissues find it difficult to live on moistened cowdung powder, the only medium supplied to them.

This case was treated throughout with the same 1 in 80 carbolic lotion, douching twice a day, for 7 days. The swelling of the face began to subside on the 2nd day, and on the 4th day his nose was found to be considerably flattened, the swelling having come down. A hole admitting a silver grooved director was also found in the middle line of the nose just midway between the root and the tip of the nose. This hole is still present. On the 5th day the nose was examined and healing ulcers were found, especially in the region of the inferior nasal concha.

(ii) *Debajanda Panigrahi*, male, age 52, an A₂ case of leprosy, had several perforating ulcers on his hands and feet, besides a few blisters. On my usual morning rounds, on 5th January, 1929, I found him with oedematous legs, arms and feet. All the ulcers were found to have undermined edges. On searching with a probe, just underneath the edges, a few dead larvæ were found. The edges were clipped all around, so as to facilitate the extraction of the larvæ from underneath the skin. With a little persistence, numerous larvæ were extracted from beneath the edges of all the wounds. Of course a certain amount of bleeding occurred. After thorough irrigation with carbolic lotion, the wounds were examined and several radiating sinuses were found around each wound. It was very difficult to deal with these sinuses; some were slit up so that they could be more effectively dealt with. In this case also only a few living larvæ could be recovered and the adults were identified to be of the genus *Sarcophagus*.

Excision of the undermined edges when necessary, slitting up of all the deep sinuses, and irrigation with 1 in 80 carbolic lotion—these were the lines of treatment adopted. After 4 days, the wounds became clean, and very few larvæ could be found. On the 5th day, the patient died suddenly of cardiac failure.

(iii) *Bancho Setti*, male, age 45, a B₂—A₂ case of leprosy, has several ulcers all over the body—the result of breaking down of the nodules. He is a particularly lazy and filthy patient. Considerable swelling of the limbs and especially of the margins of the ulcers was found. This swelling came on rather suddenly. Thorough cleaning of the wounds and exploration of the undermined edges revealed the presence of numerous dipterous larvæ underneath the skin. Excision of the undermined edges, slitting open the several sinuses and irrigation with 1 in 80 carbolic lotion were the usual lines of treatment adopted in this case too. But as there was a heavy infestation in this case warm potassium permanganate baths were also ordered in addition. As both the limbs—upper and lower—were affected, they were given the bath alternately. The duration of the bath was one hour for each limb. Immediately after the bath, the wounds were dried and dressed with E. C. (Electrolytic Chlorogen) soaked gauze and bandaged.

A few living larvæ were recovered from this case. After breeding, the adults were found to be *M. domestica* and a few *Sarcophagus* adults were also present. It is surprising to find the larvæ of both *M. domestica* and *Sarcophagus* growing together in the same patient.

The patient is making a slow recovery; but a wound on the dorsum of the right elbow joint has been heavily infested and consequently the joint is exposed, bare bones are visible. To prevent the onset of secondary infections in the bones, this wound is treated with continuous application of E. C. (strength 1 in 25).

A study of these cases brings out the following facts:—

(i) In cases of nasal myiasis, the first symptom to attract the attention of the patient as well as that of the physician is the occurrence of epistaxis—followed by sudden swelling of the face. In these cases, careful examination will reveal the presence of several dirty ulcers in the nasal cavities.

(ii) Foul smelling ulcers inside the nose, with their offensive discharges, provide an attractive pabulum for the flies. During sleep flies seem to enter the nose and deposit their eggs in the ulcers. These eggs, having got the necessary conditions of environment, viz., warmth, moisture, etc., inside the nose, begin to develop into larvæ. This seems to be the natural mode of infection.

There is no possibility of the larvæ directly crawling up into the nasal cavities during sleep, as in that case patients would be likely to give a history of some worms having entered their noses. But my careful enquiries did not elicit any such history. Further, the number of larvæ found in a case is against this possibility, as no large number of larvæ could get into the nose of even the most stupid patient without making him feel the entrance of foreign bodies.

When these newly hatched larvæ begin to burrow into the tissues, the patient feels an irritating sensation inside the nose and a certain amount of bleeding occurs. The sudden occurrence of oedema is probably due to effusion under the subcutaneous tissues of a serous fluid—the result of the burrowing action of the larvæ injuring the deeper tissues.

(iii) So far, only larvæ of *M. domestica* have been found infesting the nasal cavities of lepers in this asylum.

(iv) Open wounds in lazy, filthy and helpless patients attract the flies. In patients who move about and keep themselves active during the day, and sleep at night, covering their faces or rather their entire bodies no myiasis has occurred even in open wounds. If the wounds are dressed every day, and bandaged, no myiasis could occur. In B₂ cases, when the nodules break down and form ulcers, especially in weak and helpless patients, every small wound in the skin should be bandaged or closed with strips of adhesive plaster, so that flies may not have any opportunity to deposit their eggs into the wounds. *Sarcophagus* flies seem to be specially attracted by the open wounds of lepers.

(v) When open wounds are infested, especially those on the limbs, the treatment becomes very difficult and tedious, as the loose integuments of the extremities offer special advantages to the burrowing larvæ. As the larvæ are found beneath the skin around the wounds—specially underneath the edges—the edges should be excised and a few radiating incisions should be made around each wound, to have free access to the deep lying larvæ and to secure their expulsion. By these radiating incisions the numerous false passages created by the burrowing larvæ may be laid open and then only can these sinuses be satisfactorily dealt with. Each wound should be thoroughly explored as no larvæ may be found superficially. Irrigation with 1 in 80 carbolic or 1 in 25 E. C. is quite enough for cases of mild or moderate degree of infection. In severe cases warm potassium permanganate baths for the affected parts may be given in addition.

(vi) The great difficulty of recovering living larvæ or viable larvæ from the tissues should be noted; and the still greater difficulty of successfully breeding the few living and viable larvæ that could be extracted up to the adult stage is also worthy of attention. Gentle scraping with a small-sized Volkmann's spoon aided by irrigation with warm saline seems to be the best method of recovering living and viable larvæ.

(vii) The problem of prevention presents some difficulties, especially in the case of nasal infections. As for open wounds, closing them with bandages or strips of adhesive plaster is the best method of prevention. But obviously the nasal cavities cannot be dealt with in this way.

In all B₃ cases, especially in the old lazy and filthy patients who never move about, the nasal cavities may be painted with Hydnocreol twice a day, once in the morning and once at night, before going to bed. This method is under trial at present. Also the patients should be advised to cover up their faces when they sleep—whether during the night or the day.

Lastly, cleanliness of the person and the clothing is of great importance in the prophylaxis of myiasis, as in other diseases.

A PRELIMINARY NOTE ON A COLOUR REACTION FOR "693" AND ITS APPLICATION IN THE ESTIMATION OF THAT COMPOUND IN THE URINE.

By T. C. BOYD, F.R.C.S.I., D.P.H., F.I.C.,
LIEUTENANT-COLONEL, I.M.S.,

Chemical Examiner to the Government of Bengal,
and

A. C. ROY, M.Sc.,
*Biochemical Research Worker under the Indian
Research Fund Association.*

WE have been experimenting on a suitable colour reaction for compounds like Bayer's 693

(diethyl amine p-amino phenyl stibinate) used in the treatment of kala-azar, by means of which we could follow by a simple method the course of antimony excretion in the urine instead of depending upon the long and tedious process of antimony estimation by the methods commonly employed.

We found that on diazotising a solution of "693" with dilute hydrochloric acid and sodium nitrate solution and coupling it with α -naphthol in alkaline solution a fine red colour was produced and the depth of this colour was proportional to the concentration of the antimony compound in the solution.

After many trials the following procedure was found to give the best colour effect.

To 0.5 c.c. or more of the solution, depending upon the concentration of the compound, 1 drop of dilute hydrochloric acid was added, then 1.5 c.c. of water and the mixture cooled in ice. After about 10 minutes 1 drop of a 1 per cent. solution of sodium nitrite was added, mixed and the test tube again put back in ice for about a minute. Then 1 c.c. of about 1 per cent. solution of α -naphthol in 20 per cent. caustic soda was added and mixed. The colour formed was allowed to develop for about 5 minutes and compared against a standard solution of the substance treated in the same way.

The lowest limit for the formation of a distinct red coloration for "693" is about 0.02 mg. in 0.2 c.c. of the solution.

Urea stibamine also gives a colour reaction on similar treatment but the limit of distinct red coloration in this case is about 0.5 mg. in 0.5 c.c. of the solution.

In the case of urine from a patient treated with "693", a known volume of the urine is treated exactly in the manner described above and compared against a known volume of a standard solution made by dissolving a known weight of "693" in normal urine similarly treated. Usually a 1 in 10,000 solution is used. The colour developed is best compared in a test-tube colorimeter.

Further experiments are in progress and we hope to be able to publish a detailed account of our work shortly.

A Mirror of Hospital Practice.

A CASE OF INDUCED POLY-LEUCOCYTHÆMIA.

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P.,
and

K. C. HALDAR, I.M.P.,

*From the Kala-azar Research Laboratory,
Calcutta School of Tropical Medicine and Hygiene.*

WHEN the observations on this case were made it was not our intention to publish them, but as the case exhibits some unusual features we have

subsequently decided to publish our notes, incomplete as they are.

The patient was a Hindu male, aged 28 years, a resident of a village near Calcutta. He gave a history of fever for eight months with progressive enlargement of the spleen. The fever was at first intermittent with rigors and was diagnosed as malaria, but quinine is said to have had little action.

The patient was thin and slightly anæmic. His spleen was $7\frac{1}{2}$ inches below the costal margin, and was firm and not tender. His weight was 74 lbs. He was suffering from a high remittent type of fever, showing a single rise and fall during the 24 hours. The pulse rate was 100 per minute.

Leishmanian were found in the peripheral blood: the total white cell count was 3,980 per c.mm. and hæmoglobin percentage 70.

We were apparently dealing with a very ordinary type of kala-azar. The patient was given 8 injections of neostibosan at intervals of 48 hours, so that the treatment was completed in 15 days. As the fever continued up to the end of the second week of treatment, cinchona febrifuge (grs. 10) was given twice daily. After this the temperature fell to normal, and he had no return of fever throughout his stay in hospital. Twelve days after the completion of the course of treatment a routine blood count was done. The total white cells had increased to 9,440 per c.mm.; this was about the usual increase that is expected in such a case. The next routine blood count, which was done after another twelve days interval, showed that the white cells had increased to 25,625 per c.mm.; this was an unusually high count and made us decide to keep the patient under observation for as long a period as possible. Blood counts were done at frequent intervals. Circumstances did not always permit of a differential count being done at the time the total count was done, but blood films were usually taken and kept for subsequent counting. Unluckily some of the blood films were mislaid, so that this part of the report is not complete.

Throughout his stay in hospital the patient increased in weight and at the time of discharge was $96\frac{1}{2}$ lbs., or $22\frac{1}{2}$ lbs. more than at the time of admission.

No change at all in the size of the spleen was noticeable; it was enlarged 7 inches below the costal margin at the time of discharge, whereas on admission it had been noted as being $7\frac{1}{2}$ inches below the costal margin.

The Blood Counts.—The white blood counts at different dates are shown in Table I, and the differential counts, on the 5 occasions on which they were done, in Table II. On the chart the total white cell counts have been plotted and a graph drawn. In the case of the polymorphonuclears, the myelocytes and the small lymphocytes

the points have been plotted, but the complete graph has not been drawn as no differential count

TABLE I.

Serial number.	Day of observation.	Date.	W. B. C. per c.mm.	Hæmoglobin.
1	2	6-10-28	3,980	70%
2	29	2-11-28	9,440	75%
3	41	14-11-28	25,625	75%
4	57	30-11-28	39,760	85%
5	64	7-12-28	48,400	80%
6	71	14-12-28	67,435	90%
7	78	21-12-28	144,375	90%
8	92	4-1-29	88,000	85%
9	99	11-1-29	70,800	75%
10	106	18-1-29	29,760	75%
11	113	25-1-29	31,600	80%

was done on the day when the total count reached its highest point. These incomplete graphs indicate what would have been the general direction of the graphs had the differential counts been done on each occasion that a total count was done.

Technique.—All the total counts and the first differential count were done by the junior writer. For the total counts he used the Thoma-Zeiss counting chamber and diluting pipette. The blood was diluted 20 times and 20 fields of 50 squares each were counted. For the differential counts the senior writer used his (1922) small film method, i.e., a very small smear is made and every leucocyte on the slide is counted. At least 250 cells were counted each time. The hæmoglobin was estimated by means of a Tallqvist scale.

The Total Leucocyte Count.—At first this rose slowly, later more sharply and then, during the sixth week after treatment had been completed, it suddenly shot up to 144,375 per c.mm.; it fell with equal rapidity to the 30,000 mark, where it remained until the patient was discharged.

The Differential Count.—Up to the 41st day the rise in the total count was mainly due to the rise in the polymorphonuclears, although there was also a distinct rise in the large hyalines and transitionals. Subsequently the rise in the total count was mainly brought about by the myelocytes. The small lymphocytes were almost constant

TABLE II.

				DAY OF OBSERVATION.				
				29th	41st	64th	71st	113th
Polymorphonuclears	5,853	12,915	23,232	26,165	19,592
Lymphocytes	1,699	1,435	2,517	2,697	1,517
Large hyalines	4,920	5,034	7,283	5,814
Transitionals	4,408	3,291	4,316	3,160
Türk's irritation forms	1,699	718
Myelocytes	718	13,939	25,356	1,517
Eosinophiles	189	..	387	1,618	..
Mast cells	513
TOTAL WHITE CELLS	9,440	25,627	48,400	67,435	31,600

throughout, and, after an initial rise, so also were the hyalines and transitionals.

The Red-Cell Count.—This is not done as a routine measure as there is seldom much change in kala-azar; the count is usually about 4,000,000 per c.mm. on admission, improving to 4,500,000 or even 5,000,000 at the time of discharge. In this case the hæmoglobin percentage, which is usually a very good indication of the red cell

Discussion.—Myelosplenic leukaemia is far from uncommon in Bengal. Some of the patients with this condition have given a history of having received treatment for kala-azar, but, as an enlarged spleen is considered by some practitioners as a sufficient excuse for the administration of antimony, we have not always accepted this as evidence of a kala-azar attack. Kala-azar is a disease of the reticulo-endothelial system which

count, was estimated from time to time; the results are given in Table I.

Parasitological Investigation.—The parasites, *Leishmania donovani*, were found in his peripheral blood before admission. On the 28th day, that is 13 days after the conclusion of treatment, a spleen puncture was done; no parasites were found in the direct smear, but a culture showed that leishmania were still present. A spleen puncture was done again on the 56th day; this time the culture was sterile. This delayed disappearance of the parasites is quite frequently observed in ordinary cases of kala-azar.

is closely associated with the hæmopoietic system. One of the characteristic features of the disease is a leucopœnia; this is most noticeable in the polymorphonuclear element. The effect of treatment is to bring the leucocyte count back to normal. It has not been our practice to keep patients for long under observation when once the treatment has been completed, but in this instance certain other investigations were being made so that the rapidly increasing leucocytosis was more or less accidentally observed.

One, therefore, wonders whether this sequence of events does not occur quite frequently and

whether perhaps it should not be considered as one of the sequelæ of kala-azar, either of the disease itself, or of the antimony treatment. On the other hand, this may have been a case of myelosplenic leukaemia in which the condition was temporarily overshadowed by the superimposed leishmania infection, and that when the effects of the leishmania infection disappeared the other condition again became apparent.

The only way that this patient differed clinically from an ordinary case of kala-azar undergoing cure was that there was never any reduction in the size of his spleen.

(Postscript.—A letter was received from this patient on 20th June, 1929; in this he stated that he was in good health, had had no return of fever, but that his spleen was still enlarged.—L. E. N.)

A CASE OF FREE BILE IN THE PERITONEAL CAVITY.

By A. HAMEED SIDDIQI, B.Sc., M.B., B.S.,
Senior House Surgeon,
King George's Hospital, Lucknow.

DR. S. D. D., aged 33 years, was admitted to the King George's Hospital on the 27th October, 1928, with the complaint of diffuse pain over the epigastric, right hypochondriac and right lumbar regions of four months' duration.

A vague tender swelling was palpable in the right hypochondriac region for about one month. It was smooth and with the patient lying flat was felt about 1½ inches below the costal margin, about one inch to the right of median line. Percussion showed it to be continuous with the liver. The patient was weak and emaciated. No history of jaundice could be obtained, nor was it present on admission.

Before joining our hospital the patient consulted various surgeons in the military hospitals to which he was attached. All were of opinion that it was a case of cholelithiasis with adhesions:—

Notes on Pathological Examination.

Urine.—Nothing abnormal save the presence of triple phosphates. No bile.

Blood.—Total W. B. C. count .. 10,240 per c.mm.
Polymorphonuclears .. 61 per cent.
Lymphocytes .. 38 per cent.
Large mononuclears .. 1 per cent.

Stools.—No ova or cysts of any parasites.

Wassermann reaction.—Completely negative.

Van Den Berg's Reaction.—Immediate direct, completely negative; delayed direct, negative; indirect, faintly positive.

The patient, while the above investigations were being carried out, was treated symptomatically. The most distressing feature was pain, which prevented sleep. Different hypnotics, i.e., paraldehyde, bromide and veronal, were in turn tried and found fruitless. Morphia, given every night, had the best result.

Diet.—He was practically being starved, as he was unable to retain the smallest quantity of anything.

An exploratory laparotomy was done on the 6th November, 1928. A right paramedian supra-umbilical incision was made for about 4 inches. As soon as a nick was made in the peritoneum, pure bile started flowing, and it was thought that probably an adherent gall-bladder had been opened. Bile continued to flow until about a pint and a half had come out. The peritoneal opening was enlarged and the peritoneal cavity was carefully looked into. The gall-bladder was found to be normal in size and position. A tumour was found behind the gall-bladder on the inferior surface of liver of about the size of an orange and nodular infiltrations

could be felt in the great omentum as well. Evidently it was a case of carcinoma; a piece of infiltrated omental tissue was removed for pathological examination.

The patient's condition did not allow the investigation of the source of leaking bile. The inner surface of the peritoneum was abnormally pinkish in colour and was remarkably free from any adhesions. The general peritoneal cavity was closed with a drainage tube inside.

Pathological Examination.

Tissue.—Colloid cancer.

Fluid.—Bile, chemically.

Culture.—Negative.

The drainage tube was removed after 24 hours.

9th November, 1928.—Patient's conjunctiva showed slight yellow colouration.

11th November, 1928.—Definitely jaundiced.

12th November, 1928.—Patient's sputum was blood stained and remained so throughout the rest of his days.

15th November, 1928.—Stitches were removed; wound healed by first intention. Skin on the abdomen showed yellow discolouration.

19th November, 1928.—Patient was discharged from the hospital at his own request, and left the same day for Lahore.

23rd November, 1928.—Patient died at Lahore.

There are two points which are of especial interest in this case.

(1) Late appearance of jaundice in an established case of carcinoma of the liver.

(2) Presence of free bile in the general peritoneal cavity for a length of time.

My thanks are due to Captain M. S. Nigam for allowing me to quote his case.

A CASE OF ECTOPIC GESTATION.

By AGHORE NATH GHOSH,
Officiating Civil Surgeon, Tippera.

A FEMALE, aged 28 years, married at the age of 15, nullipara, was admitted to the Comilla Sadar Hospital on 4th November, 1927, with an abdominal tumour. She gave the following history:—

In February, 1923 her menstruation ceased and all the signs of pregnancy became evident. When she thought that she was about 3 months pregnant, she felt a sudden severe pain one night; the pain simulated labour pains but there was no bleeding, she says, from the uterus. However, the pain subsided, but she became very weak and prostrated. When the pregnancy advanced to the 7th month, she lost consciousness for several minutes one night after a sudden attack of excruciating pain. She felt as if something had given way inside; but with this attack there was a little bleeding from the uterus. A week after she had another attack of pain in the lower abdomen. This pain was, however, not severe and with this the menstruation began and lasted for 4 days, the quantity of blood lost being a little more than usual. Then almost every 5th or 6th month she used to get severe pain on the left side of the lower abdomen, generally proceeding the menstrual period which was regular, but sometimes independent of it. The pain however had become more frequent during the last 2 years and for the last two months almost constant.

Menstrual History.—Her periods began at the age of 15. From that time up to 1923 she was regular; sometimes the period lasted more than 4 days, but she never missed a period.

Previous History.—She was of indifferent health all along and about 12 years ago she had tuberculosis of the bones of right foot for which she was treated for 6 or 7 years. Her husband had an attack of gonorrhoea immediately before the marriage and she contracted the disease. There was no history of abortion.

State on admission.—She was rather pale and emaciated but there was no marked anaemia. An irregular very hard and knobby tumour, about 3 inches by 1½ inches, was found on the left side of the lower abdomen. On palpation the feeling was not unlike that of a bony tumour. The tumour was not very painful on pressure,

The uterus, on vaginal examination was less movable than normal, especially on the left side, but it was not enlarged.

From the history of gonorrhœa, of pregnancy, of attacks of severe pain with faintness, of regular menstruation till the beginning of the present illness and from the peculiar feel of the tumour, a provisional diagnosis of extra-uterine gestation (abdominal pregnancy) was made.

On 7th November, 1927, the abdomen was opened, in the usual way, by Rai Bahadur J. N. Mitra, Civil Surgeon. On opening the peritoneal cavity a shrivelled-up foetus of about five months was found almost free in the lower part of the peritoneal cavity, there being only 3 or 4 strips of narrow long bands connecting the foetus with the left broad ligament and part of omentum. These bands which did not contain any vessel were cut and the foetus was taken out without any difficulty. Another tumour, formed from the gestation sac, was found adherent to the omentum, the broad ligament and the left tube (which looked like an adherent loop of small intestine). This tumour was dissected off without much hæmorrhage. After the usual toilet the abdominal cavity was closed in three layers.

The patient made an uneventful recovery and was discharged from the hospital on 25th November, 1927.

A CASE OF MYIASIS OF A CARIOUS TOOTH.

By C. STRICKLAND, M.A., M.D.,
Professor of Medical Entomology,
School of Tropical Medicine, Calcutta.

THIS case was seen first by Dr. Chakrabarty, Assistant Surgeon on Ambutia Tea Estate, Kurseong, who showed it to me.

depositing its eggs *in situ* during the patient's sleep with her mouth open, and the maggots subsequently developed and caused the trouble.

I identified the maggots as those of *Chrysomya bezziana*, one of the common "green bottle" flies of India, a diagnosis which Colonel Patton very kindly confirmed for me, agreeing also that this was an unique occurrence.

AN OBSCURE NEUROLOGICAL CASE SIMULATING EARLY LEPROSY.

By E. MUIR, M.D., F.R.C.S. (Edin.),
Research Worker in Leprosy at the School of Tropical
Medicine and Hygiene, Calcutta, under the Indian
Research Fund Association,

and
JOHN M. HENDERSON, M.B., Ch.B. (Glas.),
Working under the British Empire Leprosy Relief
Association at the School of Tropical Medicine and
Hygiene, Calcutta.

J. S., æt, 30 years, a young Cinghalese medical man, presented himself at the Leprosy Research Department of the School of Tropical Medicine and Hygiene, Calcutta, complaining of loss of sensation in the skin of the lower right eyelid and right side of the nose of between 6 and 9 months' duration. About 9 months ago the patient became conscious of defective sensation in the skin of the lower right eyelid and upper part of the right cheek; 3 months later the con-

Fig. 1.
(After Cunningham.)

The patient was a Nepali woman, aged 52, a tea-garden cooly, particularly strong and healthy.

She complained of toothache.

On examination the left 2nd upper molar was found extensively carious, all the other teeth being in excellent condition. There was no alveolar trouble near the affected tooth, or elsewhere.

On proceeding to clear the carious cavity with a pledget of cotton wool on a probe, about a dozen maggots emerged and were collected. The cavity after cleaning and dressing was plugged with cotton wool and when the pain had disappeared the tooth was extracted and no further trouble ensued.

Dental myiasis has I believe never been reported before. Presumably a fly being attracted by the odour of putrefaction arising from the tooth had seized the opportunity of

condition had spread to the skin of the right side of the nose. After a further period of roughly 3 months, a sensation of numbness of the right side of the palate was noticed.

Previous History.—The patient had sycosis barbæ in 1922. In 1923, while stationed in Madras City, he suffered from benign tertian malaria; to the best of the patient's belief this infection was a pure benign tertian. Fever recurred intermittently until 1926 and finally yielded to intravenous quinine therapy. No history of venereal disease was obtained.

Present Condition.—There is anæsthesia to light touch involving the right lower eyelid and upper part of the right cheek, the right side of

the nose in its lower half, the right nasal fossa, the right half of the palate (hard and soft) and the alveolar margin on the same side. No other abnormality can be detected on physical examination. The teeth are sound and there is no recent lesion of the ears, eyes or throat. The Wassermann reaction is negative. The patient was stationed in Upper Burma for the past years.

Report on X-ray Examination of the Skull.—The radiogram shows (1) marked opacity in the frontal sinus, (2) a curious extension downwards of the frontal sinus into the infundibulum, (3) an unusual opacity anterior to the frontal sinus.

Discussion.—The unusual distribution of the anaesthesia together with complete absence of other signs of that disease makes a diagnosis of leprosy extremely improbable. Lesions of the nose are not uncommon in leprosy; such lesions are rather protean in their manifestations and vary from a dry rhinitis with crust formation to nodulation and ulceration. In the case under report the nasal mucosa, except for the presence of anaesthesia in the right anterior fossa, looked perfectly normal. Leprous lesions of the palate are less common; in our experience they take the form of diffuse granulomatous or nodular lesions and occur only when there are gross and obvious signs of the disease elsewhere.

It will be noted (Fig. 1), that the anaesthesia corresponds with the anatomical distribution of the superior maxillary branch of the fifth cranial nerve. Sensation is supplied to the palate by the palatine nerves which are derived from the superior maxillary division of the trigeminal nerve, *via* the sphenopalatine (Meckel's) ganglion. In this case, therefore, there is interference with the function of the superior maxillary division of the trigeminal nerve at some point between its origin from the semilunar (Gasserian) ganglion and its association with Meckel's ganglion in the sphenomaxillary fossa. The nature of the interference is at the moment obscure; the negative Wassermann result diminishes the possibility of syphilitic infection. In malaria, neuralgia is said to be of frequent occurrence especially in the ophthalmic and superior maxillary divisions of the fifth nerve, but we have not been able to find in the literature any reference to abolition of function of the superior maxillary branch of the trigeminal as a sequel to malaria. Moreover, in malaria organic nervous manifestations tend to come on abruptly, not slowly as in this case. The finding by x-ray examination of "marked opacity in the sphenoidal sinus" and of "some unusual opacity anterior to the sphenoidal sinus" seems to indicate a neoplasm; osteoma and osteosarcoma suggested themselves.

The patient has been referred to a surgical colleague who has prescribed deep x-ray therapy twice weekly for two months, and his further progress will be watched with considerable interest.

ACUTE AMOEBIC DYSENTERY TREATED BY *HEDYOTES AURICULARES*, N. O. RUBIACEÆ.

By CAPTAIN P. R. BHANDARKAR, I.M. & S.,
1164, Mint Street, Pt., Madras.

S., male adult, age about 40, a Cutchi Jain, a clerk, living in Madras.

I was called to see the case at 8 a.m. on Thursday, 28th March, 1929.

History of the onset of disease.—On 24th March he had had four diarrhoeic motions with griping during the night, followed by four or five similar loose motions during the day. During the night of the 25th he had 10 to 12 motions with mucus and blood; and on the 26th he had about 20 mucus-sanguinous motions with severe griping tenesmus, for which the doctor, called in on the morning of the 27th, gave him a hypodermic injection, possibly emetine, and also a pinkish white mixture internally. He had about 20 motions during the day and more than 30 motions during the night of 27th with unbearable tenesmus in spite of the injection and medicine. The motion had been examined by Dr. Murugesan, Bacteriologist.

The patient had a temperature of 102.8 and an anxious expression.

Bacteriologist's report: *Entamoeba histolytica* found in very large numbers, living and active ones.

I prescribed,

Liq. ext. hedyotes auriculares ..	5 i.
Tinct. opii ..	min. 40
Syrup ..	5 i.
Aqam. ad. ..	viii.

One-eighth part every four hours.

1st dose given at 10 a.m. one motion.

2nd dose " 12 noon one motion.

3rd dose " 4 p.m. one motion.

7 p.m. one motion, tenesmus reduced.

4th dose " 8 p.m. two motions before 10 p.m.

The patient slept well till 2 a.m. 29th and had one motion, slept again and woke up at 4 a.m. and had two motions. 5th dose given at 7 a.m.—had a small motion with little blood and mucus, but more faecal matter.

The motion he had at 12-30 p.m. was sent to the bacteriologist.

Bacteriologist's report.—A few amoeba are seen here and there—all dead and disintegrating (granular in appearance). No living or active amoeba seen in the specimen.

A 6th dose of the mixture was given in the evening of the 29th—had only two motions till next morning, the 30th when the patient passed a fully formed stool with blood streaks here and there. This was sent for examination and the 7th dose was given.

Bacteriologist's report.—One or two dead and dwindling away amoeba seen here and there. A few cysts of amoebae seen. Stools alkaline in reaction.

The patient's diet during the treatment was rice water, barley water, arrowroot congee, pomegranate juice and 50 per cent. diluted milk. He had been kept on whey water on the 27th.

ELECTRO-COAGULATION (SURGICAL DIATHERMY) IN MULTIPLE ANGIOMATA OF THE HEAD.

By P. P. LALVANI, L.C.P.S. (Bom.),
X-Ray Department, Civil Hospital, Karachi.

THE patient, a lady by name Sitabai, aged 40 years, resident of Karachi district, had for the last six years multiple angiomas over the left side of the head. They were situated over the temporal region, eyebrow and forehead, and extended as far as the anterior

three-fourths of the parietal region. They constituted a very extensive swelling and were all mixed together. At the fronto-parietal region the swelling assumed a size of a small orange. They were expansile and on palpation a distinct thrill could be felt. They were compressible by pressure, the swelling could be obliterated. The left eye was very nearly closed on account of pressure. The patient said that on two occasions she bled through them. On account of disfigurement and also of danger to life due to bleeding she sought treatment.

Photograph No. 1, (taken before the electro-coagulation) shows the condition described above. The case was seen by Lt.-Col. J. L. Lunham, I.M.S., acting Civil Surgeon, Karachi, in whose opinion the case was surgically inoperable and was therefore referred to me for surgical diathermy.

The tumour over the left temporal and frontal region was electro-coagulated at one sitting on 7th July, under chloroform. Two electro-coagulation needles connected to two poles of a diathermy machine were introduced through the growth, diametrically, via different ports of entry, and coagulation

some places as soon as they were withdrawn; this was stopped by means of a disc, or a button electrode. On the 7th day after electro-coagulation there was secondary hæmorrhage which was controlled. The resulting slough came off in about two weeks leaving a clean ulcer.

The remaining portion of the tumour was electro-coagulated at the second sitting about three weeks after the first one, in the same manner. On the 5th day there was secondary hæmorrhage which was controlled. The entire slough came away in two weeks and the ulcer healed in about three weeks, and she was discharged cured on 2nd September.

Photograph No. 2 (taken at the time of discharge) shows the whole growth entirely removed and replaced by pliable scar tissue. The left eye, which was closed before the treatment, is now open.

Surgical operation on such an extensive angioma was thought inadvisable on account of the danger of bleeding. Besides, the scar tissue resulting from a surgical operation would have caused a considerable amount of contraction and would very likely have resulted in ectropion of the left upper eyelid. But with diathermy the scar being very supple there is no such danger.

Photograph No. 1.
Taken before electro-coagulation.

Photograph No. 2.
Taken after treatment.

was brought about in the blood inside the tumour. During the process of electro-coagulation the heated blood was actually found bubbling. The punctures through which needles were introduced bled at

I am grateful to Lt.-Col. J. L. Lunham, I.M.S., acting Civil Surgeon, Karachi, for his valuable advice and kind permission to publish this case.

Indian Medical Gazette.

JULY.

THE NEED FOR A THERAPEUTIC SUBSTANCES ACT FOR INDIA.

WITH the rapid advance in the sciences of pharmacology and chemistry, the number of new drugs that are added each year to the pharmacopœia is very great and is increasing year by year. While many of the new drugs are extremely valuable to the physician, others are useless and some are actually harmful. In most countries there are regulations which exercise a rigid control over the nature and the quality of the drugs placed on the market, but in India no regulations exist, either to prevent the importation or the manufacture within the country of valueless or even harmful medicines.

During the last eight years a large number of Loth imported and locally-manufactured drugs have been tested in the pharmacological and chemical laboratories of the Calcutta School of Tropical Medicine and Hygiene; many of these have been found on biological assay to possess only a fraction of their claimed therapeutic activity or, in a few instances, to be totally inert, whereas in the case of others it has been found on chemical estimation that a greater portion of the alkaloid or other substance, which they were supposed to contain, has been replaced by some inactive material. Determination of the real quality or genuineness of drugs on the market is outside the scope of the general medical practitioner; he looks to the State for guidance and protection.

The climatic factor is an important one; high atmospheric temperature combined with high humidity accelerate deterioration during storage. Tinctures which when they leave England or the United States may be fully potent are frequently considerably below the pharmacopœial potency when they are given to the patient. Some years ago a number of samples of digitalis issued by well-known firms were tested and it was found that in nearly every instance 30 to 40 per cent. of deterioration had occurred. Most of the arsenicals of the salvarsan group undergo a slow chemical change during storage; this change, which is considerably accelerated in the Indian climate, not only decreases their efficacy but may increase their toxicity to a dangerous extent. In our last number we published a letter from one of the leading manufacturers in Germany warning the public against purchasing certain of their own preparations which had been condemned in Europe and which, they suspected, had been brought to India by unscrupulous importers.

In the United States of America, the Government controls the remedial agents by means of an inter-state (i.e., central) commerce clause of

the constitution. Under this act the "Food and Drugs Act" is enforced by the Bureau of Chemistry of the Department of Agriculture, while the sale of biological products such as serums, vaccines, etc., is controlled by the Public Health Service. Not only is control exercised over all drugs, serums, etc., that are meant for home consumption, but all substances belonging to this class which are imported or exported are also governed by the Act. The Act is designed to secure truthful names and reliable statements for all the remedial agents and is divided into two parts.

Part I of the Act is concerned with patent medicines and drugs which are advertised mainly in the lay press and are usually purchased by the layman himself, and Part II applies to medicines ordinarily prescribed by physicians. This Act ensures that the purchaser, whether a physician or a layman, secures an honest product. It means that pharmacopœial preparations must come up to the standard laid down in the *United States Pharmacopœia*, failing which the manufacturers will be prosecuted. In the case of patent medicines, the law requires that only those claims should be made which can be substantiated, and in this way it controls exaggerated claims, and misleading and false advertisements. Standards are provided for most of the biological products. In the case of preparations for which tests of standards are incomplete, the samples are sent to the Government Laboratory with a copy of the records of the maker's tests, and these are repeated and the preparations are finally passed for sale or rejected. The toxicity of each batch of organic arsenical products is tested before it is allowed to be sold. No licence is granted to any firm until the licensing authority is satisfied that the personnel and equipment of the firm is qualitatively and quantitatively efficient for the purpose for which the licence is sought. In addition to this licensing system, samples of finished products are bought in the open market and are tested by officers of the Government with regard to their purity and potency. By these activities a constant control is kept over these drugs, and the postal authorities are responsible for the prevention of frauds and exploitation through the post. The powers of the postal authorities in this respect are shown by a recent occurrence. An individual was advertising a fraudulent specific; all letters addressed to him were opened at the post office and, if found to relate to this specific, were stamped "Fraudulent" and returned to the sender.

In the United Kingdom, until quite recently, the purity of food and drugs was dealt with by the "Sale of Food and Drugs Act of 1875" and the "Amending Act of 1879." These Acts make it an offence to sell to the prejudice of the buyer, food or drugs not of the nature, substance or quality demanded, or to mix or sell food and drugs with substances injurious to health. These Acts lay down no standard for either food or

drugs, provided the analyst's certificate states the nature and extent of the adulteration, but various regulations made under the Act define the standard of purity for milk and milk products. The *British Pharmacopæia*, which is an official publication under the Medical Acts of 1858 and 1862 "containing a list of medicines and the manner of preparing them, together with the true weight and measures by which they are to be prepared and mixed," although not a legal standard under the Food and Drugs Act, is as a matter of fact usually accepted as such, in that the court will usually admit as *prima facie* evidence that a drug should correspond with the description of it given in the *British Pharmacopæia*.

The "Therapeutic Substances Act" was introduced in 1925. This Act controls the quality and authenticity of such therapeutic substances as cannot be tested adequately by direct chemical methods. These are divided into three groups. Group I consists of biological products, such as vaccines, toxins and antiserums. Group II includes substances such as organic arsenicals and antimonial. Group III is formed of insulin and other gland products. The manufacture of these substances is carried out by properly licensed firms who conform to the standard of strength and purity laid down by an appointed committee.

In India, public health being a provincial subject, the question of adulteration of food and drugs has been left to provincial governments and local bodies. The Calcutta Municipal Act of 1923 makes it an offence to sell adulterated or impoverished drugs. The Bengal Food Adulteration Act of 1919 refers to foods only, as do most other provincial Food Adulteration Acts, with the exception of that of the Punjab which also includes drugs. In the Bengal Act standards are laid down for six notified food-stuffs, but in none of the Acts are there any legal standards for drugs. We are not aware of any prosecutions under the Drugs Sections of these Acts having been instituted; the difficult question of standards would at once arise and local bodies are not likely to take the trouble and bear the expenses of test cases. These Acts are therefore virtually dead letters as far as the control of drugs is concerned.

So that, for all practical purposes, with the exception of the Poisons Act, 1919, there are in India no laws which regulate the importing, manufacturing, advertising or selling to the public of therapeutic substances of any kind, potent or inert, benign or harmful. The time has perhaps not yet arrived when legislation could be introduced on American lines controlling the advertising and the sale of fraudulent specifics and patent medicines for which extravagant claims are made; the practitioners of the various systems of medicine would immediately demand that all the drugs not used by them should be placed under a ban and we should certainly demand that a number of drugs used in the indigenous systems that we have tested and found valueless

should be proscribed. But we do consider that some legislation should be introduced with reference to drugs used in modern scientific medicine to protect, primarily, the patient, who is liable to be dosed with useless or dangerous drugs, secondarily, the doctor who has no guarantee that the patient will receive drugs of the nature and potency which he prescribed, and finally, the honest manufacturer or importer who at present is compelled to compete with unscrupulous opponents.

If laws are to be passed insisting on drugs being of a certain standard, the first step must be a decision on the matter of standards. The simplest method would be the introduction of an *Indian Pharmacopæia*. With the help of the British and American pharmacopæias this should not be a very difficult matter, but it will take time; meanwhile the *British Pharmacopæia* could be adopted as the standard.

The therapeutic substances for which legislation might be introduced fall into two classes: the imported, and the Indian-manufactured products.

Imported drugs and other therapeutic substances.—At the present time the great majority of the therapeutic substances used by practitioners of scientific medicine in India are imported. In most instances these are manufactured by reputable firms who employ a staff of chemists and pharmacologists, but as there is practically no control over imported drugs there is nothing to prevent inferior, useless and dangerous drugs being brought into the country. In most of the foreign countries from which drugs are imported there is a strict control of all drugs manufactured for home consumption, but in some of these countries this control is not extended to drugs made for export. Here the question of climate, referred to above, comes in; drugs which may be fully potent when they leave their factory may have lost much of their potency by the time they are landed in India.

Under the League of Nations' agreement the customs authorities are compelled to exercise control over certain narcotic drugs, and in addition they have the power to exclude and confiscate drugs whenever actual fraud can be proved, as in the case of drugs marked "B. P. standard" which fall below this standard. They have their chemical laboratories for testing these drugs, but they do not assay them biologically.

The powers and responsibilities of the customs authorities in this respect might be increased. It might not be practicable, nor even advisable, for them to set up their own laboratories for carrying out biological assays, but they could pick out samples from each batch and send them to some central laboratory. The problem with regard to imported therapeutic substances would not end here; during their voyage to India they are only subjected to adverse climatic conditions for a comparatively short time, but the time that elapses between their arrival in India and their consumption by the patient may be, and in most

cases certainly is, very much greater. Another method of checking imported drugs would be for government agents to purchase samples from retail dealers and to send them to be assayed. This measure would lead to a greater knowledge of the keeping properties of various drugs and other therapeutic substances, but by itself would achieve little else. The dealer's stock, which might be very small, could be confiscated, but, unless he is to be given some guidance in the matter, it would be unfair to penalise him further for purchasing what he honestly considered a potent drug. It would not be fair to penalise the manufacturer or the importer, who may have respectively prepared and landed in India a potent drug which, if kept under favourable conditions, would have retained its full potency for a number of years. One thing that could be done is to insist on each bottle or packet having stamped on it the date of manufacture, the date of arrival in India and the date up to which it may be expected to retain its full potency or a large percentage of its potency—the percentage being specified—if kept under reasonably satisfactory conditions. At the same time rules for the storage of therapeutic substances could be formulated. Thus, by systematic examination at the port of entry and by sampling the stocks of retail dealers, the responsibility could be placed and the right person penalised. The work of the customs authorities would not be as great as it at first appears. As we have said, the majority of the imported goods come from respectable firms who test their goods thoroughly before sending them out; the testing of such goods would be merely formal and would only have to be done from time to time.

Indian-manufactured therapeutic substances.—Many of the plants from which pharmacopœial tinctures are made grow in India and during recent years an increasing number of firms have been established for the manufacture of tinctures and other similar substances for use in India. The time may not be far hence when, instead of these raw materials being exported, we shall manufacture these drugs ourselves for export. Some of these firms are also manufacturing gland extracts, vaccines and serums, and others are preparing and placing on the market potent organic compounds of antimony for intravenous administration. At present few of these manufacturing firms have any arrangements for assaying and standardising the potency, or testing the toxicity of the drugs they make; this can usually only be done by biological methods and a trained staff is necessary. There is in existence no law to prevent these untested drugs being placed on the market, or to prevent different batches of a preparation of antimony, for example, which bear the same label varying from time to time both in composition and in toxicity, and always differing materially from the compound which they claim to be.

The manufacturers of therapeutic preparations should be compelled to hold a licence, which

licence should only be given to those manufacturers who comply with certain regulations.

One of the principal conditions should be that they maintain a trained staff for testing and assaying the preparations which they place on the market. Government agents should be permitted at any time to enter the factory and take samples. At the same time samples would be collected from retail dealers as in the case of imported drugs, and, as the climatic conditions are as likely to cause the same deterioration in locally-made drugs as in imported ones, the same rules as to labelling and dating each packing would have to be applied. In the case of antimonials and of arsenicals, the relative toxicity and the percentage content of antimony or arsenic of each batch would have to be declared and some indication of their keeping properties given, so that the public would be safeguarded against high toxicity and gross variations in composition. It might be suggested that in the case of a small firm, who made perhaps only one drug, this would impose a great hardship. Provision could possibly be made for a small concern of this nature having their preparations standardised or tested in some government laboratory for a fee, but their preparations would be subsequently subjected to the same scrutiny as those of the larger manufacturer.

Without the introduction of any new and drastic laws a considerable amount of control of manufacturers of therapeutic preparations could be applied by means of the excise authorities; certain *bona fide* manufacturers are allowed the privilege of keeping "bonded" stores of alcohol. This privilege could be reserved for manufacturers who comply with the regulations. As alcohol is essential for the preparation of most therapeutic substances, the withdrawal of this privilege would be a very serious matter and would prevent them placing in the market any drugs, in the preparation of which alcohol is used, at a competitive price. However, it would be essential for the mechanism for sampling and testing the drugs to be in existence as a guide to the excise authorities, as otherwise this method would be open to abuse.

The introduction of legislation on the lines that have been suggested above is a matter for the central rather than for the provincial governments. The work of testing the drugs is outside the scope of any organisation at present in existence. It seems probable that neither the customs nor the excise authorities would care to undertake such specialised work, and it is certainly not within the scope of the provincial chemical examiners or of the public health laboratories, nor could it in any way be considered to be the work of the Medical Research Department. It would therefore be essential to set up a new organisation under the central government with a number of inspectors to collect the samples and a central laboratory where these could be tested. The central laboratory would have to be well equipped and staffed with well-trained men; a

pharmacologist, a chemist and a biochemist would be necessary. It is obvious that the laboratory should be situated at one of India's three main ports of entry, and, as Calcutta is far ahead of the other two towns in the matter of local manufacture of pharmacological products, it is indicated as the most suitable site. Subsidiary laboratories could eventually be established at Bombay and Madras.

It is not essential that a full working scheme should be inaugurated immediately; in fact such a step would be inadvisable. It would be better to begin by including only a limited number of drugs, for example, digitalis, ergot and a few other galenicals, and the antimony and arsenic compounds. But it should be made possible for the number to be added to each year without the introduction of any further enactments. The growth of the necessary organisation will thus be gradual.

This scheme would certainly cost money, but we do not consider that there should be any difficulty in justifying this expenditure. It is a public health measure which sooner or later must be adopted, and it is a matter in which India is far behind all other countries of a similar standing. It is certain that the introduction of legislation on these lines would very shortly react favourably on the internal trade of the country. Many doctors feel that patriotism and perhaps economy are their only excuses for prescribing locally-made unstandardised products; this new measure would make both classes of drug equal in respect of standardisation, and it would then simply be a matter of individual preference or price as to which was used.

With regard to external trade, India cannot hope to compete in foreign markets under the present conditions, and, as so much of the raw material for the preparation of medicines is exported, it is obvious that her opportunities for foreign trade are considerable. If it were considered essential, no doubt the scheme could be made to pay its way by charging a small stamping duty on each package imported and a licensing fee for the local manufacturers, but we do not consider this at all desirable from many points of view.

The criticism which will be immediately levelled against this scheme is that it will further increase the cost of drugs used in "Western Medicine." We are by no means certain that this will be the case. It will certainly stop the sale of extremely cheap goods in which the cheapness is only apparent; the drugs having been heavily adulterated are really more expensive than the pure product. It is, for example, not cheap to buy a 5-grain quinine tablet which only contains one grain of the alkaloid, even if it is half the price of the genuine article, and an inert drug is not cheap whatever the cost.

Corrigendum.

In the May, 1929 issue of the *Gazette*, p. 253, third line from bottom, in the left hand column "1|10ths c.c." should read "100ths c.c."

Medical News.

THE BRITISH EMPIRE CANCER CAMPAIGN. THE GARTON PRIZE AND MEDAL.

THE very valuable work which the British Empire Cancer Campaign has carried out for many years in investigating the ætiology and prevention of cancer must be well known to our readers. The Garton Prize and Medal which has recently been instituted by the Grand Council of the Campaign will be of interest to many of our readers. Particulars with regard to it are as follows:—

THE GARTON PRIZE AND MEDAL.

Particulars of Rules and Regulations to which all candidates must subscribe.

The Prize and Medal has been instituted by the Grand Council of the British Empire Cancer Campaign with the object of promoting investigations into the nature, causes, prevention and treatment of cancer.

A Medal (suitably inscribed and engraved with the seal and motto of the Campaign), together with an honorarium of £500, will be awarded to the person, or group of persons who shall submit the essay embodying the results of original investigations which, in the opinion of the Judges, appointed by the Grand Council of the British Empire Cancer Campaign, is the best contribution towards the *EARLY DIAGNOSIS OF CANCER*.

In the event of several dissertations of sufficient merit being submitted, the Prize may be divided, or additional awards made.

The Prize will be reserved if, in the opinion of the Council, no dissertation of sufficient merit be received.

Candidates, who may be of either sex, must be *British subjects domiciled in the British Empire or Dominions* and not at the time members of the Grand Council of the British Empire Cancer Campaign.

The honorarium may be awarded either to an individual or to a group of persons who jointly submit a dissertation.

The dissertations shall be printed or typewritten in English, and embody the results of original investigations carried out, either wholly or in part, during the three years immediately preceding the year in which the Prize shall be awarded.

The dissertations shall not bear the name of the author or authors, but shall be distinguished by a motto or device, and be accompanied by a sealed envelope containing the name and address of the author, and having on the outside the motto and device corresponding with that on the dissertation.

The dissertations shall be addressed to the Honorary Secretary, British Empire Cancer Campaign, 19, Berkeley Street, London, W.1, and be delivered not later than 31st December, 1931.

The Prize dissertation (with all accompanying illustrations and preparations) shall become the property of the British Empire Cancer Campaign, and shall be published at their discretion under the name of the author or authors.

Dissertations not approved for a Prize shall, upon authenticated application within three years of the award on the specified subject, be returned together with the unopened envelopes containing the names and addresses of the authors.

The award of the Garton Prize and Medal will be made early in 1932.

The British Journal of Actinotherapy and Physiotherapy.

THE March 1929 issue of this journal contains an interesting paper by Dr. Kathleen Vaughan,

who has made a special study of osteomalacia as it occurs in Kashmir and elsewhere in India. This covers much the same ground as articles which we have published in this journal, for she attributes osteomalacia largely to light deficiency, and considers that the purdah system is responsible for its widespread incidence in India.

Other features of the same issue are a "Note on the Action of the Visible Rays" by Professor Leonard Hill, F.R.S., the well-known physiologist, and a discussion on the relief of pain by the intensive application of heat by Dr. J. Harvey Kellogg. Other authoritative articles deal with the possibilities of luminous and infra-red rays in therapy, and the uses of diathermy.

The British Journal of Actinotherapy and Physiotherapy is a new journal which not only covers the field of actinotherapy but also all aspects of treatment by physical methods. It has a very strong advisory editorial board, including such well-known names as those of Professor Leonard Hill, Professor W. E. Dixon, Sir Henry Gauvain of Alton, Dr. Axel Reyn of the Finsen Institute, and Dr. Rollier of Leysin. The annual subscription to the journal is 17s. 4d. net. We are asked by the editors to state that specimen copies of the journal are available at 2s. from the publishers at 17, Featherstone Buildings, London, W.C. 1.

THE THIRD INTERNATIONAL CONGRESS OF THE WORLD LEAGUE FOR SEXUAL REFORM.

We are asked to state that the Third International Congress of the World League for Sexual Reform will be held in London from the 9th to the 13th September, 1929. The League defines its chief objects as follows:—

- (1) The political, economic and sexual equality of men and women.
- (2) The liberation of marriage and divorce from Church and State control.
- (3) The control of conception, so that procreation may be undertaken only deliberately, and with a due sense of responsibility.
- (4) Race betterment by the application of a knowledge of eugenics.
- (5) Protection of the unmarried mother and the illegitimate child.
- (6) A rational attitude towards sexually abnormal persons.
- (7) The prevention of prostitution and venereal disease.
- (8) Disturbances of the sexual impulse to be regarded as more or less pathological phenomena, rather than as crimes.
- (9) Only those sexual acts to be considered criminal which infringe the sexual rights of another person.
- (10) Systematic sexual education.

The League certainly has a strong body of supporters, for they quote Dr. Wansey Bayly, Arnold Bennett, Caradoc Evans, Prof. Patrick Geddes, Prof. Julian Huxley, Somerset Maugham, and other well-known names. The League also publish a journal. The subscription to the Congress is one guinea. Enquiries about the Congress may be addressed to Dr. Norman Haire, Hon. Secretary to the Congress, 127,

Harley Street, London, W. 1; or to Capt. A. P. Pillay, O.B.E., M.B., B.S., Sholapur.

ALL-INDIA OPHTHALMOLOGICAL SOCIETY.

THE following is a report of the proceedings of the preliminary meeting held in Bombay on 15th and 16th March, 1929:—

"According to the notice issued under the names of Drs. R. P. Ratnakar (Bombay), F. Kugelberg (Tirupattur), B. G. S. Acharya (Lucknow), S. K. Mukerjee (Calcutta) and G. Zachariah (Madras), a preliminary meeting of ophthalmic specialists was held at the Seth Gordhandas Sundardas Medical College, Parel, Bombay, on 15th March. The meeting began at 6-30 p.m.

The following doctors were present:—

Dr. B. P. Banaji, F.R.C.S.I., Dr. R. P. Ratnakar, D.O., D.O.M.S., Dr. K. N. Karanjia, F.R.C.S.E., Dr. B. S. Sathaye, F.R.F.P.S., Dr. C. N. Shroff, D.O.M.S., Dr. J. Hansraj, D.O.M.S., Dr. Nanavati, D.O.M.S., Dr. Palkhiwalla, D.O.M.S., Dr. G. T. Modi, D.O., Dr. C. R. Athavale, D.O.M.S., Dr. Sardesai, L.R.C.P. & S., Dr. Abdulla bin Abdulla, M.D., Dr. J. M. Damany, D.O., D.O.M.S., Dr. Ghaswala, Dr. V. H. Bhandare, Dr. Chitnis, Dr. E. V. Srinivasan, M.B., Dr. G. Zachariah, D.O.M.S. and Dr. Subba Rao.

Letters regretting their inability to be present were received from Drs. B. G. S. Acharya (Lucknow), S. K. Mukerjee (Calcutta), F. Kugelberg (Tirupattur), B. K. Narayana Rao (Bangalore), R. K. Naidu (Poona), P. D. Desai (Bombay), R. D. Ranji (Bombay), J. N. Duggan (Bombay), N. A. Baxi (Bikaner), R. S. Shah (Rajkot), M. A. Dixit (Surat).

Dr. Banaji was proposed to the chair.

Dr. Zachariah detailed the events that led up to the calling of the preliminary meeting. A draft appeal had been drawn up and sent to Col. Coppinger, Col. Wright, Dr. Acharya, Dr. Narayana Rao, Dr. Duggan, Dr. Mukerjee, Dr. Ratnakar, and Dr. Kugelberg, with a covering letter asking for their support in issuing an appeal for the formation of an All-India Ophthalmological Society. Several of them heartily co-operated, and under their names an appeal was issued in July 1928 to all ophthalmic specialists. It was also published in some of the medical journals. Replies to this appeal were received from several men all over India, favouring the formation of such a society. It was therefore decided to hold a preliminary meeting in Bombay on the 15th of February, to consider the formation of the society. But the meeting had to be postponed at the last moment on account of the riots. The meeting was subsequently fixed for the 15th March.

After this preliminary statement was made, it was proposed by Dr. Sathaye and seconded by Dr. Shroff that an All-India Ophthalmological Society be formed. This was carried unanimously.

A tentative constitution which had been agreed upon by the signatories of the original appeal was then put forward. Discussion on this was carried on till 8-30 p.m., when the meeting was adjourned to 12 a.m. the next day.

At the adjourned meeting on the 16th, all those who attended on the previous day except Drs. Hansraj, Damany, Ghaswala, and Bhandare, were present. The constitution was further discussed and a final one framed.

The following Office-Bearers were next elected:—

President: Lieut.-Col. W. V. Coppinger, I.M.S.; Vice-Presidents: Dr. F. Kugelberg and Dr. B. P. Banerji, F.R.C.S.; Secretaries: Dr. G. Zachariah, D.O.M.S., and Dr. C. N. Shroff, D.O.M.S.; Treasurers: Dr. R. P. Ratnakar, D.O., D.O.M.S., and Dr. K. N. Karanjia, F.R.C.S.E.; Committee Members: Dr. J. N. Duggan D.O., Dr. Sardesai, L.R.C.P. & S. (Bombay), Major E. O. J. Kirwan, I.M.S., Lieut.-Col. H. Gidney, I.M.S., Dr. S. K. Mukerjee D.O., D.O.M.S. (Bengal), Dr. B. G. S. Acharya, D.O. (U. P.), Dr. B. K. Narayana Rao, D.O. (Mysore), Dr. E. V. Srinivasan, M.B. (Madras), Major Dick, I.M.S., and Dr. S. P. Shroff, F.R.C.S. (Punjab).

Finally it was decided to hold the first meeting of the society in Bombay during the third week of December beginning on the 17th or 18th."

Membership to the society is open to "all medical practitioners who practice ophthalmology as a speciality or are interested in ophthalmology and whose qualifications are satisfactory to the committee."

The subscription is Rs. 15 per year payable in advance.

Those who are desirous of becoming members are requested to send in their applications with their subscriptions to Dr. G. Zachariah, D.O.M.S., Flitcham, Marshall's Road, Egmore, Madras.

(Note.—Although the ideal is an excellent one, we cannot help feeling that the formation of an *All-India* Ophthalmological Society is too ambitious a scheme and unlikely to produce good practical results. The names of those present at the meeting called to form the society do not strike us as being representative of ophthalmology in All-India. The meetings will presumably be held in different cities each year and we cannot help fearing that the subsequent meetings may be no more representative of All-India than was the one reported above. The distances between the big cities in India are very great indeed and to induce the busy practitioner to travel 1,300 miles, say, from his home, he must be promised good value for his money.

The more practical plan would have been to form provincial societies which hold two or more meetings each year and then to form an ophthalmological section of the Indian Science Congress where from time to time there could be an interchange of ideas between provinces. However, the society has now been formed and we wish it every success.—EDITOR, I.M.G.)

Current Topics.

Some Aspects of the Surgery of the Spleen.*

By A. W. SHEEN, C.B.E., M.S. (Lond.), F.R.C.S. (Eng.).

(*The Lancet*, Vol. CCXVI, March 9th, 1929, p. 497.)

"With spleen's dead weight though heavy grown,
In life's rough tide I sunk not down,
But swam till Fortune threw a rope,
Buoyant on bladders filled with hope."

(*M. Green, born 1696, died 1737.*—"The Spleen.")

Historical Introduction.

A TRIBUTE to Hunter's work on the spleen is only appropriate. Hunter recognised that the organ was not essential to life, described it in over 40 vertebrates, and spoke of accessory spleens. He knew of injury and of enlargement in man. The "General Principles of the Blood" shows how Hunter sought for the solution of problems, many of which beset us to-day. There are nine original spleen specimens of Hunter's in the Hunterian Museum, including rupture, abscess, and cyst in man and normal spleens of various animals.

The case records of Hippocrates contain examples of enlargement of the spleen. In one work of the Hippocratic collection it is said "those persons whose spleen is large have their bodies meagre," which gave rise to Trajan's comparison that the Imperial Treasury was like the spleen, because when that was rich the people were impoverished. Suggestions in Pliny and the Talmud that the spleen was removed in men and in horses to increase their speed find confirmation in the recent work of Macht and Finesilver who, experimenting on rats trained to walk a tight rope, found that their speed was increased after splenectomy. It is now 300 years since Malpighi successfully tied the splenic vessels in a dog. The operation of splenectomy in man and animals has been performed by many workers in the past and is now being performed for various blood disorders.

Summary.

(1) Splenectomy is indicated in splenic anæmia (including Banti's disease) and in purpura. Each of these diseases is divided into a thrombocytopenic and a thrombocythæmic class. In our present state of knowledge operation should be reserved for the former class.

(2) Splenectomy is of value in selected cases of myelogenous leukaemia, but does not lead to a permanent recovery.

(3) After splenectomy for splenomegaly in a case of inherited syphilis the Wassermann reaction was negative three years later.

(4) Cases which at present can only be classified as splenomegaly do well after splenectomy.

(5) Attention is particularly directed to the necessity of a blood examination in cases of unexplained hæmorrhage from the stomach or uterus.

(6) All blood examinations when splenectomy is contemplated should include an enumeration of the blood-platelets.

(7) The morbid histology of the removed spleen is often difficult to interpret. Preoperative diagnosis may have to be revised in the light of the histological findings.

(8) Splenic anæmia (with Banti's disease) may only be a symptom-complex. A case, clinically Banti's disease, proved to be tubercle of the spleen and other viscera.

(9) Clinical appearances like Gaucher's disease may not be confirmed on examination of the removed spleen.

(10) An x-ray photograph will often show an enlarged spleen and such photograph may aid in diagnosis. This is illustrated by a case of hydatid of spleen.

* Abstract of the Hunterian Oration delivered at the Manson House, London, on 4th March, 1929. The oration was illustrated by a large number of specimens, photographs, microphotographs, drawings, microscopic and lantern slides.

(11) Radon applications will produce shrinkage of the spleen.

(12) Transfusion is of value as an adjunct to operation.

(13) Liver diathermy was used at one splenectomy with apparent benefit.

(14) A median incision is recommended for splenectomy with the operator standing on the right side of the patient.

Iodised Tincture of Guaiacol in the Treatment of Synovial and Serous Affections.

By JOHN MABERLY, M.R.C.S. (Eng.).

(*The Lancet*, Vol. CCXVI, March 2nd, 1929, p. 437.)

THE object especially in view was the treatment of pulmonary tuberculosis. The fact that guaiacol apparently had some beneficial action as an internal antiseptic in that disease suggested that its combination with iodine might give more definite results. Administration of the compound in several advanced cases of pulmonary tuberculosis over periods varying from one to eight weeks made it clear that, although the drug was non-toxic, it had no definite antiseptic action, at any rate in the finer lung tissue. Its use in place of potassium iodide in the class of cases in which I had been accustomed to use the latter drug, such as gummata and late neuro-syphilitic affections, proved that it was more efficient. In children with a tendency to enlargement of the tonsils and adenoids, which we now look upon as being probably dependent on a deficiency in thyroid extract, the tinctura iodo-guaiacol also appeared beneficial. Some interesting results in South Africa suggested that the drug had antiseptic action in the serous fluids and membranes, and experimental administration in pleurisy and synovitis confirmed this idea.

In my lung ward at the military hospital at Roberts Heights in 1917 and 1918 five cases of dry pleurisy came under treatment among malarial patients from East Africa. The symptoms in each case were typical, with dull patches, obscured breath sounds, friction, and pain on breathing. The temperatures were variable on account of the presence of malaria. All these cases cleared up rapidly on administration of one-drachm doses of tinctura iodo-guaiacol, given three times a day for the first 24 hours and then twice a day. Relief from pain was obtained within 24 hours and the physical signs disappeared in three or four days. During the last two years similar rapid relief from pain and symptoms has been obtained in patches of pleurisy among sanatorium patients suffering from pulmonary tuberculosis in England. In pulmonary tuberculosis especially one meets with cases in which there are old, permanently adherent patches of pleura which are subject to acute attacks occasionally. In these, although the pain and signs of active microbic infection quickly disappear, the dull patch of adhesion remains.

Whilst I was on military service more than one case of pleurodynia was sent into my wards diagnosed as pleurisy. This rheumatic form of nerve muscular affection does not come under the action of the tinctura iodo-guaiacol, but the preparation has proved curative in uncomplicated cases of acute pleurisy with effusion and also in the dry type. Cases which come under treatment after a definite amount of effusion has taken place naturally take longer to clear completely than do those in which the treatment is undertaken at an earlier stage. The resolvent action of the drug may, I think, be relied upon to create absorption in most cases without surgical interference. Where evacuation of the effusion seems necessary, aspiration or evacuation by simple incision, with immediate closing of the wound, is all that is necessary; the antiseptic and resolvent action of the drug should then be effective in completing the cure. If the pleura is left open and drained of its fluid, the drug fails to act so satisfactorily.

In many cases, especially in England, acute pleurisy is complicated with an unhealthy condition of the adjacent lung tissue, usually of a septic or pneumonic type. In these cases the results of administration of the tinctura

iodo-guaiacol are not satisfactory or definite as in the uncomplicated cases. The drug has no disinfectant action in the finer lung tissue and, although the pleura will improve, the lung condition with cough and temperature may continue. In two cases of pneumothorax, one tuberculous and the other non-tuberculous, the results were very satisfactory. Healing and resolution took place in a very short time.

In the treatment of synovitis and teno-synovitis of septic and tuberculous types similar antiseptic and antiphlogistic action has been evident.

A number of cases of tuberculous and septic types of synovitis have at various times come under treatment, and in each case the same antiseptic and healing action has been obtained. The drug was tested in advanced tuberculous disease of the spine and hip-joint in which suppuration and disease of the cartilages or bones was present. In these cases it completely failed to have any definite effect. Its therapeutic action has proved to be confined to the synovial membranes only; when once the disease has extended to the other tissues, it has no longer any curative action. The same want of any definite disinfectant action is found if a synovial membrane, such as that of the knee, is opened and kept drained of its fluid, as in the case of the pleura. The antiseptic action, both in the pleura and synovial membranes, apparently depends on the presence of the serous or synovial fluids and the integrity of the membranes. It is not evident in the blood or other tissues of the body with the exception of the ciliary membranes. In traumatic inflammation of the joints, and in sprains about the joints and tendons, the tincture has a rapid antiphlogistic action. The pain and inflammation disappear after administration of the drug, though the effusion may persist for a variable time.

Conclusions.

The uniform results obtained in a fairly large number of cases of pleurisy and synovitis of various types justifies the conclusion that in tinctura iodo-guaiacol we have a drug which has a definite selective antiseptic and antiphlogistic action in these membranes, provided they are closed, and one which fills an important gap in our materia medica for the treatment of septic, tuberculous, and traumatic inflammation of those membranes. It also exhibits the well-recognised resolvent effect of iodine.

The therapeutic effects of the tincture in the pleura and synovial membranes suggests that a similar action would be present in the other serous membranes and spaces, such as the cerebro-spinal and peritoneal. A limited experience of the use of the drug in meningitis, and in syphilitic and other infections of the cerebro-spinal system, supports this contention and further work on these lines appears very desirable. In the cases in which I have used the drug with apparent success lumbar puncture was not performed. In three cases of severe meningitis treated by another observer, lumbar puncture and the instillation of medicated serum was performed before and during the administration of the tincture. The results were completely negative. In any future work on these lines I would suggest that lumbar puncture should be avoided. It seems most likely in the case of a drug which only acts in a certain environment that any interference with that environment would nullify its action.

Dosage.

One fluid drachm given twice a day is sufficient in ordinary adult cases. In acute or dangerous conditions two or more drachms have been given every four hours for two or three doses. After that the smaller dose given once or twice a day has been found sufficient. Children are tolerant of the drug and take half to one drachm given in a similar manner. The addition of a little simple syrup to each drachm of the tincture, and water to half a fluid ounce is not an unpleasant mode of administration. Chloroform either alone or in solution is quite incompatible.

It is very difficult in general practice, without the facilities of a hospital and skilled laboratory help, to carry out to a satisfactory conclusion any therapeutic

investigation, especially if the results are unexpected. One has to wait a long time for suitable cases, and when they do occur they are not under the skilled supervision which is desirable for scientific records.

Note.—The British Drug Houses, Ltd., have undertaken to place the preparation at the disposal of the medical profession.

Combined Drug Therapy in Some Problems of Cardio-vascular and Renal Disease.*

By J. G. MURRAY, M.D.

(*Southern Medicine and Surgery*, Vol. XCI.
February 1929, p. 69.)

It is the purpose of this paper to crystallize our thoughts regarding the relative value of certain drugs in the treatment of two important problems of cardio-vascular-renal disease, namely, oedema and high blood pressure. We meet with these complications frequently, especially in one particular type of cardio-renal disease. I have in mind the oedematous, dyspnoeic hypertensive type with a decompensating heart and a small grey, granular kidney of the so-called chronic interstitial nephritis and arteriosclerosis. In other words, the typical old cardio-renal patient of the charity ward.

Conclusions

First, we observed that digitalis in large doses in combination with citrin (cucurbo-citrin) was more effective than either drug alone, digitalis improving the force of the heart action, and citrin lowering the vascular tension.

Second, it was evident that novasurol and ammonium chloride produced more effective diuresis in combination than did either drug separately.

Finally, the combination of drugs giving the most convincing and most consistent results in these decompensated cardio-renal-vascular cases were found to be: digitalis acting on the heart, citrin relieving vascular tension, and novasurol and ammonium chloride, one or preferably both, increasing the urinary output. Thus by the use of these four drugs in combination, we get direct action together on heart, artery and kidney.

Practical Notes.

(Abstracted from *The Practitioner*, Vol. CXXI,
December 1928.)

The Treatment of Migraine.

M. SEROG presents an analysis of twenty cases of severe migraine in which he has obtained remarkable improvement by the use of intravenous injections of strontium. Three injections of a strontium salt are given, 5 c.cm. on two consecutive days and the third two days after. From the results obtained and the known action of strontium in causing an increase in the tone of blood vessels, Dr. Serog concludes that the basis of the condition migraine lies, not in vascular spasm, but in hypotonic disturbances of the vaso-motor system.—(*Medizinische Klinik*, August 17th, 1928, p. 1279.)

The Treatment of Sterility in Women.

E. Douay has found the following treatment successful in cases of sterility due to atresia of the cervix uteri, whether congenital or caused by displacement of the uterus or by spasm. Under general anaesthesia the cervix is dilated, and a bilateral incision is made into it. Without curettage, an elastic tube is then passed into the uterus; this tube is of the same type as an in-dwelling catheter, with dilated ends. Vaginal douching is carried out for 48 hours and the tube may be left in place for as long as two months.—(*La Gynécologie*, August, 1928, p. 483.)

* Presented to the Greenville County Medical Society, 5th November, 1928.

The Treatment of Ozæna.

E. Feldstein observes that the aetiology of ozæna still remains a mystery, in spite of much research and many enticing theories. It has been well recognized that the paradiphtheritic bacillus is encountered with remarkable frequency in the nasal secretions in ozæna, and Dr. Feldstein's bacteriological examinations have confirmed this. The logical consequence of the discovery of the paradiphtheritic bacillus was the employment of Roux's serum in the treatment of ozæna; but the results, though successful, were fleeting. Dr. Feldstein, however, has been employing, with great success, the diphtheria anatoxin of Ramon; intramuscular injections are given twice weekly for two months, beginning with half a c.cm. and increasing to 3 c.cm., diluted with an equal quantity of physiological serum. A second series of injections is often necessary two or three months later. The crusting, the unpleasant odour, and the atrophic pharyngitis soon disappear under the influence of this treatment.—(*Journal des Praticiens*, October 20th, 1928, p. 681.)

The Treatment of Vomiting in Children.

F. Hamburger, in dealing with the numerous conditions which give rise to severe vomiting in children, describes the treatment he has successfully employed in the chronic vomiting associated with catarrhal conditions of the stomach in the neurotic type of school child. He gives the following mixture in five-drop doses three times a day before meals:

R			
Tinct. gent.	g. 2.0 (m.xxx.)
Tinct. nuc. vom.	g. 3.0 (m.xiv.)
Tinct. chin.	g. 15.0 (ñiv.)

With this he gives atropine sulphate in doses of g. 0.001 (grs. 1[150]) as this tends to lessen the irritability of the gastric mucous membrane. An easily assimilated diet must be given at the same time. It is sometimes advisable to give the atropine by subcutaneous injection if it is not well tolerated by the mouth. For the distressing vomiting which accompanies whooping-cough, Dr. Hamburger has found papaverine, g. 0.3 to 1.0 : 150, one teaspoonful three times a day, of great help.—(*Münchener Medizinische Wochenschrift*, September 14th, 1928, p. 1605.)

Fractures of the Ankles.†

By FRANK D. DICKSON, M.D.

(*The Journ. Amer. Med. Assoc.*, September 22nd, 1928,
Vol. 91, p. 845.)

Treatment.

It is the routine in our clinic that all ankle fractures be reduced at the earliest possible moment and fixed in a plaster cast.

Reduction is made under full anaesthesia. The ankle is grasped with one hand, pressure being made outward in the region of the internal malleolus. The foot is grasped with the other hand well back toward the heel, the thumb resting just below the external malleolus and the fingers grasping the inner side of the heel. With the hands in this position, the foot is inverted and pushed sharply inward. Particular care must be taken to see that the heel is inverted and not just the movable anterior part of the foot, as it is through the posterior part of the foot that the fragments are controlled. Only a moderate degree of inversion is necessary but no harm comes from too much inversion. When backward or forward displacement of the foot is present, this must be corrected by appropriate manipulation. In the occasional case in which there is an inversion displacement instead of an outward displacement, reduction is the opposite from that described here and the foot is put up in its normal position, care being taken to avoid

† Read before the Section on Surgery, General and Abdominal, at the Seventy-ninth Annual Session of the American Medical Association, Minneapolis, June 15th, 1928.

over-correction because of the danger of later flatfoot. The essential feature of the reduction is a restoration of the ankle mortise. Failure to achieve this results in a faulty weight-bearing surface at the ankle joint, and a painful and impaired extremity which can be improved only by later operative intervention. The position of the bones should be checked at intervals by the help of x-rays.

With the foot inverted and as close to a right angle as possible, the cast is applied, over a raw cotton bandage which is about one-fourth inch thick, and is immediately bivalved. This enables one to take care of subsequent swelling, allows of easy access to the entire limb for inspection, and at the same time holds the fractured bones firmly in place. Many experienced surgeons prefer to fix the leg in a pillow splint or fracture box for the first three days to a week before applying plaster. It is my feeling, however, that the fracture can best be controlled by the immediate application of plaster, and that swelling is less and disappears more rapidly with such firm fixation. All agree that immediate reduction is best.

I shall mention Debet's gypsum apparatus only to say that it has become quite a popular form of dressing in ankle fractures, but one that seems more fitted for use in fracture clinics than in general practice.

The after-treatment consists in removing the anterior half of the cast at the end of the second week and starting light massage and toe movements, the posterior shell remaining in place. In four weeks, the foot is removed from the plaster shell and gentle motion is allowed. At the end of from six to eight weeks, depending on the severity of the fracture, the cast is discarded and a shoe used into which a hard felt arch is fitted. This supports the arch and maintains inversion of the foot. At times, it is desirable to elevate the inner edge of the shoe three-sixteenths of an inch for a month, or until full strength has returned to the supporting muscles.

Pyorrhœa Alveolaris.*

By HUMPHREY HUMPHREYS, O.B.E., M.C., M.B.,
Ch.B., M.D.S., L.D.S.

(*The Brit. Med. Journ.*, January 19th, 1929, p. 99.)

TREATMENT.

It is an axiom that all sound treatment of disease should be directed towards its cause, and not to its symptoms. Over the predisposing causes of pyorrhœa we have as yet no control, and if our conception of its exciting causes is well founded it follows that our sole aim in treatment should be the continued prevention of oral stagnation; and in fact the conception of oral stagnation as its cause rests not only on the evidence of pathology, but on the clinical fact that the therapeutic measures directed against it are the only ones that do produce a permanent result. What measures, therefore, are open to us? We cannot expect to see the adoption of a diet so coarse and astringent that it would be sufficient in itself, and the treatment possible divides itself into surgical and medical procedures.

Surgical Treatment.

The paramount surgical treatment is a complete removal of all the calculus, and this scaling, in the great majority of cases, will have to be repeated at regular intervals. It is obvious that, however thoroughly the calculus is removed, the cause that led to its deposit in the first instance will bring about the same condition again; and the medical measures I shall describe, directed to the removal of that cause, are seldom so thoroughly carried out or so perfectly effective that the need for subsequent scalings will not arise. Another surgical measure of great value is the abolition of any pockets that may exist—that is, the removal of the gum to the level of the floor of the pockets, by the knife, the cautery, or by escharotic drugs. The existence of pockets renders the task of preventing stagnation around the teeth, which is the goal of all our treatment, peculiarly difficult, and the clinical results of gum resection are uniformly excellent.

Medical Treatment.

The surgical measures I have mentioned, though they arrest the course of the disease for the time being, cannot be expected to effect a permanent cure. The patient will be no less liable to oral stagnation, a fresh deposit of calculus, and a recrudescence of the disease than he was before, and the surgical measures must be followed up by some daily measure of oral hygiene which will, as far as is humanly possible, prevent a recrudescence of pyorrhœa by preventing oral stagnation. No measure that is not repeated daily can hope to maintain a permanent cure, and it follows that effective medical treatment can only be undertaken by the patient, and will be effective in proportion to the diligence we can persuade him to practise.

There are three methods I have tried in my own practice: (1) daily irrigation of the gums and interdental spaces with a powerful spray from an atomizer; (2) daily cleansing of interdental spaces, and any pockets in the gum that are not resected, with hydrogen peroxide applied through a fine root syringe; and (3) saline massage. The salt promotes a flow of serum into the pockets and interdental spaces by osmosis; the massage first squeezes this out and then causes the pockets to fill up again with serum. Stagnant areas are thus sluiced out by the patient's own serum.

Daily medical treatment by the patient himself somewhat on these lines is, I believe, the only treatment likely to give results that are permanently satisfactory. The other forms of medical treatment are mostly aimed at what we now know to be complications of the disease, such as infection of the pockets with pyogenic organisms, rather than at the primary condition; and conditions such as pus formation usually disappear spontaneously in response to the measures I have mentioned. If they do not, then a course of special treatment may sometimes do good—either the old method of treating the pockets with caustic drugs, or a course of vaccine therapy, or ionic medication, or treatment with high frequency current. Nothing is more easy than to effect a cure of pyorrhœa if by cure is meant an arrest of pus formation. Only too often the so-called cures have meant little more than success in eliminating this particular complication of the disease for the time being.

While it remains true that active pyorrhœa does not adversely affect the general health as much as was formerly believed, and far less frequently than apical infections, it is not to be thought that it is wholly innocuous. Its ill effects are most often seen in diseases of the digestive tract, as its toxic products drain into the mouth rather than into the blood; very few cases have occurred in my clinical practice where diseases of the rheumatic group were produced.

The relatively innocuous nature of pyorrhœa compared with apical infections is usually explained as the difference between an open and a closed infection, the toxic products of pyorrhœa draining freely into the mouth and the bacteria being killed by the gastric juices, while the toxic products of apical infections must of necessity find their way into the system. But there is another and more significant difference between the two conditions. An infection of the gums is freely exposed to all the defensive mechanisms of the body, phagocytes, antibodies, and antitoxins, which in most cases constitute an adequate defence. But an infected pulp chamber constitutes a stronghold for bacterial growth, completely protected from all the natural defence forces of the body where germs can multiply and discharge their toxins and themselves into the system with impunity.

Remarks on the Treatment of Empyema.†

By F. G. THOMSON, M.A., M.D., F.R.C.P.

(*The Brit. Med. Journ.*, January 19th, 1929, p. 89.)

THE principles to which any ideal form of treatment for empyema should conform are:—

(1) Operative procedure should be such as involves the minimum of time and the minimum of shock.

† An address given to the Trowbridge Division of the British Medical Association, November 1928.

* A post-graduate lecture delivered in Birmingham on November 8th, 1928.

(2) If it is necessary to employ the method of open drainage, this should never be performed until it is reasonably certain that the empyema cavity has become sealed off from the rest of the thorax by adhesions.

(3) In connection with the last it is imperative to distinguish between pneumococcal empyema, in which adhesions are usually formed by the time the empyema is diagnosed, and streptococcal empyema, where adhesions are not usually formed till later.

(4) In order to minimize the risk of secondary infection the opening in the chest wall should be no larger than is sufficient to admit a suitable drainage tube, and should fit closely around the tube when it is placed in position.

(5) The cavity should be sterilized as early as possible by frequent irrigation with some suitable antiseptic, to prevent the formation of dense fibrous adhesions, which prevent the expansion of the lung and the early closure of the cavity.

(6) The lung should be encouraged to expand by ensuring a negative pressure in the pleural cavity throughout the period of drainage.

(7) Convalescence should be assisted by giving plenty of nourishing food, and whenever possible, by treating the patient entirely in the open air.

The method of treatment which would appear to fulfil these principles more completely than any other is that of closed continuous-suction drainage. The technique usually employed, of introducing a stretched rubber tube through a metal cannula, which is allowed to remain in position, presents a very real disadvantage in the fact that the cannula is very apt to become displaced, especially in a restless child, and come out of the chest, pulling the drainage tube with it. This difficulty is entirely obviated by using a self-retaining rubber catheter, which is either introduced direct through a very small incision into the chest, or through a cannula, which is withdrawn immediately the drainage tube has been inserted. I have had an oval trocar and cannula specially made to enable a larger catheter to be introduced between the ribs than would otherwise be possible, but I am not sure that this method presents any material advantage over the method of direct introduction through a small incision in the chest wall. Two other disadvantages have been cited against this form of treatment—namely, that it is difficult to ensure adequate drainage, and that after-treatment requires almost continuous supervision by specially trained nurses. With regard to efficiency of drainage, we have not found the difficulties so great as would be thought. Irrigation of the cavity by Dakin's solution, two or three times a day, seems to soften or disintegrate those large masses of fibrin which so often impede the free passage through the tube. If the latter appears to be blocked it is detached from the suction apparatus, and, by means of a glass syringe, Dakin's solution is alternately forced gently through the tube and sucked out again. By doing this a large amount of fibrin can often be removed, and when the suction apparatus is replaced drainage is found to proceed quite satisfactorily. The last objection to continuous suction, that it requires unremitting attention, is only partially true. Once it is satisfactorily started very little attention is required, unless the tube gets blocked and requires syringing out, as it occasionally does. Irrigation with Dakin's or some other antiseptic ought to be carried out at least two or three times a day, no matter what method of drainage is adopted, and it is much easier to detach the suction pump and irrigate through the catheter than it is to remove the messy dressings from a patient's chest and irrigate through an ordinary open tube. One way and another, I do not think that this method requires more attention than can easily be given in the ordinary routine way in a hospital ward or a nursing home.

After removal of the catheter I have, in all cases, put a fine tube into the sinus to drain the small cavity remaining. The sinus is usually healed completely after three or four days, but in four of my patients the wound, after closing up, has broken down again, and a small abscess has discharged, after which the sinus has again closed up and given no further trouble. This is perhaps due to the wall of the sinus itself being infected, and

can probably be obviated by treating the latter with flavine or some similar preparation. In all cases except one the cure has, I believe, been complete, and, so far as one can tell, permanent. One patient, who originally had a very large staphylococcal empyema of ten weeks' duration, returned to his work as a miner some six weeks after discharge, and came back to hospital two months later with an abscess pointing over the old sinus; some six ounces of pus were evacuated from the cavity, which rapidly healed and has not, so far, recurred. Another patient had a double empyema, both sides being drained simultaneously, and closing on the seventeenth and eighteenth days respectively. This patient has remained fit ever since, and I am informed he has been for some months working about his farm as usual.

The average period during which drainage has been required has been nineteen days. One particularly satisfactory feature in all has been the rapid expansion of the lung, as shown by the amplitude of respiratory movements on the affected side, and the return of breath sounds at the base.

The advantages that I think one can justly claim for treatment by continuous suction drainage are:—

(1) Introduction of the catheter is rapid and easy, and entails virtually no shock.

(2) Anaesthesia is correspondingly brief, and, if necessary, the operation could be done, except perhaps in infants, with a local injection of novocain.

(3) The tube causes little or no pain.

(4) Nursing of the patient is much easier and cleaner.

(5) The risk of secondary infection of the empyema is very much diminished.

(6) The wound closes quicker than by open drainage.

(7) Re-expansion of the lung is more rapid and complete.

Sleep in the Treatment of Acute Disease.

By J. WALTER CARR.

The Lancet, p. 1181.

(Abstracted from *The Medical Review*, Vol. XXXII, January 1929, p. 15.)

A WOMAN of 65 was seen in consultation. She had been ill for 12 days with increasing bronchitis, which had got much worse during the last 24 hours. Her temperature was 100°, pulse 115, respirations 36, with orthopnea, working of the alae nasi, and much inspiratory recession. Expectoration had gradually been diminishing and had almost ceased, but abundant large and small, moist, non-consonating adventitious sounds were heard all over the lungs, especially at the left base. It seemed very doubtful whether she would live another 24 hours. She was treated with stimulant expectorants, vigorous counter-irritation to the chest, both front and back, and inhalations of oxygen at frequent intervals. Two days later she had just held her own, but her colour was bad, sputum still very scanty, and she was obviously becoming exhausted; she felt worn out, for she had had only short snatches of unrefreshing sleep. The situation appeared wellnigh hopeless. It seemed that after another restless night of constant, ineffective cough, heart failure would follow; on the other hand, it seemed equally certain that any drug sufficiently powerful to compel sleep would cause the secretion in the bronchial tubes to accumulate and lead to asphyxia.

With much hesitation the writer gave by mouth a tablet of 1/6th grain of morphia and 1/100th of atropine. She slept fairly soundly for several hours, but the colour became worse and respirations increasingly shallow. She was kept alive by oxygen given through a tube passed into the nostril, which fortunately did not interfere with her sleep. When she awoke she felt better, and began to cough more effectively. Her condition remained critical for some days, and the morphia and atropine had to be repeated one night, but improvement, though slow at first, was fairly continuous; she

began to expectorate increasing quantities of thick, purulent sputum and eventually recovered.

Had the rule not to give morphia to an elderly patient with advanced general bronchitis not been broken, the writer believes she would have succumbed. The rule is excellent, but, like all others in medicine, must not be adhered to blindly, although in such desperate cases the doctor is likely to feel that, as the patient will probably die anyhow, it is better that the end should be brought about by the disease rather than by the remedies. The risk was great, but less, it seems, than that of another sleepless, exhausting night. The morphia was given by mouth because it seemed likely that its action, whilst equally effective, would be more gradual and therefore safer than hypodermically. The atropine is presumably useful by diminishing the secretion in the bronchial tubes and so the danger of asphyxia.

In many forms of heart disease morphia as a narcotic is still more generally helpful, without the danger necessarily attendant upon its exceptional use in severe bronchitis. Its value in advanced aortic disease, in which as soon as the patient drops off to sleep he is disturbed by dyspnoea, is generally recognized. More hesitation is felt in giving it in mitral disease, with a failing, irregular heart, and general oedema. The lungs are more or less water-logged, there is probably some albuminuria, and it is feared that morphia may lead to dangerous accumulation of secretion in the bronchial tubes. This need not be anticipated; sound sleep is as valuable a tonic to a fibrillating heart as digitalis; at times probably even more valuable, for digitalis or any other cardiac tonic is likely to be more effective if the patient can enjoy at the same time the benefit of restful sleep.

The early stage of acute pneumonia affords another example of the value of morphia or opium. In the later stages, especially in the elderly, their use is attended by considerable danger of respiratory failure; but during the first 2 or 3 days, by securing sleep, they conserve vitality for the trying time to come and probably diminish the chances of delirium, one of the gravest risks to life in pneumonia. They are, of course, particularly useful when pain is causing sleeplessness.

In the above instances morphia or opium was used rather than one of the milder synthetic hypnotics. Some of these are very valuable, but in acute illness, in which fairly deep sleep lasting several hours is urgently required, none is so reliable or so lasting in effect as morphia or opium.

Therapeutic Notes.

(Abstracted from *The Prescriber*, Vol. XXIII, February, 1929, p. 70.)

EPHEDRINE and the Heart.—W. A. Bloedorn and P. F. Dickens, of Washington, D.C. (*Arch. Int. Med.*, 1928, Sept., 322), warn against the use of ephedrine in patients showing evidence of cardiac injury. In a case diagnosed as asthma, in which ephedrine had been used, they observed signs of serious cardiac embarrassment, including pulsus alternans, marked tachycardia, and cardiac decompensation. Extreme care is necessary in the diagnosis of bronchial asthma, as cases of so-called cardiac asthma are frequently put in this group. If during the administration of ephedrine the patient exhibits toxic symptoms such as palpitation, tachycardia, arrhythmia, or vaso-motor disturbances, the drug should be promptly discontinued.

New Remedial Agents.

Salyrgan: A Mercuric Diuretic.

(Abstracted from *The Prescriber*, Vol. XXIII, February 1929, p. 71.)

THE employment of organic compounds of mercury as diuretics is comparatively recent. Calomel and other mercurials have for many years been recommended for this purpose, but they have never come into general use. The organic mercurials were originally designed not as diuretics but as antisyphilitics, and their diuretic properties have come to light only in the last few years.

The first compound to find this new application was *Novasurol*. This is a double salt of sodium mercuri-chlorophenyl-oxyacetate with diethylbarbituric acid (barbitone). A year ago a new mercurial diuretic was introduced under the name of *Neptal* or "440B," which has the same chemical composition as *Salyrgan*. The composition of neptal (as of salyrgan) was given as sodium mercury-salicyl-allyl-amido-acetate, and its diuretic properties had been favourably reported upon by French workers.

Recently American observers have been reporting on the diuretic properties of salyrgan, and a searching chemical examination has been made of it in the laboratories of the American Medical Association. The result of this examination shows that while the presence of certain groups and radicals claimed by the German manufacturers was confirmed, the formula as originally published is not strictly correct. Salyrgan appears to be a definite chemical compound—sodium hydroxymercuric-methoxypropyl-carbamylphenoxy-acetate, or $\text{NaOOC} \cdot \text{CH}_2 \cdot \text{O} \cdot \text{C}_6\text{H}_4 \cdot \text{CONH} \cdot \text{C}_2\text{H}_5 \cdot (\text{O} \cdot \text{CH}_2)_2 \cdot (\text{HgOH})$. Salyrgan, called in America *Mersaly*, is a complex synthetic mercurial prepared by the action of mercury acetate and methyl alcohol on salicyl-allyl-amido-acetic acid and subsequent conversion to the sodium salt. It contains 39.6 per cent. of mercury in non-ionizable form.

Salyrgan has been found to exert a destructive action on the spirochete of syphilis in rabbits, but is used chiefly as a diuretic. It induces diuresis only provided sufficient renal tissue is still intact, and is therefore contra-indicated in acute diseases of the kidney as well as in advanced nephritis. It is effective in ascites and oedema of cardiac and cardio-renal origin; also in ascites resulting from cirrhosis of the liver. It has been tried in hydrothorax, pericardial effusion, and in the ascites of tuberculous peritonitis, but without uniform results.

Salyrgan is supplied in the form of a 10 per cent. solution. As diuretic, an initial dose, intramuscularly or intravenously, of 0.5 c.c. of the solution is given to test tolerance; this is increased to 1 c.c. or to a maximum of 2 c.c. if required; injections are made at intervals of from three to five days.

Reports on the use of salyrgan, both as an anti-syphilitic and as a diuretic, have appeared during the past few years in continental literature. Quite recently a careful study of its value in oedema has been made by Barker and O'Hare, of Boston, Mass. For the past five years these workers have been particularly interested in the oedemas of non-cardiac origin, and have experimented with numerous drugs in their attempts to get rid of the stored fluid in such cases. For some time they used *novasurol* with benefit, but noticed that a proportion of their patients showed some form of mercurial irritation, and they used the drug with some hesitation. During the past year they have employed salyrgan as a diuretic in thirty patients exhibiting various forms of oedema, ascites, and pleural effusion. The dosage followed was that given above, the intravenous route being found to give a better and more prompt response. In all cases (except four, in which the failure is more or less explicable) the diuresis began in from one to four hours and was complete in from eight to twelve hours. The drug is therefore best given in the morning. In patients who responded poorly to salyrgan, ammonium chloride or nitrate was given in conjunction with the mercurial, as is recommended in the case of *novasurol*. This had the effect of making the salyrgan much more effective. The ammonium salt is given in doses of 8–15 gm. daily, being started usually from three to four days before administration of salyrgan. In no case has any evidence of toxicity or irritation been observed. The action of salyrgan seemed to wear off after a time in some cases. The cases of cardiac oedema, ascites due to cirrhosis of the liver, and the anasarca of nephrosis showed the greatest diuretic effect.

Barker and O'Hare conclude that salyrgan is a good diuretic with a wide range of application, and is relatively non-irritating. It is particularly valuable in circulatory failure and the ascites due to cirrhosis of the liver and chronic nephrosis. Like *novasurol* it is more effective in the presence of acid-forming salts, and

the ammonium ion seems to be most effective when supplied as ammonium chloride or nitrate.

The Acnes.

By W. N. GOLDSMITH, M.A., M.D., M.R.C.P.

(*The Medical Press*, February 6th, 1929, p. 112.)

Introduction.

THE clinical appearance of acne is very well known. The comedo results from a hyperkeratosis of the funnel-shaped opening of the follicle. Its free extremity is coloured not by a deposit of dirt, but by oxidation of the keratin itself. When they exist alone they constitute "acne punctata." The topography is very special. It scarcely ever passes beyond the waist, nor the upper two-thirds of the arms, nor the boundary of the scalp, which always escapes. The eruption is continuous, but shows exacerbations in the spring, during menstruation, and after departures from normal régime.

Ætiology and Nature.—An essential condition for acne is what Darier calls *la Kérose*: the patients always have seborrhœa, pityriasis simplex, or dandruff, and sometimes seborrhœic eczematides. The predisposed terrain pre-exists and survives the acnes. It is said persistently to be favoured by sexual excitation and functional or organic genital troubles, especially when in women it is localised to the chin, but I have not observed such a close association. The onset at puberty, and its disappearance by the age of thirty, does suggest strongly some endocrine influences, but the genital organs themselves may play no more direct part than they do in the disappearance of tinea tonsurans at puberty. The determining cause is almost certainly a local infection.

Bacteriology.—The comedos contain myriads of small bacilli, some pityrospora of Malassez, and some cocci. The pustules are either sterile, or they contain a few white staphylococci or some acne bacilli.

In 1925, I carried out some work on the staphylococci of acne vulgaris, comparing the staphylococcal flora of the pustules, comedos, and surface of the skin of acne patients, and of normal controls. Thirty-three individuals were examined, and about ninety separate strains investigated. Methods used included growth on agar, in broth, in gelatine, on Löffler serum; the reduction of nitrates, formation of hæmolyisin, agglutination, formation of lipase, and pathogenicity for mice. Several strains of staphylococcus pyogenes aureus from furuncles were used as standards for comparison.

My conclusions were:—(1) I found no difference between the staphylococcal flora of acne pustules, surface of the skin of acne patients and normal skin. (2) This flora is composed preponderantly of white, and only to a very small extent of coloured, strains (mostly golden-yellow or brown, occasionally lemon-yellow). (3) None of these coloured strains proved to be staphylococcus pyogenes aureus or citreus. (Thus I came across not a single staphylococcus pyogenes aureus or citreus on the skin of the cheeks of fourteen normal persons, and nineteen acne patients, nor in the acne lesions.) (4) Whether among the many varieties of white staphylococcus any should be identified with staphylococcus pyogenes albus, I could not decide for certain. According to the usual definition, that it resembles the staphylococcus aureus in all except pigment, then none were identical. But two strains of so-called staphylococcus pyogenes albus obtained from Kral's laboratory for comparison did resemble a few of my strains. I am not yet quite convinced that such an organism as staphylococcus pyogenes albus really exists. (5) A series of intradermal reactions performed with a vaccine of cocci from acne pustules, showed that there was no difference in the reaction of acne skin and normal skin.

These investigations failed to establish any evidence supporting the idea that staphylococci play any part in

the causation of acne vulgaris. It still remains to test the claims of the acne bacilli.

General Treatment.—I do not know of any internal treatment that can be relied upon. Staphylococcal vaccines are irrational. Acne bacillus vaccines do sometimes seem to help, but generally do not. In one case a generalised eruption followed its administration. Possibly this was an "acneide" comparable to a trichophytide, but I do not know of any other such cases. General ultra-violet light baths, in one case, completely cleared up in a short time a case which did not respond to local ultra-violet rays, but I have not tried this in many cases.

Local Treatment.—This, on the contrary, will clear up any case if perseveringly persisted in, but there will always be a tendency to relapse, till the age of about twenty-five has past. The best results are obtained by producing a mild, dry exfoliation. This is best effected by a paste of equal parts of powder and grease, containing sulphur and resorcin, of each 6 per cent. to 25 per cent. The strength of these active ingredients must be increased at the expense of zinc oxide or talc until the desired peeling is obtained. It is simply spread on at night after thoroughly washing with soap and water, and cleaned off in the morning. Ultra-violet light will also produce considerable improvement at first, but it is difficult to maintain its effect, and it is time-consuming. In nodular cases a course of x-rays is needed, and is always effective in softening the nodules. It is only in this type that I consider their use advisable. If definite fluid abscesses form it is best to aspirate them. This is the only instrumentation that is desirable in any stage.

Drug and Occupational Acnes.

These are closely related to acne vulgaris, and clearly show how important a part is played by predisposition, whether the eruption is determined by external or internal agents.

Iodides and, to a lesser degree, bromides, produce, in certain subjects particularly, either at once or after prolonged administration, an acne-like eruption. It seems to attack particularly those in the age period susceptible to acne vulgaris. It is generally rather acute in onset, inflamed and infiltrated. The distribution is also similar to that of acne vulgaris, but the comedos are not seen. I remember one case of acne vulgaris in which, after its development, bromide had to be administered for epilepsy. Whenever bromide was taken the eruption became greatly aggravated, but it was not possible to distinguish the bromide from the ordinary acne vulgaris lesions. I do not know if a critical study has been made of the bacterial contents of bromide or iodide acne, but this would be an interesting study.

The various tars, especially oil of cade, can produce in those who handle them or use them for treatment an eruption of reddish-brown papulo-pustules with central comedos very much like acne, but this occurs more especially on the limbs, and these lesions generally contain the staphylococcus pyogenes aureus. It looks, therefore, as if this acne merely consisted of a staphylococcal folliculitis predisposed to by a special external irritant. Much the same may be said of the paraffin acne, but here there is the added feature of a plugging of the pilosebaceous follicles by hyperkeratosis at their orifices.

Chlorine acne, and which is especially observed in those who work in the electrolysis of sodium chloride, shows the characters of acne vulgaris, but immeasurably exaggerated, and with an extraordinary profusion of large comedos, and an extension to regions which acne vulgaris respects. In spite of many researches on the subject we are still ignorant whether it is the free chlorine or some combination that is responsible, or whether the chlorine acts externally or by inhalation. Possibly the halogens render the follicles susceptible to a staphylococcal infection as tar does, in which case it would be definitely distinguished from acne vulgaris; but as I have pointed out above, a true acne vulgaris can, apparently, be greatly aggravated by bromide.

Ophthalmological Notes.

(Abstracted from *Amer. Journ. Ophthalm.*, Vol. XII, February 1929, p. 150.)

Antonibon, A. Modification of the action of some ophthalmic drugs by potassium. *Ann. di Ottal.*, 1928, V, 56, May, pp. 403-419.

SEVERAL authors have claimed that the addition of potassium salts to local anesthetics increases their effect. The author tried to confirm this with respect to the action of cocain, novocain, stovain, tropococain, eucain, halocain, and tubocain and also of the common cycloplegics and miotics on the normal human cornea, adding KCl to these drugs to make a concentration of one per cent. With two per cent. cocain, the average time required to abolish the corneal reflex was 31.2 seconds, while with cocain and KCl this was reduced by about a half (16.3 seconds). A definite reinforcing effect, though somewhat less marked, was noted with one per cent. cocain and two and four per cent. novocain. With the other anesthetics, the effect of KCl was less marked.

In the case of the mydriatics, the size of the pupil was noted at intervals until maximal dilatation. With atropin and KCl mydriasis developed at about the same rate, but dilatation from one to two mm. greater was produced than with atropin alone. A definite reinforcement of the mydriatic effect of scopolamin and eumydrin but not of homatropin was noted.

With eserin, no increase in the miotic effect was noted, but with pilocarpin this increase was definite, averaging 0.6 mm. A definite increase in the effect on tension was also noted with eserin in normal eyes, while in a case of glaucoma this difference was marked.

The reinforcing effect of KCl on the action of some drugs must be considered as an example of true synergism, since KCl alone causes no effect similar to that of these drugs. The author suggests that this synergistic effect may prove of practical value in the use of eserin for glaucoma.

Frydman, R. Protein Therapy in Ophthalmology. *Rev. Gen. d'Ophth.*, 1928, V, 42, March, p. 85.

At the ophthalmic clinic of the university of Geneva the author treated fourteen cases with cibalbumin, which contains one per cent. egg albumen. Ocular affections of gonococic origin undoubtedly were improved by the protein treatment. In iritis the results were often transitory, and relapses were frequent both during and after treatment. One case of serpinous ulcer of the cornea was cured by the treatment; another was not affected. The results were excellent in a case of panophthalmitis due to a perforating foreign body.

The author concludes that protein treatment by intramuscular injection presents no danger for either the general organism or the eye and is easily applicable to ambulatory cases; that it gives remarkable results in a large number of ocular affections, especially of the deep membranes; but that it is not a panacea.

Vasek, E. Miscellanea collected from modern ophthalmologic therapy. *Ophthalmologicky Sbornik*, 1928, V, 2, p. 207.

KNAPP's tattooing with two per cent. acid gold chloride solution without adrenalin or tannic acid was tried in ten cases. In old dense leucomas it was a failure; the thin leucomas were coloured dark purple, but after one year a diminution in the depth of colour was apparent.

Lagrange's colmatage for raising intraocular tension was performed in two cases of myopic retinal detachment and one case of traumatic detachment in a hyperopic eye. Only the last case remained for observation; the tension rose, the retina reattached itself, the field of vision widened, and vision rose from perception of hand movements to 5/15.

Glaucosan was used in one case of advanced simple glaucoma, in two cases of glaucoma secondary to occlusion of the pupil, and in one case of iridocyclitis with high tension. In the last case the result was good; in the two secondary glaucomas intraocular tension rose

further. Iridectomy was performed on the primary glaucoma after a few glaucosan treatments.

Two cases of retrobulbar neuritis were treated with intra-nasal tampons of cocain-adrenalin. In one case the treatment was combined with inunctions of grey ointment, and this case recovered promptly. In the other case two months tamponage improved vision from hand perception or hand movements to 5/50; after two series of mercurial inunctions it rose to 5/15.

Zuckermann-Zicka, Z. Light Therapy in Ophthalmology. *Ophthalmologicky Sbornik*, 1928, V, 2, p. 219.

THE writer is very enthusiastic about the effectiveness of ultra-violet and x-ray therapy in eye diseases. In eczematous keratoconjunctivitis she is very successful with ultra-violet irradiation. She irradiates the entire body, except the head, with two lamps, one in front and one behind, every other day. When the treatment ceases to produce an erythema, the irradiations are discontinued for two or three weeks and then resumed again. The eyes should be carefully protected; exposure to light may produce a stubborn and painful conjunctivitis. In tuberculous affections of the uvea she combines ultra-violet irradiations of the entire body with local x-ray therapy. In intractable cases of squamous blepharitis and chalazia which resisted every other method of treatment, she obtained good results with an x-ray exposure after protecting the eyeball with a glass prothesis. Eighty per cent. of epitheliomas of the lids were cured by x-rays. She reports a case of myxoepithelioma of the orbit treated with x-rays, in which there was no recurrence after three years.

Armstrong, J. J. P. Radiant light in gonorrhoeal ophthalmia. *Physical Therapeutics*, 1928, V, 46, April, p. 159.

USING a deep therapy lamp of 1,500 watts with a white globe, Armstrong treated eighty cases of gonorrhoeal ophthalmia, all in the second stage. Smears were examined in thirty-four cases and found positive, the rest being taken for granted from the history. Twelve men had a cloudy cornea and two had beginning marginal ulcers. The average number of light treatments was nine, the light being used twice daily, one hour at a time. The least number of treatments was eight, and the greatest fourteen. At the end of this time all pain, swelling and pus had disappeared, and the patients were discharged with a zinc lotion to be used every two or three hours.

Only the eyes are exposed. The light is applied at a distance of eighteen inches and gradually raised to twenty-five or thirty inches according to tolerance, and left for one hour. This is done twice daily. Compresses of hot Epsom salts in solution are applied at home by the patient himself every fifteen minutes, followed by irrigation with fresh twenty per cent. argyrol every four hours. Other local measures are used as indicated. Relief of pain is prompt and the healing process is speeded up. One illustrative case is reported.

The Morbid Anatomy of Sprue.

By F. P. MACKIE, V.H.S., O.B.E., M.D., M.Sc., D.P.H., F.R.C.S., F.R.C.P.,

LIEUTENANT-COLONEL, I.M.S.,

and

N. HAMILTON FAIRLEY, O.B.E., M.D., D.Sc., F.R.C.P. (*Indian Journ. Med. Res.*, January 1929, p. 799.)

SUMMARIZING our experience of the eight autopsies under review, we propose to describe in general terms the post-mortem appearances of an advanced case of sprue.

Most of our cases were Anglo-Indians and, owing to the great objection which this class of patient has to post-mortem mutilation, it was not found expedient to remove the brain and spinal cord or to carry out such a full examination of the skeleton as was required to show the complete distribution of aplastic or hyperplastic marrow in the long bones. As we have never met with clinical

evidence of organic disease of the brain or spinal cord or of the peripheral nerves in any case of sprue during life, the omission of these organs from the necropsy would not appear to be a matter of much importance. On the other hand, a limited examination of the osseous system may occasionally lead to erroneous views regarding the real condition of the marrow.

Commentary.

Comparatively little has been written on the morbid anatomy of sprue and many of the most quoted references such as those of Thin (1890), Wethered (1890), Faber (1904) and Justi (1913) have been based on an examination of one or two cases. Faber injected the abdominal cavity of his case with formalin immediately after death and found intestinal ulceration unassociated with atrophy of the gut wall.

On the basis of this observation he explained thinning of the gut wall as being due to distension with gas and atrophy of the mucous membrane as a post-mortem phenomenon dependent on loss of surface epithelium and destruction of villi. Justi in the main supported these conclusions. More recently Faber (1927) has reopened the subject when discussing intestinal atrophy in pernicious anaemia and maintains that when a similar technique is adopted (i.e., the immediate intraperitoneal injection of formalin after death) the signs of intestinal atrophy are absent in this disease also.

The influence of the above-mentioned factors is certainly a matter to be considered and we hope to get an opportunity of investigating the method at subsequent autopsies. Quite apart, however, from the vexed question of thinning of the intestinal wall and its causation, we do not consider that the slow destruction of the epithelium of the mucosa described in our cases can be adequately explained either by meteorism or necrobiotic changes, or by a combination of both factors occurring under tropical conditions.

The most careful descriptions of the morbid anatomy and histology of sprue are to be found in the well-balanced and eminently sane writings of Manson-Bahr (1915 and 1924), whose work should be read in the original. Amongst other things this author rightly points out that cases of sprue which usually come to autopsy represent the terminal condition of the disease, the chronic starvation accounts for many of the late appearances, and that the only hope of discovering the initial and underlying cause depends on studying materials derived from very early cases. He also regards sprue as being primarily a disease of the alimentary tract—a view which we thoroughly endorse.

In addition to intestinal atrophy and nutritional disturbances, we have been impressed with the increase in the hæmolytic bacteria of the intestinal flora and the invasion of the atrophic mucosa with cocci and other organisms. These factors, we believe, result in a state of chronic toxæmia which further increases the aplastic anaemia, glandular deficiencies and other metabolic disturbances described as complicating advanced sprue.

In respect of McCarrison's (1921) researches on the effect of vitamin deficiency as a factor in the production of bowel disease, one of us (F. P. M.) has recently published a paper* on this subject. The condition set up by a complete absence of vitamin C in monkeys produced a state of affairs which cannot be identified with sprue, but that is not to say that subminimal amount of vitamins over a length of time cannot at least contribute to the conditions which we have described in this paper. On this subject we keep an open mind, being well aware from personal observations in Bombay that the incidence of sprue and its distribution in the community are difficult to reconcile with any hypothesis of dietary deficiency unless it be based on decreased absorption rather than deficient intake of vitamins in the diet.

Summary and Conclusions.

(1) The changes in the tongue are those which have already been described by other observers. The mucous membrane is thinned and atrophic and the lingual papillae may disappear. There is desquamation of the epithelial layers and occasional loss of tissue amounting to superficial ulceration with little sign of inflammatory reaction.

(2) The changes in the intestine are most marked in the ileum, but are present to some degree throughout the whole tract. They are chiefly those of thinning and atrophy of the mucous membrane with marked degeneration and ultimately the almost complete disappearance of the absorptive and secretory epithelium. Here, again, the change is one of degeneration and aplasia, and if it is preceded by inflammation there is little evidence of such in the terminal stages of the disease. There is evidence of blood destruction in the mucosa, suggesting the absorption of some hæmolytic substance from the intestine and the destruction of blood *in situ*.

(3) The disposition of micro-organisms in the gut wall favours the view that there is *ante-mortem* invasion by bacteria such as is known to occur in conditions of malnutrition due to vitamin deficiency.

(4) A specific atrophy of cardiac muscle out of all proportion to any decrease explicable in terms of mere starvation was noted in two cases of our series. On the other hand, the depreciation in the weights of the other viscera—notably that of the liver, spleen and kidneys—can be explained on the latter basis.

(5) The liver, kidney and the adrenals sometimes show microscopical changes of a degenerative nature such as might be induced by the action of a toxin. Iron pigment is laid down in moderate amount especially in the liver, but not in the same quantities as characterise pernicious anaemia.

(6) The bone-marrow as seen in the femur or tibia shows in most cases marked aplasia. The red marrow where present is much reduced in quantity, though in two instances there was extensive hyperplasia similar to that seen in pernicious anaemia. A moderate grade of hyperplasia was seen in another case. Such findings suggest that in sprue there is a toxin which primarily stimulates and later leads to the exhaustion of the hæmopoietic function so that in the terminal stages of the disease an almost complete aplasia results. This supposition is borne out by the condition of the blood as seen during life.

(7) These and other studies lead us to believe that sprue is primarily a disease of the intestinal tract which, if progressive, results ultimately in degeneration and destruction of the absorbing and secretory tissues and the production of a condition of slow progressive starvation. The absorption of toxins from the damaged mucosa perhaps associated with actual bacterial invasion, appears to be an important factor in the progressive anaemia and other late manifestations of the disease.

Reviews.

SURGERY IN THE TROPICS.—By Sir Frank Powell Connor, D.S.O., F.R.C.S., D.T.M. & H., Lt.-Col., I.M.S. London: J. & A. Churchill. 1929. Pp. IX plus 293; with 99 illustrations. Price, 12s. 6d.

SIR FRANK CONNOR and the Calcutta Medical College are to be congratulated on this excellent little book, the publication of which is fully justified. It is meant to supplement the teaching of the ordinary textbooks, and the author's objectives, to confine the subject into a reasonably small space, and to present a picture of surgery as practised in the tropics, have been fully attained. The chapters on the surgical aspects of the dysenteries, and of infections caused by parasitic worms and insects, which occupy its greater part are well and clearly written. An excellent account of the various complications of amœbiasis is evidence that much thought and research have been devoted to these affections in Calcutta, while there is a very good description of the puzzling pathology and of the treatment of filariasis. The peculiarities of tuberculosis and syphilis, as met with in the tropics, are concisely and fairly described, and the book also contains a very good account of tropical granulomata. It is a pity that limitations of time and space have not permitted a fuller discussion of the diseases caused by pyogenic and non-pyogenic bacteria and of the influence of diabetes which, more than anything in the tropics, can test a surgeon's capacity. The notes on anthrax (no mention is made of treatment with salvarsan) and on tetanus are disappointingly brief, but we hope to see a more detailed account of these and other surgical conditions in a fuller volume at which the author hints in the preface. The illustrations are many and good, though perhaps the addition of a few more pictures of pathological specimens and slides would have been of great help to the student. The few case reports that are included are excellent, we wish there had been space for more. The book concludes with an interesting appendix of the prevalence of diseases in India, mainly based on a survey attempted by the Calcutta School of Tropical Medicine. Lack of accurate record keeping by any except the larger hospitals in India, render the compilation of such a review extremely difficult, but the tables reproduced give the reader a very good idea of the scope of tropical surgery and complete an extremely interesting and useful volume. The book is very well produced and should prove popular in the medical colleges and schools of the country.

E. W. C. B.

A TEXTBOOK OF MEDICINE.—By Various Authors. Edited by J. J. Conybeare, M.C., M.D. (Oxon.), F.R.C.P. Edinburgh: E. & S. Livingstone, 1929. Pp. XV plus 976 with 16 text illustrations and 8 plates. Price, Rs. 16-14 or 22s. 6d. net. Available from Messrs. Butterworth and Co. (India), Ltd.

THIS latest textbook of medicine by various authors of which Dr. J. J. Conybeare is the editor and part author, aims at steering a middle course between the bulky and at times unmanageable "manuals" or "systems," and the short, snappy and somewhat skimpy synopses. On the whole, it fulfils its avowed mission and it should be popular with students (undergraduate and post-graduate alike) at least in the West. The section on tropical diseases is always the Achilles' heel of textbooks of medicine of Western origin and the volume under review is, to our regret, no exception. It cannot be expected of such a book that it should cover the vast field of tropical medicine even superficially, but such information as it does give should, in our opinion, be approximately accurate and up to date. For example, the statement (on p. 78) that "we have in emetine an absolute specific for amœbic infections" is certainly not true of chronic amœbiasis. Cinchona febrifuge and plasmoquine find no place in the section devoted to the treatment of malaria. The use of tartar emetic in kala-azar, in India at least, is restricted to those cases in

which financial considerations prohibit the exhibition of the much more active pentavalent compounds of antimony; nor is the destruction of bed-bugs as suggested on p. 94 likely to reduce materially the incidence of kala-azar.

The remainder of the book is good, although it suffers slightly from that lack of balance which is almost inevitable where different sections are the work of different hands. The sections which particularly attracted the reviewer were those dealing respectively with renal diseases (a short 50 pages only—but wholly admirable) and with diseases of the nervous system. The short chapter on diseases of infants will be found useful, though possibly in future editions a few paragraphs on ophthalmia neonatorum might be considered.

Printing and general format are good and the price is very reasonable.

J. M. H.

LONDON HOSPITAL LECTURES ON FORENSIC MEDICINE AND TOXICOLOGY.—By the late F. J. Smith, M.A., M.D. (Oxon.), F.R.C.P. (Lond.), F.R.C.S. (Eng.). Third Edition revised by George Jones, M.B. (Oxon.), M.R.C.S., L.R.C.P., D.P.H. London: H. K. Lewis and Co., Ltd. 1929. Pp. XX plus 440. Price, 10s. net.

THIS little volume has taken shape from the lectures delivered to the London Hospital students by the late Professor Smith and has been revised and brought up to date by Dr. George Jones. Essentially designed for students preparing for examinations, the subject-matter has been thoroughly crystallised and condensed. This has not handicapped the book in any way; on the other hand, the author is to be congratulated for the clear way in which he has dealt with the whole subject.

In the first three lectures there is a clear exposition of the principles underlying medical jurisprudence. The medico-legal aspect of the law-court proceedings has also been definitely laid down. This section ought to make a strong appeal not only to students, but also to practitioners who are called upon to give evidence in the law courts. Sub-section IV (Lecture VIII) deserves special mention for it gives a concise and yet an explicit description of the ways of testing and giving opinion on blood stains.

The section on toxicology does not appear to have received proper justice at the hands of the author. Classification of the various poisons is not very satisfactory, and in places important things like administration or absorption of poison through wounds have not been mentioned. Snake-bite has not been included and in the section on poisonous plants many poisonous plants commonly found in India and elsewhere have not been mentioned.

The comparative charts scattered throughout the book and the examination questions appended at the end will certainly make the book extremely useful as an examination manual.

R. N. C.

A TEXTBOOK OF UROLOGY.—By Daniel N. Eisen-drath, M.D. and Harry C. Rojnack, M.D. London: J. B. Lippincott Company. 1928. Pp. 942, with 700 text illustrations and 11 coloured plates. Price, Rs. 31-8 net (42s.). Available from Messrs. Butterworth and Co. (India), Ltd.

ALTHOUGH expressly written for the general practitioner and the medical student, this is really a book of reference for them. The most useful chapters are those on the genitalia and their diseases. The complaints commonly met with in general practice are thoroughly dealt with. The chapters on the vas deferens, spermatic cord, and epididymis are very complete and thorough. The authors also mention that blood-borne infections of the epididymis are not uncommon, contrary to old ideas. The use of heavier type to lay stress on important points is very helpful. The whole subject has been expressed in brief and comprehensible form. This is a book that can well be recommended for the perusal of surgeons who wish to specialise in urology.

S. N. M.

PHYSIOTHERAPY IN GENERAL PRACTICE.—By E. Baillis Clayton, B.B., B.Ch. (Cantab.). Second Edition. London: Baillière, Tindall and Cox. 1928. Pp. X plus 231, with 53 figures in the text. Price, 12s. 6d. net.

THIS book, which is a second edition, includes an extra chapter devoted to ultra-violet light, the faradic and galvanic, sinusoidal, diathermic and high frequency currents.

The author has set himself a difficult task in attempting to explain his subject in 226 pages. That he has not been unsuccessful is obvious from the appearance of a second edition in such a short space of time. The book is one whose perusal would well repay any nurse, medical student, or general practitioner who wants to know something of the subject, for the author has succeeded admirably in giving a general survey of physiotherapy.

It cannot, however, be ranked as a textbook, for to attempt to explain electrical treatment in some 17 pages is obviously not only impossible but absurd. For instance, his definition of a faradic current is "an interrupted current which is induced from a primary to a secondary coil to raise the E.M.F." If this statement were given by an unfortunate first year medical student in his degree examination for physics, it would lead to his rapid discomfiture at the hands of his professor.

However, the main part of the book is devoted to exercises, and this is well done, with many helpful diagrams and photographs of patients actually performing the movements. From this point of view the book can be strongly recommended, for the author deals with several diseases and injuries which a general practitioner is constantly seeing, such as tennis elbow, sprained ankle, rheumatoid arthritis, and constipation, to select a few at random.

Altogether the book is certainly worth reading, and is well written. The paper is good, and the general arrangement of the material, with a good index make it easy to look up quickly any particular subject.

J. A. S.

TROPICAL NURSING.—By A. L. Gregg, M.A., M.D., M.Ch., B.A.O. (Dublin), D.T.M. & H. (Lond.), L.M. (Rotunda Hospital). With a foreword by the Hon. Sir Arthur Stanley, G.B.E., C.B., M.V.O. London: Cassell and Company, Ltd. 1929. Pp. XI plus 199. Price, 6s. net.

ONE cannot speak too highly in praise of this book; it is decidedly the best of its kind which one has read.

Every disease that may be met with in the tropics is well described, with all the symptoms and nursing treatment.

To all nurses, both those trained at home as well as those in India, who intend taking up work here one can heartily recommend it.

E. T.

(Lady Superintendent, Medical College Hospitals, Calcutta).

THE PHARMACOPŒIA OF THE KING EDWARD VII MEMORIAL HOSPITAL, BOMBAY.—Compiled by Abraham S. Erulkar, M.D. (Lond.), with the assistance of the Pharmacopœia Committee of the Hospital. Calcutta: Butterworth and Co. (India), Ltd. 1929. Pp. 101. Price, Rs. 2 (Postage extra). Available from the office of the Dean, K.E.M. Hospital.

THE possession of a pharmacopœia of its own is always a necessity in big teaching hospitals, for it has a twofold object—it not only serves the purpose of a book of guidance and reference for students, but it also materially facilitates the work of the attached dispensary in the way of prompt serving of prescriptions. The publication of the new pharmacopœia of the King Edward VII Memorial Hospital, Bombay, will therefore be welcomed. It has been compiled by Dr. Erulkar, M.D. (London), in collaboration with the Pharmacopœial Committee of the Hospital. The compilation of a manual of this nature is not an easy and straightforward task for it involves both chopping and trimming of age-long prescriptions

and incorporating formulæ of recent origin. Additions of new prescriptions appear to be few and far between, notable amongst which are Mist. Kurchi Liquid and Infusion Granati Radix—both indigenous drugs of reputed merit. The retention of "Injection Sparteine" in the Pharmacopœia will not probably suit the taste of present-day physicians in view of the fact that recent researches have thrown considerable doubt on its pharmacological action. The omissions, on the other hand, of santonin powder with Pulv. Rhei and Scammony, triple carbonate powder of bismuth, magnesium and sodium and inhalation of Tincture Benzoin Co.—all well-known formulæ—will be resented by many. On the whole, however, the Committee deserve congratulations on having managed the whole affair with judgment and consideration.

The chapter on poisons and their antidotes at the end of the book contains much useful and practical information. The posological table containing the official and non-official preparations in the appendix will be welcomed by students as well as by members of the staff for ready reference in cases of doubt. The Gaubius' table of proportionate doses for different ages, the dentition table, the obstetric table, and the table containing approximate food values in grams per ounce of common articles of food are all features of note and special mention.

The interleaving of the book is a good idea. This further enhances its utility as a pocket book and a constant companion of the medicos, both inside and outside the hospital.

The price, Rs. 2, for a pocket size book of 100 pages is a little high. The Pharmacopœia of the Calcutta Medical College, which is of the same size as this, is priced annas thirteen only.

R. N. C.

HEALTH OF THE SCHOOL CHILD.—By Parmanand Ahuja, M.B., B.S. Karachi: Model Printing Press. 1928. Pp. X plus 75. Price, 6 annas.

THAT "the child is the father of the man" is an age-old proverb which, in other words, means that "the nation marches on the feet of little children." There is no doubt about the nation being moulded in the nursery and the school; and therefore books that help in the proper moulding of the nation, or, in other words, in laying the concrete of its foundation, are most welcome to-day. For, we must confess, especially in this country, that the entire science and, we should add, the art of child education and child guidance based on a right understanding of child psychology and child hygiene are as yet but little known, less understood and hardly studied, it being not yet sufficiently realised in practice that the essential conditions of the advancement of any community are character and health—and both these are planned and settled and built up during the formative years of a child's life. Dr. Parmanand Ahuja's "Health of the School Child" is a helpful study in the line indicated by the title and is a welcome publication. The author has given considerable thought to the study of the subject; and this small book of 75 pages covers an extensive ground of useful and thought-provoking suggestions on such subjects as school sanitation; child hygiene; health of the teacher; eye and eye-sight; brain and body; medical inspection of schools, and a criticism of the present scheme of studies. The book is written in a patriotic spirit and in a preacher's racy and eloquent style, largely embellished by quotations and appeals to the feelings. One might have wished to see the chapters more scientifically grouped and arranged; and as it is mainly written for teachers and parents, a few more factors and principles of child guidance could have been usefully introduced, and the subjects more scientifically, and therefore not less eloquently, treated, giving the reasons for the recommendations made. A sudden detailed treatment of the anatomy, and physiology of only one sense organ, the eye, useful and interesting as it is is a little out of proportion to the general treatment of other subjects. But as we have said, we welcome publications in this line to enable and help teachers and parents and the public to pay greater and better attention to this most important subject, the body and mind of the

boy and the girl, and lift their education out of the narrow groove into which it has fallen; and Dr. Ahuja's book is an excellent little popular book for such educational reform. As it is very moderately priced, it should be within the reach of all, and carefully read and digested by parents and teachers who have the welfare of the child and the nation at heart.

D. N. M.

DISEASES OF THE GALL-BLADDER AND BILE DUCTS.—By E. A. Graham, A.B., M.D., W. H. Cole, B.S., M.D., G. H. Copher, A.B., M.D. and S. Moore, M.D. 1929. London: Bailliere, Tindall and Cox. Pp. XV plus 477 with 8 coloured plates and 224 text figures. Price, 35s. net.

THE diagnosis and differential diagnosis of disorders of the gall-bladder and bile ducts within recent years, thanks mainly to the development of the art of cholecystography, has attained to a much greater degree of precision than ever before. The authors of this excellent book have been prominently associated with the newly discovered knowledge of the gall-bladder and their exposition of the subject appears to be, for the moment, the last word thereon.

The opening chapters of the book deal respectively with the anatomy of the extra-hepatic bile passages and with the physiology of the gall-bladder. The discussion on the lymphatics of the gall-bladder beginning at p. 30 is particularly interesting. This section is taken very largely from an important paper by Sudler published as long ago as 1901 and unaccountably neglected by later workers; Sudler's histological work has radically altered our conceptions of the pathology of cholecystitis. The section headed "Experimental Cholecystography" in Chapter II, also calls for special mention. The technique of cholecystography depends on the observation of Abel and Rowntree (first made in 1909-1910) that the phenolphthaleins as a class are largely excreted in the bile. Graham and Cole, the senior authors of the book under review, following up and extending this observation, showed that when phenolphthalein containing either iodine or bromine is injected intravenously into animals or man, it also is excreted in the bile and a sufficient concentration of the halogen is obtained in the gall-bladder to cast a shadow when exposed to the roentgen ray. From this observation, first made in 1924, the science of cholecystography has gradually grown.

The physiology of the emptying of the gall-bladder is fully discussed and a mass of experimental evidence is adduced to support the view that contractions of the gall-bladder muscle are not alone responsible for this phenomenon. The washing out of the organ by the influx of fresh bile from the liver is probably the most important factor in this process.

The chapter on the pathogenesis of cholecystitis is remarkable chiefly for a satisfying refutation of a commonly accepted view, viz., that cholecystitis most frequently arises from "contact infection" of the mucosa of the gall-bladder from the bile. After an adequate discussion of the whole subject, the conclusion is reached that the majority of cases of cholecystitis in man arise as a result of lymphatic spread from a pre-existing hepatitis. This new conception of the pathogenesis of cholecystitis is intimately related to the histological work of Sudler already mentioned.

Space does not permit of more than a passing reference to the authors' work on gall stones: mention should, however, be made of the interesting historical introduction and of the authors' disbelief in the prevalent conception of the outstanding importance of infection in the aetiology of cholelithiasis.

Chapter VII, comprising just over 100 pages, is in many ways the most important in the book for it gives a complete exposition of the subject of gall tract radiology and particularly of that branch of it which is now known as cholecystography. Physiological principles and technique, the substances used and their modes of administration, the interpretation of results and the contra-indications to the employment of this method of investigation are all subjected to a detailed critical

analysis. The fact that no fewer than 108 out of a total of 224 figures are included in this chapter alone, adds still further to the clarification of the subject.

The remainder of the book deals mainly with hepatic function tests and with the surgical treatment of affections of the gall-bladder and bile ducts. With regard to hepatic function tests, the authors conclude: (a) that no individual test can be deemed satisfactory on account of the diverse functions of the liver, and (b) that the dye tests, including chiefly phenoltetraiodophthalein, bromsulphalein and phenoltetrachlorophthalein together with methods of estimating bilirubin (van den Bergh and icterus index tests) are of most value. By using the first named dye, a combination of cholecystography and hepatic function test can be carried out.

The surgical section calls for no special comment. The authors prefer the radical operation of cholecystectomy rather than the more conservative cholecystostomy whenever the gall-bladder shows definite evidence of disease.

In order adequately to criticise this book, a knowledge of the subject equal to, or greater than, that possessed by Dr. Graham and his colleagues is requisite. Even if we did possess this knowledge we should still find our criticisms included in the contents of the book, for the authors do not confine themselves exclusively to their own particular views but give a fair all-round presentation of the various aspects of the subject discussed.

The only flaw that we detected is one for which the authors cannot be held responsible. We cannot claim to have read this book line by line—albeit the interest of its contents merits it—yet despite this fact we found a relatively large number of printing errors. On p. 85, line 19, "though" should be "thought"; the first line of the main paragraph on p. 166 contains a "to" for an "in" while confusion of type in the succeeding 5 or 6 lines makes the context at first sight quite unintelligible. On p. 337 in the third line from the bottom, "and" should be "an," while on p. 339 the reference to p. 334 is confusing—p. 344 is meant. The last named page seems to be particularly unfortunate for in it we also find "reticulo-endothelial" masquerading as "reticulo-endoghelial." On p. 350 (line 6) an unwanted "r" has obtruded itself into the word "obtaining" while on p. 357 (line 25), "is one tube" should be "in one tube" Pp. 388 and 389 are also disfigured, the former containing a "with" instead of a "which," while the latter deprives one of its "patients" of a humble but necessary "S."

That we may not be considered neglectful in any particular let us hasten to add that the indexes—for an adequate recognition of which the authors plead in an extract from a 17th century writer—resemble in their excellence the contents of the book in general.

J. M. H.

AIDS TO PSYCHOLOGY.—By J. H. Ewen, M.R.C.S. (Eng.), L.R.C.P. (Lond.). 1929. London: Bailliere, Tindall and Cox. Pp. VII plus 163. Price, 3s. 6d. net.

PSYCHOLOGY is not a subject that lends itself readily to expression in a condensed form, and the author is to be congratulated on presenting even the bare outlines in the limited scope of 163 pages. The subject is treated on conventional lines and obviously owes much—as the author acknowledges in his preface—to the classical studies of Stout, McDougall, Hart and others. The book has been written more particularly with an eye to the needs of those studying for a diploma in psychological medicine; by such students it will doubtless be found useful as a source of quick revision. The Students' Aids Series, to which this is a useful addition, now numbers 40 odd volumes and deals with subjects as far apart as the analysis and assay of ores, metals, fuels, etc., on the one hand and rational therapeutics on the other.

J. M. H.

INSOMNIA AND DRUG ADDICTION.—By P. C. Collingwood Fenwick. London: H. K. Lewis and Co., Ltd. 1928. Pp. XII plus 56. Price, 2s. net. Paper covers.

In this book the author has given a general survey of drugs of addiction, their symptoms and treatment. The

subject has been put in a condensed and easily understandable form to make the publication useful to general practitioners and medical students. The author has briefly described the effects produced by most of the narcotic drugs used for addiction purposes, including opium, morphine and cocaine.

He gives a few simple methods of treatment for the habits and insomnia caused by the drugs. Although he does not go into details of such treatments as recommended by Lamber Town, Scalet, Pattey and others, his suggestions regarding nursing home treatment are good. The book will be welcomed by medical students especially, who are taught so little about this important subject.

R. N. C.

THE DIAGNOSTICS AND TREATMENT OF TROPICAL DISEASES.—By E. R. Stitt, A.B., Ph. G., M.D., Sc.D., LL.D. Fifth edition, 1929. Pp. XXX 918 with 249 illustrations. London: H. K. Lewis and Co. Price, 31s. 6d. net.

THIS is an old friend in a very new guise. The new edition differs from the former ones chiefly in the absence of the sections in small print, the type being uniform throughout, except in the appendix, and in the thick quality of paper used; consequently in place of the relatively thin volume to which years of use have accustomed us, we have now what is rather a comprehensive and voluminous survey of the whole subject, rather than a student's pocket book.

Dr. Stitt's two well known books have for many years been favourites with students and general practitioners in the tropics. The amount of carefully selected, well arranged, and well indexed information in them is amazing. And the 5th edition of the present volume is much more than a revision; it is almost a re-written work. Special attention should be paid to the author's treatment of yaws, pp. 149 to 173. Here there is a wealth of new illustrations—many of them exceptionally fine ones—an account of the most important experimental work of Schöbl in 1928 on yaws in monkeys, and a review of the possible—if not probable—identity of *T. pallidum* and *T. pertenue*. Fig. 68, after Choisser, shows that yaws may cause severe aortitis, and Fig. 69, after the same author, that it may result in aortic aneurysm. In brief, the position taken up (and one must admit that there is evidence in its favour) is that yaws is infectious syphilis of childhood, and that the Haitian native, who has practically always had yaws in childhood, is protected from syphilis in adult life.

Six new chapters are included in the new edition: on melioidosis; food injuries and vitamin deficiencies; injurious plants; common cosmopolitan helminthic infections; injurious arthropods, fish and coelenterates; and poisonous snakes. The sections on medical and surgical practice in the tropics have been re-written. So also has the section on malaria, where the material has been re-arranged, and recent work on plasmochin and the large volume of new knowledge acquired as the result of the treatment of general paralysis by experimentally induced malaria are reviewed. Yellow fever has been transferred to the section dealing with the filtrable viruses, in accordance with recent experimental findings. In the present edition there is also included an appendix in four sections; an index of clinical diagnosis; laboratory procedures—which is brief but very much to the point; an index of essential laboratory procedures; and a section on tropical hygiene. This is the only portion of the book in small type; it constitutes no less than 241 pages of most valuable matter brought into compact compass. The question of residence of Europeans in tropical climates is fully dealt with.

Turning through the book, one is struck with several new features. First of all, the amount of information included is simply enormous; the work is much more than a manual of tropical diseases; it is an account of all the diseases, both tropical and non-tropical, encountered in the tropics. Secondly, the printing, format, and general get-up of the book are an immense improvement on former editions. Thirdly, the illustrations are of very varied degree; some of the old ones to which we have

been accustomed for years are not too good, and might well be replaced by better ones; on the other hand, the new edition is important for the wealth of new and admirable illustrations included, especially in the sections on yaws, amœbiasis, leprosy, and malaria. (In a future edition we consider it probable that the author will have to go in for a few colour plates, though the present edition admirably illustrates how much can be done with black and white and half-tone illustrations only.) The well known frontispiece of the malaria parasites really requires colour,—and also deletion of the "parthenogenetic macrogametocyte" of *Plasmodium vivax*.

"Stitt" has long been a favourite with medical workers in the tropics. The present edition is a very great improvement on previous ones, and we have no doubt that it will prove extremely attractive to our readers.

R. K.

BIRCH'S MANAGEMENT AND MEDICAL TREATMENT OF CHILDREN IN INDIA. Seventh edition. —By Lieut.-Col. V. B. Green-Armytage, M.D., F.R.C.P., I.M.S. and Major E. H. Vere Hodge, M.D., M.R.C.P., I.M.S. Pp. 482; illustrated. 1929. Calcutta: Messrs. Thacker, Spink and Co. Price, Rs. 10.

THIS is the 7th edition of a very well-known, not to say famous, book. In 1844 Surgeon Henry Hurry Goodeve of the Bengal Medical Service, realising that in India there were many European mothers situated in remote stations far away from any immediate medical aid for their children in the *mofussil*, wrote the first edition, not as a medical textbook or to replace the necessity for skilled medical attendance, but as a household companion and volume to consult in emergencies. The book immediately became a standard work in India, and has remained such for many decades. Four editions followed within ten years, and in 1872 the book was entirely re-written by Brigade-Surgeon Edward Birch, I.M.S. He was Civil Surgeon of Hazaribagh, later Superintendent of the Presidency General Hospital, Calcutta, and later still Principal of the Medical College, Calcutta. Thus his opportunities for observing the ailments of European children in India were almost unlimited, and the book became even more widely popular than it had been before.

In the new 7th edition Colonel Green-Armytage and Major Vere Hodge have not attempted a revision; they have completely re-written the entire volume, which is now expanded to a compass of 482 pages, with several illustrations. The senior author has for many years been especially associated with obstetric work and the diseases of children in India, whilst the specialist knowledge of their brother workers in Calcutta on different lines of work has been fully culled from (and freely acknowledged) by both authors. The result is a work which is authoritative, most eminently practical, and one which will be invaluable not only to European mothers in India, but to educated Indian mothers as well; for it covers a very wide field.

There are no less than 58 chapters in the book, and it is one which it is almost impossible to review. Introductory sections deal with infant mortality in India and the pros and cons of bringing up European children in this country. The mother's health during pregnancy is then fully dealt with, and here full dietetic instructions are given for the expectant mother, based upon the senior author's many years of study of the requirements and conditions. Chapter IV deals with the management of the infant from the day of its birth, and Chapter V with nursing and allied topics. Sections on diet in childhood, artificial feeding of infants in India with special reference to Indian conditions, and dentition and its management follow. A chapter on rickets and scurvy follows, in which the preventive line of treatment is fully detailed. The general hygiene and morbid habits of childhood are next discussed, and there follows a chapter on the modes of spread of the diseases of children. Chapter XIII on the examination of sick children is particularly full and detailed, and may be studied with as much profit by the medical practitioner

as by the mother. The chief causes of fever in children in India are then discussed, and the authors next proceed to a consideration of the principal diseases of children in India.

The senior author lays special stress on *B. coli* infections in young children in India, and considers this condition to be one of the most important causes of obscure fever in such subjects. The common and worldwide febrile affections of children are then considered, and fevers peculiar to the tropics are next dealt with. We are very emphatically in agreement with the authors' recommendation that, after the malarial fever has been controlled by quinine, a course of iron and arsenic treatment should follow; this is essential to build up the damaged hæmopoietic system, and neglect of it may lead to relapses. In brief, use quinine to sterilise the infection as far as possible, then iron and arsenic to build up the body resistance; it is an old rule, and one which all clinicians of experience in India are well aware of. "Quinine for three months" should to-day be replaced by quinine for three weeks, followed by iron and arsenic for one month or longer.

Sections follow dealing with diseases of the nervous system—a most important subject in young children, with diseases of the throat and lungs, and the authors next consider that bane of infantile life—diarrhoea and dysentery. Here the instructions given are admirable, and will enable the nursing mother or the mother of an older child to treat the condition intelligently and even with success in the absence of professional medical aid. "Abdominal pain in childhood" is a well constructed chapter, dealing with the causes which are not important, and contrasting those which are. A consideration of infantile jaundice then leads to a very well written chapter on that mysterious disease of infants in the tropics—"infantile liver." Here the dietetic and hygienic rules laid down are admirable. Diseases of the skin, eye, ear, and local systems are then dealt with, injuries of different sorts and poisons. Even insect stings and snake-bite are discussed. A most useful chapter on the administration of remedies to young children is followed by an appendix on the preparation of special diets and prescriptions for young children.

Undoubtedly the authors have done their work extremely well, and this book is one which every European (and, for that matter, Indian) mother should not be without. It is an invaluable *vade-mecum* for the class of reader to whom it is intended to apply. It emphatically does not attempt to replace resort to skilled professional attendance, which is to-day far more universally available than when its first edition was planned. But to the anxious mother in the *mofussil* it will be a sound and intelligent guide.

Throughout the book on almost every page the authors have resorted to the use of heavily leaded type for important instructions; even in places to leaded capital type. This makes the book one which is very easy to consult. On the other hand, it makes it less readable in general, though the chief value of the book will be as a ready help in times of trouble rather than as a volume for leisure hours.

The authors of this new edition have done their work well, and many an anxious mother in India will find this book a most valuable stand-by in times of distress and anxiety.

R. K.

OBSTETRIC FORCEPS: ITS HISTORY AND EVOLUTION.—By Dr. Kedar Nath Das, C.I.E., M.D., Professor of Midwifery and Gynaecology, Carmichael Medical College, Calcutta. Pp. 903, with 878 illustrations. 1929. Calcutta: The Art Press. Price, Rs. 30; Foreign, £2 2s.

DR. KEDAR NATH DAS has for several years been the doyen of the medical profession in Calcutta, and this admirable and most interesting monograph is what we should have expected of him—erudite, of great historical interest, and with an appeal to a wide circle of readers, to those interested in the history of obstetrics as well as to the practising obstetrician. The compilation of the materials for this book was commenced in 1917; and

some idea of the enormous labour involved in writing it may be gained from the statement that it includes no less than 2,072 references to the literature, from the earliest dawn of obstetric history to the present date. Every possible source of material has been studied and the result is a complete monograph, historical, complete, and noteworthy. Finally, a word of praise should be said with regard to the printing, illustration, and binding of the book, which are all excellent for an Indian press.

The subject-matter of the book falls into six main sections; the pre-Chamberlen period; the Chamberlens, 1601–1818; the 19th century; and the 20th century; together with subsidiary chapters dealing with the classification of forceps, chronological tables of forceps, and the obstetric forceps in allegory, literature, and art.

It is clear from a study of the Ayurveda—1500 B.C.—that the ancient Hindus used two, if not three, instruments for facilitating delivery of a dead fœtus, but all appear to have been intended for dismemberment of the dead fœtus rather than for the delivery of a living one. Hippocrates, of whom a wonderful composite portrait which shows the "father of medicine" apparently in a contemplative mood is given on p. 12, and Soranus of Ephesus both describe instruments for embryotomy, and a traction hook and ring knife are figured on p. 14 from the Naples Museum. Avicenna, 980–1030 A.D., a celebrated Arabian obstetrician of Bokhara, apparently delivered living children with a rudimentary type of forceps, but appears to have more usually used it for embryotomy. Ambroise Paré, 1549, used a rudimentary cranioclast, not very unlike the instrument of the present day. About this time universal resort was apparently had to hooks of different patterns in cases of difficult delivery, with the result that the fœtus was always delivered dead, and usually dismembered. Amand used a net with attached tapes by which traction could be exerted on the head.

The real inventors of the modern obstetric forceps were the family of the Chamberlens, 1602–1818. Of these there were several generations, and the original William Chamberlen with his wife and children were Huguenots who fled from Paris to England in 1569. In Section II of the book, Dr. Kedar Nath Das gives us a most interesting historical account of this family, illustrated with old-fashioned woodcuts. One of them—it does not appear to be certain which of the many in the long family line—invented the obstetric forceps, and the mode of construction and use of this instrument remained a family secret for two or three generations. Hugh Chamberlen, senior, born 1630, mentions this family use of an apparatus for the safe delivery of living children as a family secret. Hugh Chamberlen, junior, 1664–1728, is buried in Westminster Abbey. The type of forceps used by the Chamberlens was the precursor of all present-day instruments; it was for direct traction, with notched handles to fit into one another, the union being strengthened by binding the joint around with tape.

Hugh Chamberlen, junior, visited Holland in 1693, and there appears to have entrusted his secret to a certain Roger Roonhuysen, who at once formed a commercial syndicate for the use of obstetric forceps, and for the next sixty years made money out of it. A certain Rathlaw in 1732 refused to purchase Roonhuysen's secret, but obtained a pattern of the forceps through the agency of a student of the latter, who was present at a confinement attended by Roonhuysen, when the latter was suddenly called away by the burgomaster and inadvertently left his forceps behind him. Rathlaw published a full description of the instrument, whose construction was now no longer secret. Later on he tried to sell the secret to the French, but by that time it was no secret. The lever principle was introduced into the forceps by Jacques de Bruin, a pupil of Roonhuysen's.

Coming to the 18th century, a distinguished surgeon-accoucheur named Palfyn, 1650–1730, appears to have independently hit on the idea of seizing the head of the presenting fœtus with two spoon-like instruments, one applied on either side. He demonstrated the use of this instrument to the Académie des Sciences in Paris in 1723. At first the handles of the two spoons were bound

together by a napkin, but later a mobile hook or ring was employed.

From these beginnings the use of obstetric forceps became universal, and many and repeated improvements were introduced. These are dealt with by Dr. Kedar Nath Das in the main sections of the book. By 1746 medical schools all over Europe were practising with several patterns of forceps, which in general resembled one another, the chief discussion centering around the best method of locking the handles. Levret, 1747, introduced the pelvic curve to the blades. Smellie, 1752, introduced the long forceps with a pelvic curve. It was apparently not until 1840 that the idea of axis traction was introduced into the forceps—by Hermann, and his forceps were such that traction on both the main and the subsidiary handles had to be employed simultaneously. Simpson, 1811—1870, used both short and long forceps. Hubert, 1860, first clearly enunciated the law that the direction of traction must coincide with the line which constitutes the axis of the blades of the forceps, i.e., axis traction; and this was soon followed by the application of "tractors" to the blades of the forceps themselves, especially by Laroyenne in 1875. Tarnier, 1877, appears to have been the first to apply steel tractors with a separate handle to the blades themselves; and it appears to have saved his general practice from ruin. The principle of the traction rods now became established.

Many minor improvements followed; and, as is well known, Dr. Kedar Nath Das has himself devised two types of "Bengal forceps," designed to fit the curves of the average Bengali woman, one a short type, the other with axis traction; these are illustrated and described on pp. 701 and 702. Still later modifications are such as that of Beck, 1916, in which the cephalic portion of the blades becomes mobile by turning a key placed in the bottom of each handle. By this arrangement one or both blades can instantly be either fixed or liberated; and the blades can rarely slip, even when faulty traction is applied.

Appendices in the book deal with measurements of the many different types of forceps described, whilst Section XI deals with the obstetric forceps in allegory, literature, and art. A Polish book on midwifery, published in 1778, shows an angelic *dai* attending a labour case, with a very fat Cupid bringing her a forceps. Laurence Sterne in *Tristram Shandy* has quite a lot of delightful writing about Dr. Slop and his methods of midwifery—here quoted, especially the passage where "my uncle Toby" presented his clenched fists to symbolise the foetus and had them badly bruised by Dr. Slop's application of forceps. Even French political caricature has resorted to the obstetric forceps in illustrating the birth of the Empire.

Truly a delightful and most interesting book, replete, scholarly, well devised, well written, and of very great historical interest.

R. K.

DISEASES OF INFANTS AND CHILDREN.—By H. D. Chaplin, A.M., M.D. and L. T. Royster, M.D. Sixth Revised Edition. London: Baillière, Tindall and Cox. 1928. Pp. XV plus 675, with 10 plates and 184 figures in the text. Price, 30s. net.

THIS book was first published twenty years ago and the appearance of a sixth edition is proof of its popularity and usefulness.

The authors have succeeded in their aim, to present the subject in as compact a form as may be compatible with thoroughness.

The greater part of the book deals with the diseases of infants, and in this section the feeding of infants is described at length with care and accuracy.

An interesting subject is the ketogenic diet treatment of epilepsy in children.

During the last three years 35 per cent. of cases so treated have shown complete cessation of attacks.

The book is very well produced and profusely illustrated. There is little doubt that its popularity will continue.

H. H.

SURGICAL PATHOLOGY.—By C. P. G. Wakeley, F.R.C.S. (Eng.), F.R.S. (Edin.) and St. J. D. Buxton, M.B., B.S. (Lond.), F.R.C.S. (Eng.). Bristol: John Wright and Sons Ltd. 1929. Pp. XVI plus 904, with 382 illustrations, many of which are fully coloured. Price, 45s. net.

Most of the textbooks on general surgery devote a great many pages to pathology, but there are very few books that deal entirely with the pathology of surgical conditions.

In their preface the authors state: "The aim has been to put forward such an account of the pathological side of surgery as may help readers with their clinical work." They have succeeded in this aim and have produced a book which, properly used in the museum, will be of the greatest help to students.

There is nothing new in the arrangement or presentation of the subject.

The greater part deals with special pathology, but a portion necessarily touches on general pathology.

The authors write with a remarkable clearness and the descriptions are concise.

The illustrations are new and extremely good, above all they illustrate accurately the descriptions in the text.

It seems doubtful whether the coloured pictures of tubercle bacilli in pus (p. 70), or of gonococci (p. 88), are necessary in a work of this calibre.

This book should be available in every medical school for reference and for use in the museum. There is no other that can take its place.

It will prove invaluable to all who contemplate sitting for the higher surgical examinations, but we cannot justifiably recommend it as a necessity to the Indian student who is working for a pass degree. He is already overburdened with expensive books.

H. H.

A LABORATORY MANUAL OF PHYSIOLOGICAL CHEMISTRY.—By D. Wright Wilson. London: Baillière, Tindall and Cox. 1928. Pp. 272. Price, 16s. net.

THIS is a revised edition of the book formerly written jointly by the present author and Professor Walter Jones and is chiefly intended as a guide to students for laboratory work. The book is divided into two portions. Part I treats of inorganic constituents such as phosphorus, calcium, magnesium, sulphur, etc., standard acids and alkalis, electrolytic dissociation, colloids, carbohydrates, proteins and fats. All these have been clearly described within the short space of about 46 printed pages, of which 10 pages have been usefully devoted to the discussion of electrolytic dissociation. The student, it is hoped, will get much help from the perusal of these chapters, especially when preparing for examination.

Part II of the book deals with body-tissues and fluids, such as bone, muscle, the cell nucleus, saliva, gastric and pancreatic juices, blood, urine, etc. In the section on quantitative gastric analysis, the author has only described tests for estimating the total acidity and free HCl of strained gastric juice; but in view of the fact that quantitative gastric analysis after a test-meal is thought to be of great value in the diagnosis of peptic and gastro-duodenal ulcers, gastric carcinoma and other allied conditions, we should have liked to see a separate section devoted to a more detailed description of the recent tests (including the fractional test-meal) for these pathological conditions. In the section dealing with pathological urine, the author has described the main pathological items such as albumin, glucose, acetone, aceto-acetic acid, bile and blood. In the case of blood in the urine, the author has only described the old guaiacum test, but the recent tests such as the benzedine and pyramidon tests, etc., have not been mentioned. Quantitative methods of analysis of total acidity of urine, total nitrogen, urea, ammonia, uric acid, creatinine, chlorides, inorganic phosphates, inorganic sulphates, total sulphur, sugar, etc., have all been described and this will be very useful to students. A short section dealing with the detection of the common drugs in the urine, as also the analysis of urinary calculi would have been a very useful addition.

One inconvenient feature of the book which strikes us most is the absence of an alphabetical index which will prove a serious handicap to the reader. We should certainly like to see it supplied in the next edition.

Apart from the few drawbacks mentioned above, the book will prove to be a most useful aid to students in their laboratory work and we would gladly recommend it to them as such.

J. P. B.

Annual Reports.

SIXTIETH ANNUAL REPORT OF THE DIRECTOR OF PUBLIC HEALTH OF THE UNITED PROVINCES OF AGRA AND OUDH FOR THE YEAR ENDING 31ST DECEMBER, 1927. BY LT.-COL. C. L. DUNN, C.I.E., D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH. ALLAHABAD: SUPERINTENDENT, GOVERNMENT PRESS, U. P. PRICE, Rs. 3-8.

As usual, Col. Dunn's report gives a large volume of information regarding public health affairs in the United Provinces.

General Population—Vital Statistics.—The provincial birth and death-rates shown in the report have been calculated on a population of 45,375,787 which is according to the census of 1921 and excludes the population of the Indian States of Rampur, Tehri-Garhwal and Benares.

As stated in previous years' reports, prompt reporting, and the accurate registration of vital statistics are the basis of all public health work, but on account of the illiteracy of the chaukidars, who are the recording agency in rural areas, the figures furnished by them provide but a very rough idea of the state of the public health of the province. In order to improve the existing conditions, various measures are adopted in the districts staffed with rural public health establishments.

The provincial birth-rate for the year 1927, showed an increase of 2.52 over that of the preceding year and of 2.74 over the quinquennial average—the rates for the two years and for the quinquennial period being 36.72, 34.20, and 33.98 per mille of the population, respectively. The provincial death-rate for the year was 22.59 the lowest on record as against 25.10 in 1926 and 25.31, the quinquennial average. The low death-rate is chiefly due to low mortality under the head "fevers." The fall in the general mortality may to some extent be due to under-reporting, but the low death-rate combined with the increased birth-rate clearly points to the healthiness of the year.

The total number of births recorded during the year under report was 1,666,479, giving a birth-rate of 36.72 as against 1,552,054 and 34.20, respectively, in the preceding year. The quinquennial average was 33.98. The highest birth-rate (3.93) was recorded in October and the lowest (2.16) in each of the months of May and June.

The number of males born to every 100 females born was 112.27 or practically the same as in the preceding four years.

The total number of deaths recorded during the year under report amounted to 1,025,075 of which 550,457 were males and 474,618 females, the resulting rates being 22.59, 23.14 and 21.98 respectively. The corresponding figures and rates for the preceding year were 1,138,884; 610,233; 528,651; 25.10; 25.65; and 24.49 respectively. The mean ratio of deaths per mille of population during the previous five years was 25.31. The year's death-rate was the lowest on record.

According to months, the highest death-rate from all causes (2.32) was recorded in June and the lowest (1.64) in March.

During the year under review, the mortality among infants as among adults was the lowest on record. The information so far received from Medical Officers

of Health employed in municipalities shows that out of 949 deaths reported as due to tetanus, 748 deaths were verified by them and only 497 were found to be actually due to this cause. The municipalities of Naini Tal, Mussoorie, Dehra Dun, Hardwar, Bareilly, Moradabad, Agra, Hathras and Jhansi reported no deaths from this cause.

The provincial infantile death-rate of 1927 (151.75) was the lowest recorded. As in 1926, twenty-five districts returned infantile death-rates above, and twenty-three below, the provincial average.

During the year under report, the incidence of mortality among infants was highest in the month of September (25.625) and lowest in the month of March (15.330).

In 1927, the death-rate by classes was 24.05 amongst Muslims, 22.56 amongst Hindus, 6.96 amongst "other classes" and 4.20 amongst Christians.

The total number of still-births registered during the year under review was 14,612 against 13,948 in the preceding year, indicating an increase of 664. Among the districts returning the largest number of still-births Gorakhpur, as usual, easily stood first with 3,524.

The district medical officer of health ascribes this fact to the defective reporting by chaukidars who in a very large number of cases report deaths after child-birth as still-births.

During the year under report, as many as 3,147 deaths (which occurred within the limits of the practice of Government Medical Officers as well as in the medical institutions) were verified by civil surgeons and their subordinates.

By far the largest number of these deaths (2,007) was, as usual, returned as due to "all other causes." Next in order came pneumonia (376), tuberculosis of the lungs (219) and dysentery (181). Tuberculosis of other organs claimed 67 deaths, malaria 61, cholera 50, all other infective diseases 38, and tetanus 35. Enteric fever was responsible for 21, syphilis for 18, and pyrexia of uncertain origin for 17. Deaths from plague, kala-azar, beriberi, rheumatic fever and rheumatism, gonorrhoea, smallpox, influenza and leprosy numbered between 3 and 15. No deaths were recorded under heads relapsing fever and scurvy. Of the 3,147 deaths 400 were among children, 1,996 among adults from 16 to 45 years of age and 751 among adults of 46 years of age and upwards.

In 1927, the vaccination staff tested 703,277 entries of births and 512,057 entries of deaths or a total of 1,215,334 entries, as compared with 1,120,831 in 1926, showing a very satisfactory increase of 94,503. The percentages of omissions discovered in respect of births and deaths were 0.95 and 0.55, respectively.

History of the chief diseases.—During the year under report, cholera was responsible for 28,285 deaths, giving a ratio of 0.62 per mille of the population against 6,166 and 0.13, respectively, in 1926. The mean ratio for the previous five years was 0.38. The largest number of deaths (9,328) occurred in June and the smallest (10) in January.

In eleven districts the mortality from cholera was above the average for the province (0.62).

The year 1927 being a *Kumbh* year it was anticipated that cholera would prevail in the district of Garhwal and the first case which occurred at Bijni Chatti was imported from Hardwar. This was followed by successive outbreaks of cholera on the pilgrim route from which infection was carried into the interior of the district. Altogether 1,102 deaths in the district and 11 deaths on the pilgrim route were reported to have occurred against 5,527 deaths during the last *Kumbh* year; Barahsyun sub-division remained practically free from the disease while only a few sporadic cases were reported from Lansdowne sub-division. Prompt measures were taken to check the spread of the disease and the energetic efforts of the local and provincial public health staffs brought the disease under control. As many as 12,873 anti-cholera inoculations were performed. Leaflets containing simple rules of sanitation and precautions against cholera were also distributed through sanitary inspectors and vaccinators. The

special anti-cholera scheme was continued in the Garhwal district.

The death-rates from cholera in the urban and rural areas in 1927 were 0.29 and 0.65, as against 0.09 and 0.14, respectively, in the preceding year.

The total number of deaths registered from *smallpox* during the year under report was 7,894 against 12,020 in the preceding year, showing a decrease of 4,126. The death-rates for the two years were 0.17 and 0.26, respectively, and the average for the previous five years 0.11. 1,497 deaths occurred among children under one year and 3,308 between one and ten years. The highest number of deaths (1,243) was recorded in May and the lowest (82) in November.

Of the 90 towns, 24 were altogether free from the disease while in 43 the number of deaths did not exceed ten.

The mortality from *smallpox* in urban areas in 1927 was 0.34 per mille of the population and in the rural tracts 0.16 as against 0.86 and 0.22, respectively, during the year 1926.

15,570 deaths occurred from *plague* in 1927 against 57,297 in 1926, the death-rates during the two years being 0.34 and 1.26, respectively. The quinquennial mean was 1.14.

Out of 90 towns, 32 suffered from the disease, the highest mortality being noticeable in Aonla (18.12), Shahabad (11.93), Ujhani (7.24) and Lakhimpur (4.76).

Throughout the year over five lakhs of rats were trapped and killed. In Agra there was a severe epidemic of *plague* from February to May, 1926, and the anti-rat campaign was started for the first time in July, 1926. Both officials and non-officials were doubtful of its success in view of the objections raised by sentimental people. The system adopted in Agra has, however, not only proved effective but highly successful, inasmuch as the endemic foci were eradicated and the most orthodox and sentimental people who would not kill a fly, started catching rats in their own houses. With the exception of Bareilly where a few cases of *plague* occurred in February and March and where the anti-rat campaign was stopped by the municipal board for some months, none of the above mentioned places were visited by *plague*, although in the previous year or two *plague* raged there in an epidemic form.

It is hoped that under the medical officers of health the anti-rat campaign will not only prevent the outbreaks of *plague* but will successfully check its spread in cities if the disease is imported from infected neighbouring towns or districts.

The death-rate from *plague* in urban areas was 0.43 against 2.14 in the last year. In the rural areas it was 0.33 against 1.20.

Fevvers claimed 786,552 deaths in 1927 against 867,939 in 1926. The death-rates for the two years were 17.33 and 19.13, respectively, and quinquennial average 19.31. The largest number of deaths was recorded in June and the smallest in March.

According to the sub-classification, 680,618 deaths were accounted for by malaria, 4,874 by enteric fever, 14,208 by measles, 83 by relapsing fever, 188 by kala-azar and 37,817 by other fevers. These figures are, however, not reliable for the reasons given in previous years' reports.

During the year under review the mortality from fevers in urban areas was 16.19 and in the rural tracts 17.41 as against 18.47 and 19.15, respectively, in the preceding year.

During 1927, the recorded number of deaths from relapsing fever, enteric fever and kala-azar was 108, 6,797 and 203, respectively, as against 716, 10,266 and 151, respectively, in 1926.

Special reports received from the civil surgeons and district and municipal officers of health show that there was no epidemic of *relapsing fever* during the year under report in any district.

A further sum of Rs. 3,000 was paid by the local government as their share of expenses required in connection with the Commission appointed by the Government of India in 1924 to enquire into the origin and

progress of kala-azar and the measures necessary to combat the disease.

During the year under report, only sporadic cases of influenza occurred in some districts.

The joint secretaries of the anti-tuberculosis league, Lucknow, report that during the year under review, the subscriptions paid and promised for the establishment of a special tuberculosis hospital in Lucknow amounted to Rs. 83,649 and the amount actually in hand was Rs. 67,377. Strenuous efforts are being made to raise more funds.

During the year under report the number of deaths caused by *dysentery and diarrhoea* was 12,186 against 12,120 in 1926, the corresponding death-rates for the two years being the same, viz., 0.27. The quinquennial mean was 0.25. May recorded the maximum number of deaths (1,456) while February returned the minimum (506).

Five towns out of 90 are reported to have enjoyed immunity from these causes while in 14 the number of deaths did not exceed ten. This is probably due to defective reporting.

The urban and rural death-rates from these causes in 1927 were 2.14 and 0.13 as against 2.41 and 0.11, respectively, in 1926.

During the year under report *respiratory diseases* were responsible for 29,028 deaths, yielding a death-rate of 0.64. The corresponding figures for the preceding year were 30,260 and 0.67, respectively. The average for the previous five years was 0.60. The highest mortality was recorded in January and the lowest in July.

The urban mortality from respiratory diseases in 1927 was 6.95 and the rural mortality 0.19 as compared with 7.22 and 0.21 respectively, in 1926.

During 1927, deaths ascribed to *injuries* numbered 20,419, as compared to 21,670 deaths in the preceding year. Of these 1,789 were suicides: 13,207 were due to wounds or accidents. Snakes and wild beasts were responsible for 5,031 and rabies for 392.

During the year 1927, 125,141 deaths from *all other causes* were registered as compared with 131,412 in 1926. The death-rates for the two years being 2.76 and 2.90, respectively.

During 1927, deaths from child-birth numbered 1,518 as against 1,817 in 1926.

A scheme drawn up in consultation with the Principal, King George's Medical College, Lucknow, for the establishment of a centre for free treatment of venereal diseases in Lucknow was submitted to government and is under their consideration. Literature on venereal diseases is in the course of preparation by the United Provinces Hygiene Publicity Bureau.

Water Supplies.—Statements indicating the results of the chemical and bacteriological analyses of municipal water supplies for the year 1926-27, were submitted to the Board of Public Health, United Provinces. The results in Dehra Dun, Mussoorie and Muttra were bad. To improve the water supply at Dehra Dun arrangements are in train for installing a chlorinating plant at the source of supply and better results are thereby expected. The Superintending Engineer, Public Health Department, has been asked to make enquiries into the bad results in Muttra and Mussoorie.

Anti-mosquito Work.—Anti-mosquito work in Lucknow was organised by the Provincial Hygiene Institute and the Assistant Director of Public Health (Malaria) in co-operation with the Municipal Board, Lucknow. The students of the D.P.H., L.P.H., and Sanitary Inspector classes were allotted to the various wards and they made a detailed survey of the breeding-places of mosquitoes all over the town and later supervised the weekly oiling of depressions where breeding was taking place.

Research Work.—The research work in *plague and cholera*, which started in 1926 with the help of the Indian Research Fund Association, was continued during 1927.

Plague Research Work.—The inquiry regarding the comparative transmission of *plague* by *X. cheopis* and *X. astia*, to which reference was made in the last year's report, was continued by Dr. A. N. Goyle, M.B., Ph.D., financed by the Indian Research Fund Association at a

cost of Rs. 36,437. The results of his investigation have been incorporated in a paper published in the April number of the *Indian Journal of Medical Research*, 1927, under the title "Comparative Experiments on the Transmission of Plague by Fleas of the Genus *Xenopsylla* (*cheopis* and *astia*) with a Discussion on the Flea-Species Distribution in its Relation to the Incidence of Plague." The experiments as detailed in this paper tend to show that *cheopis* is a much more efficient vector of plague than *astia*; for out of fifty-two experiments in which *cheopis* was used, successful transmission occurred in twenty-five, while under exactly the same conditions only nine out of fifty-two experiments were successful with *astia*.

Cholera research work. *The observation area.*—This year (1927) completes the first year of the existence of the cholera research in the United Provinces carried on by Dr. Saranjam Khan, M.B., B.S., D.P.H. (U. S. A.), D.T.M. & H. (London), and financed by the Indian Research Fund Association at a cost of Rs. 29,409. For the purposes of the inquiry, in order to be able to carry on experimental work in the field, it was desirable to select a suitable area in these Provinces, i.e., an area showing a heavy and persistent infection with this disease. The district of Gonda was selected; this district shows a high death-rate from cholera and has never been free from it for a single year out of the 50 years of available records (1877-1926).

From 25th August, 1927, to the end of November, 1927, a total of 2,631 samples of water were examined. Non-agglutinating vibrios were isolated from 40 per cent. of sullage water, 39 per cent. of tank and lake water, and 31 per cent. of well water.

Sixty-five per cent. of the stools of healthy people showed the presence of non-agglutinating vibrios.

Research work in pilgrim centres.—Research work was carried on with laboratories on the spot in the Dadri fair in Ballia district, the recent Kumbh Fair at Hardwar and the Magh Mela of Allahabad.

Work in Hardwar was started during the middle of the month of February and is still in progress without interruption.

Cinema films on health subjects.—The production of motion picture plays on health topics was continued during the year. The following films were completed:—

- (1) "Why die of Cholera?"
- (2) "A pilgrimage to Hardwar Kumbh Fair, 1927."
- (3) "The Tragedy of Smallpox."

The first was ready in March, 1927, and was first shown at the Public Health Exhibition held in Lucknow in March and then sent to Hardwar, where performances were given during the Kumbh Mela for about one month. Film No. 2 was first shown at Calcutta on the occasion of the 7th Congress of the Far Eastern Association of Tropical Medicine and No. 3 at Lucknow when the delegates to the Congress visited the place on their northern tour.

The charge of the malaria branch was held by Captain D. Clyde, I.M.S., throughout the year. Dr. B. M. Roy acted as senior assistant and Dr. P. N. Chatterji as junior assistant.

Malarial surveys were made of the following places during the year:—

- (i) Banbassa.
- (ii) Kashipur and Bazpur tahsils, Naini Tal district.
- (iii) Certain villages in the Moradabad district.
- (iv) Daryabad, Bara Banki district.
- (v) Khurja town.
- (vi) Bhimtal.

Laboratory work.—(a) In connection with various surveys 2,260 blood films were examined, 311 of which or approximately 13.76 per cent. showed malarial parasites.

(b) 26,991 anopheline mosquitoes were received and classified in connection with a scheme for mapping out the provincial distribution of the various anophelines.

(c) Over 300 "carrier" anopheline mosquitoes were dissected for oöcysts and sporozoites.

Malaria training class.—A class of ten officers of the Public Health Department—four D.P.H.'s and six L.P.H.'s—was given one month's intensive training in malaria and anti-malarial measures.

Colonel Dunn again comments on the defective reporting of cholera outbreaks in the province. The procedure adopted of supplying two service postcards to each *patawari* for prompt reporting of cholera cases proved useful and it is recommended that the scheme be now sanctioned as a permanent measure.

ANNUAL REPORT ON THE WORKING OF THE CIVIL HOSPITALS AND DISPENSARIES IN THE MADRAS PRESIDENCY FOR THE YEAR, 1927. BY MAJOR-GENERAL F. H. G. HUTCHINSON, C.I.E., K.H.S., I.M.S. PRINTED BY THE SUPERINTENDENT, GOVERNMENT PRESS, MADRAS, 1928. PRICE, Rs. 2-12.

THE Annual Report on the working of the civil hospitals and dispensaries in the Madras Presidency has only recently come to hand. The following are some of the more interesting features contained therein.

Number of hospitals and dispensaries.—At the beginning of the year under report there were 959 medical institutions of all classes in the Presidency. One hundred new dispensaries were opened during the year and 21 were closed. Thus at the end of the year there were 1,038 medical institutions in the Presidency, i.e., 69 Government institutions, 27 State Special, 791 Municipal, Local Fund and Kural, 31 Private aided, 68 Private non-aided, and 52 Railway dispensaries.

In-patients.—Patients treated in in-door departments of medical institutions of classes I, III, IV of the Presidency during the year numbered 170,966 against 159,043 in the previous year. The number of in-patients shows an increase of 7.49 per cent. over the number treated in 1926. This rise is due to the opening of several new dispensaries in the Presidency and also to the increasing popularity of the hospitals.

Deaths.—There were 8,500 deaths during the year as compared with 8,052 in the previous year. The death-rate was 4.97 against 5.06 in 1926.

Daily average attendance.—Consequent on the increase in the number of in-door patients, the daily average attendance which was 7,078 in 1926 rose to 8,025 in 1927.

Beds.—There were 4,632 beds for males and 3,717 for females during the year under report, as compared with 4,478 for males and 3,616 for females during 1926.

Out-door patients.—10,452,460 patients sought out-door relief at the various hospitals and dispensaries of classes I, III, IV and VII as compared with 10,059,359 for the previous year. The total number of both in-door and out-door patients treated was 10,623,920 against 10,218,402 in 1926.

The chief diseases treated among the in-patients were malaria, diseases of digestive, generative and respiratory systems. Among the out-patients the diseases most prevalent were those of the digestive system, injuries (general and local), malaria, syphilis (primary and secondary), dysentery, and all diseases of the respiratory systems.

Communicable diseases accounted for 1,377,884 patients with 3,784 deaths in 1927 against 1,371,496 with 3,671 deaths in 1926. The diseases treated in their order of prevalence were malaria, dysentery, syphilis (primary and secondary) and influenza.

Leprosy.—13,368 persons were treated for leprosy during the year. Government are gradually increasing the facilities for treatment aided by the grants from the provincial branch of the British Empire Leprosy Relief Association. The need for extension is also revealed by the fact that 47 pupils attending secondary schools were found by medical inspectors suffering from leprosy.

Gonorrhœa and syphilis.—64,974 cases of gonorrhœa and 85,101 cases of syphilis were treated. In every district these diseases are widely prevalent. The efficient treatment of 85,101 cases of syphilis would cost in drugs alone about 17 lakhs of rupees.

The recommendations of the British Social Hygiene Council's Delegation are under the consideration of Government.

Beriberi.—10,824 cases of beriberi were treated and though every district reported cases, the vast majority came from Guntūr, Kistna, East and West Godāvāri and Vizagapatam. The application of Lt.-Col. R. MacCarrison's studies in nutrition would bear great fruit in these districts.

26,287 cases of pulmonary tuberculosis and 11,215 patients with other forms of tuberculosis were treated.

834,794 patients suffering from malaria attended hospitals. If 100 grains of quinine had been given to each, no less than 11,928 lb. of quinine would have been consumed at a cost of some two lakhs of rupees.

Smallpox.—The total number of patients treated for smallpox during the year was 547 with 25 deaths.

Anti-hookworm campaign.—Anti-hookworm campaign continued to be carried on with the assistance and co-operation of the Rockefeller Foundation of America.

Government and Local Fund hospitals assisted in the campaign and 76,047 cases received treatment during the year.

Of the patient treated in all classes, Hindus were as usual the largest number. Next in order of numerical strength came Muhammadans, others, Europeans and Anglo-Indians. There has been an increase under all classes of patients treated during the year.

The total number of operations performed in all classes of institutions was 428,749 on 422,066 patients. Of these operations, 422,066 were principal and 6,683 secondary. The corresponding figures for 1926 were 453,346 on 441,846 patients. The ratio of deaths per cent. to total operated on works out to 0.27 against 0.26 in 1926. The number of operations returned as "major" during 1927 was 33,363 with 865 deaths and a calculated death-rate of 2.59 per cent. against 29,419 with 842 deaths and a calculated death-rate of 2.86 during 1926.

Labour cases.—In 1927, 50,033 normal and 6,557 abnormal cases were conducted by the staff of the medical institutions as compared with 54,349 normal and 7,501 abnormal cases during 1926. The percentage of death to total delivered was 0.45 during the year.

Private, aided and non-aided institutions.—The total number of in-patients treated in this class of institutions was 21,036 with 702 deaths. There were 763 beds for males and 546 beds for females. The number of admissions for principal diseases was 12,921, 9,531 were cured, 380 died, and 1,767 were discharged otherwise.

Out-door patients.—545,940 patients sought out-door relief at these institutions.

Labour cases.—Two thousand six hundred and twelve labour cases were conducted by the staff of these institutions. The percentage of death to total delivered was 1.7.

Dieting.—The new scales of diet sanctioned for Government hospitals in the Madras City were also introduced into the mofussil Government hospitals.

Medical relief in rural areas.—The year has been characterized by the opening of more rural dispensaries and of transferring certain rural dispensaries to better centres where they would be of more utility to the rural population. The total number of rural dispensaries sanctioned up to the end of 1927 was 337, out of which 306 have been opened. Besides this, 11 rural dispensaries were maintained by the Taluk Boards at their entire cost.

General.—Arrangements were made during the year for the Dental Surgeon of the Government Rayapuram Hospital to afford dental treatment to in-patients at the Government General Hospital, Madras, on certain specified days in the week.

REPORT ON THE WORKING OF THE RANCHI INDIAN MENTAL HOSPITAL, KANKE, IN BIHAR AND ORISSA FOR THE YEAR, 1927. BY CAPTAIN J. E. DHUNJIBHOY, I.M.S., SUPERINTENDENT, INDIAN MENTAL HOSPITAL, RANCHI. PATNA: SUPERINTENDENT, GOVERNMENT PRINTING, BIHAR AND ORISSA, 1928. PRICE, Re. 1-4.

Accommodation.—The total accommodation of this hospital is as follows:—

Male	1,014
Female	272
Total	1,286

Of this, three-fourths are for Bengal and one-fourth is for Bihar and Orissa.

Throughout the period under report, the hospital remained over-congested. The question of providing additional accommodation to relieve congestion is receiving the serious attention of Government.

Patients.—The maximum number resident in the hospital on any one night during the year under report was 1,196 males and 242 females, total 1,438; against 1,172 males and 219 females, total 1,391, in the previous year.

The number of patients resident in the hospital at the beginning of the year under report was 1,170 males and 219 females, or a total of 1,389 of both sexes.

Total admissions.—The total admissions registered during the year were 228 males and 54 females, total 282; against 177 males and 45 females, total 222, (excluding 46 males and 37 females, total 83, who were received on transfer from the Dacca Mental Hospital) in the previous year.

Total re-admissions.—The total re-admissions during the year under report were 11 males and one female, total 12; as compared with 10 (7 males and 3 females) in the previous year. Out of the total re-admissions (12), 9 males were re-admitted after trial as sane under section 471 of the Criminal Procedure Code. Actual re-admissions due to relapses were only two non-criminal males and one non-criminal female.

Cases under observation.—There were 16 cases (15 males and 1 female) under brief periods of observation in this hospital during the year under report, as compared with 5 patients in the previous year, of whom 12 (11 males and 1 female) were ultimately certified and admitted to the hospital. Out of the remaining 4, 3 were released as not certifiable and 1, although certified to be insane, was released by the committing magistrate as he was not dangerous to himself or others and as there is no accommodation in this hospital at present for such harmless cases.

Total population.—1,671 patients (1,398 males and 273 females) were treated in the hospital during the year under report compared with 1,564 (1,323 males and 241 females) in the previous year.

Daily average strength of the hospital was 1,409.53 (1,181.54 males and 227.99 females) as compared with 1,350.66 (1,146.87 males and 203.79 females) in the previous year.

Ratio per cent. of cures to the daily average strength was 15.74 males and 14.04 females, total 15.54; against 8.54 males and 7.36 females, total 8.36 in the previous year.

Ratio per cent. of cures to the total admissions during the year under report was 30.87 males and 13.20 females, total 27.41; compared with 7.41 males and 5.06 females, total 6.78 in the previous year.

Percentage of deaths to daily average strength.—There were 44 deaths (39 males and 5 females) against 52 in the previous year. The percentage of deaths to daily average strength was 3.30 males and 2.20 females, total 3.12; as compared with 4.01 males and 2.89 females, total 3.85 in the previous year; and the percentage of deaths to total admissions was 4.14 males and 1.89 females, total 3.70 in the year under report against 2.31 males and 2.53 females, total 2.37 in the preceding year.

Daily overage sick.—The daily average number of patients treated for bodily ailments was 57.59 males and 7.86 females, total 65.45.

General health of the patients has been good and there was no outbreak of any kind of epidemic disease.

Post-mortems.—During the year under report 40 post-mortems were performed and interesting specimens of brains and other parts were preserved for demonstration purposes.

Accidents and injuries.—Some minor injuries and accidents took place during the year under report but none were serious or worth mentioning.

Escapes.—There was only one case of escape during the year under report against 5 in the previous year. The incident took place while the patient was working outside the hospital in the vegetable garden. He was subsequently recaptured.

Suicide.—There was no case of suicide in the year under report. There were two cases of suicide by hanging in the previous year.

Criminal Insanes.—The daily average strength of criminal patients was 561.16 males and 44.66 females, total 605.82 during the year under report, against 549.04 males and 42.77 females, total 591.81 in the preceding year.

The treatment of the mental condition.—As already reported in the previous year's Annual Report, the treatment received by the patients in this hospital is up to the level of the latest methods employed in all modern mental hospitals.

Hydrotherapy.—Which is one of the most important lines of treatment, could not be carried on extensively as no quiet or secluded place, which is necessary for this kind of treatment, was available owing to over-congestion of the hospital. Nine cases, however, underwent this treatment. The maximum number of hours of treatment a single patient received was 528 and the minimum was 36.

Vigorous efforts were made throughout the year under report to carry out occupational therapy in its various branches and much improvement and success were achieved in this direction. Except old, infirm, and acute cases, all patients are employed in one or other kind of occupation for which enough facilities exist in this hospital.

Recreation.—Patients immensely enjoy the outdoor and indoor games which exist in this hospital. Those who are not able to play enjoy watching the games.

During the year under report the Kanke Dramatic Club entertained patients with two theatrical performances in which some of the patients also acted.

Throughout the year under report musicians were employed to entertain the patients four times a week in the male section and twice a week in the female section.

Feasts were given to all the patients during the Pujah and Holi festivals. Special feasts were given to Hindu, Muhammadan and Christian patients during their respective festivals. Patients' religious feelings and sentiments are respected as far as practicable, and many are encouraged to observe fasts on religious grounds if they so desire and a special diet is arranged for them.

Diet.—The diet of this hospital is worked out with the greatest care as it affects the well-being and happiness of so many people; it is chiefly based on vitamins and caloric values. During the year under report a further scientific survey of the diet was made and it was found that the diet was a little deficient in its fat constituents. To meet this deficiency half a chatak of good ghee per head per diem was immediately sanctioned.

Patients' clothing and bedding.—During the year under report scales of clothing and bedding befitting a modern mental hospital were drawn up and submitted to Government for sanction. It is hoped that the scale may be sanctioned as early as possible.

The destruction of clothing and bedding is becoming markedly less every year, which proves beyond doubt that the patients are becoming more content, better cared for, and less irritable. The destruction is less in spite of the fact that strong, ugly looking, coarse jail clothing was entirely replaced by lighter and more comfortable materials. This observation lends further

support to the argument that the more patients' attire approaches to that of the normal, the more contented they will be, and incidentally less destruction and more economy will result.

Parole.—Dependable and non-dependable patients are allowed to go out daily for their morning and evening walks, the former without and the latter with attendants. The hospital char-a-banc is as usual in great demand by patients for motor drives and shopping at Ranchi.

Cinema.—The claim for a machine as one of the most valuable forms of psychotherapy is undisputed, so much so that a mental hospital without a cinema machine is never considered "modern."

Sanitation.—There was no epidemic disease of any kind either in the hospital or in the staff line, except one case of smallpox in the staff line, the victim being one of the attendants; he was immediately removed to the Ranchi Sadar Hospital and all his contacts were thoroughly disinfected and segregated. Stringent sanitary measures such as vaccination of all patients and staff, etc., were taken.

Nursing staff.—Male nurses for the male section and additional female nurses for the female section have not been appointed yet, and hence there is still a complete lack of nursing in the male section and inadequate nursing in the female section. The sooner this vital question is settled the better.

Attendant staff.—A slight degree of improvement in the standard of work of the attendant staff was noticed during the year under report. Still, much remains to be desired in their work. The attendant staff in charge of the suicidal wards deserve great credit, for it was entirely due to their vigilance that no patient throughout the year under report committed suicide though numerous desperate attempts were made by many potential suicides.

Manufacturing Departments.—The manufacturing departments of this hospital were in full swing throughout the year under report, and goods valued at Rs. 23,000 were manufactured and made over for the use of the hospital by these departments. It must be distinctly understood that the manufacturing departments of this hospital are run purely on a therapeutic basis and not on a commercial basis as in jails, hence a large profit cannot be expected from these departments. The profit made by the manufacturing departments during the year under review was Rs. 13,000, less cost of raw materials.

Captain J. E. Dhunjibhoy, I.M.S., held charge of the hospital throughout the year except during the period 17th to 31st December, 1927, when his duties were performed by Dr. J. Roy.

Correspondence.

HERPES ZOSTER AND VARICELLA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The following case may be of interest, as it points to the close association of herpes zoster and varicella—

A constable of the local police barracks was attacked with typical herpes zoster on 7th March, 1929. Another constable living in the same room in the same barrack and sleeping in the next cot at a distance of only about 3 feet away from the first was attacked with varicella on 30th March, 1929. The herpes zoster patient lived in the same room until the 15th March, 1929, when he was admitted to hospital for treatment.

There have been no cases of varicella in this locality since January, 1928; the locality is a very isolated one, and the second patient had not left the locality since the last week in January, 1929; so that the infection could not have been brought in from outside. The possible source of infection appears to have been the

of herpes zoster who shared the same room as the second patient up to the 15th March, 1929.—Yours, etc.,

BIJOY KRISHNA CHATTERJEE, M.B. (Cal.),
D.T.M. (Bengal).
Assistant Surgeon.

ASSAM BENGAL RAILWAY HOSPITAL,
LUMDING, ASSAM,
21st April, 1929.

INTRAVENOUS PITUITRIN.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With regard to the correspondence from Dr. R. K. Bhattacharjee in your issue for last April regarding the intravenous use of pituitrin, my own experience of this method has been as follows:—

In several cases of malaria when the patients were in an almost moribund condition, I used intravenous injections of quinine bichloride grs. 10 in 10 c.c. of normal saline with 10 minims of adrenalin chloride solution added. The injections were given very slowly at the rate of 1 c.c. per minute.

In several other cases associated with collapse I used pituitrin 1 c.c. in 5 c.c. of normal saline, given slowly at the rate of about 2 c.c. per minute, without having ever noticed any of the untoward symptoms referred to in the correspondence. My practice has been to prepare the normal saline with doubly distilled water, and to stock it in 5 c.c. and 10 c.c. ampoules for ready use in emergency cases. I seal the ampoules on a spirit lamp with a blowpipe. With a little practice this can easily be done in the mofussil.—Yours, etc.,

S. N. GUHA, L.C.P.S.

BINODEPUR, JESSORE,
19th April, 1929.

INTRAVENOUS IODINE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Nature's great gift of iodine is proving so widely useful in the world of therapeutics that it would be helpful if some skilled pharmacologist would undertake a study of its mechanism of action and publish his results. From what has appeared from time to time within the columns of the *Indian Medical Gazette* within the past decade, intravenous iodine seems to be growing more and more popular in the medical world.

The first very valuable article was contributed by Major Porter in 1921, in which he mentioned that it was a proved fact that iodine and iodides produce increased leucocytosis, and that intravenous iodine produces an extremely rapid hyper-leucocytosis, the count rising to almost three times the normal, and remaining raised for some days. Hence perhaps it should be given with great caution and in small doses to anæmic and asthenic patients, and perhaps to none more frequently than once a week. The author recommends a dose of up to 4 grains intravenously, and also mentions a few cases of influenzal broncho-pneumonia treated with iodine given intravenously in saline solution. Normal saline is undoubtedly a better diluent than simple water inasmuch as it counteracts the irritation caused by nascent iodine. With this diluent I gave several injections into my left dorsal radial vein before it became obliterated (subsequently causing much trouble by the extensor tendon slipping away except on very limited movements of the thumb). On the other hand I have seen much harm done to the veins of the arm and ankle by single injections of solutions in distilled water.

The second important paper was that by Colonel Jeudwine in 1923, who described a large number of cases treated, thus adding a good deal to our knowledge of this new remedy. He recommends doses of $\frac{1}{2}$ to 2 grains, diluted to 10 c.c. The greater the dilution, the less injurious and less painful the effect upon the vein; and the thinner the vein, the greater the local trouble caused by the irritant action of the iodine. The saline wash though recommended by this author may perhaps be replaced by dissolving the iodine in saline.

As regards reaction, it is usually mild. In febrile cases, such as pneumonia, it raises the temperature by a degree or two. In my own case, after my blood (or system) had become rather saturated by a number of infectious, an injection of gr. 1 in 5 c.c. of distilled water was followed by disagreeable iodism (pains in the joints and muscles, lasting a few hours). With a subsequent injection of gr. $\frac{1}{2}$ in 5 c.c. only very mild iodism appeared in the nose and throat. (This in fact is the place where iodism, if it ensues, is first felt within half an hour of the injection. Next the effect is seen in the urine which appears to contain more solids, to have a high colour, and to produce irritation on micturition.) Weakness was felt after every injection for some three days, especially after the later injections. Reaction seems to depend upon idiosyncrasy.

In 1925 it was recommended that adrenalin chloride solution, 10 minims per dose, should be added to the injection. This seems to be a good corrective, whether the action of the iodine be a direct one or an indirect one through the thyroid. In tuberculous cases the use of this remedy, alternating with injections of 3 per cent. sodium morrhuate solution, seems reasonable in cases with a temperature not exceeding 100°F. Sodium morrhuate seems to act best in afebrile or only slightly febrile cases, and not to be suitable for acutely febrile ones.

In a past number of the *Antiseptic* the hypodermic use of 5 per cent. "glyceriodine" is recommended, the author stating that this is as good as intravenous iodine. I have tried these injections on myself, and found: (i) that the solution was too thick to pass through the needle except when it was quite warm; (ii) that the burning which it causes is indescribable. I therefore diluted it with saline, but the smarting produced was still quite enough to make any patient who is not paralysed dance with pain. I then diluted the preparation first with an equal part of glycerine, and then with an equal part of normal saline at the time of injection. This injection is tolerable, the pain only lasting for a couple of minutes, and being limited to the site of injection. I have used this solution in cases for several weeks, viz., a 2½ per cent. solution of iodine in glycerine, freshly diluted with an equal part of normal saline just before injection, in doses of from 0.5 to 2 c.c., i.e., gr. $\frac{1}{4}$ to gr. 1 of iodine. Beneficial it is undoubtedly, but more than gr. 1 of iodine cannot be administered readily or conveniently by this method. The 2½ per cent. solution of iodine in glycerine also differs in colour from the "5 per cent. glyceriodine"; it is darker in colour than the latter.—Yours, etc.,

M. ASLAM OMAR, L.M.P. (Agra).

GONDA, UNITED PROVINCES,
15th April, 1929.

MEDICAL SCIENCE IN INDIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Colonel Gill's lecture delivered before the Punjab branch of the British Medical Association (reported as a "special article" in the *Indian Medical Gazette* for March 1929) is interesting from several points of view. He has attempted a comparative description of the development of medicine in the East as well as the West, a subject of extreme interest to every student of medicine. His opinion of early Indian medicine, the medicine of Charak and Sushrut, is refreshing, being entirely free from the ordinary bias and prejudice of the average foreign writer and critic on the subject at the present day. He has rightly stated that the medicine of India at the time of Charak and Sushrut was permeated with "the scientific spirit" as shown by "a desire, by observation and experiment, by induction as well as by deduction to prove the secrets of Nature and to build thereon a rational system of medicine." No doubt it is "worthwhile to take stock of the situation, to trace the history of medical science in India and, having then clarified our ideas in regard to the past, to consider briefly the present and the future."

But while tracing the history of medical science in India, certain mis-statements have crept in, in his otherwise interesting lecture and this is not unnatural, considering that there is no comprehensive authoritative history of the development of medicine in India, which has yet to be written.

Some of these mis-statements are as follows:—

(i) To what extent the Aynurvedic system was influenced by Greek thought and vice versa is not certain, but there is some reason to believe that each borrowed from the other. (ii) It is more than probable that the scientific spirit reached a higher stage of development in Greece than elsewhere. (iii) Demonology and the debased system of magic and spells overwhelmed and crushed the pure science that flowed from the spring of Sushrut at a very early period of Indian Medicine.

(i) *The influence of Greek thought on Indian Medicine.*

The priority of Indian over Hellenic civilization has been admitted by several distinguished European scholars writing on the subject; e.g., Schulze in his *Historic Medicine*, Royle in his *Antiquity of Hindu Medicine*, Wise in his *Commentary on the Hindu System of Medicine*, Professor Wilson in the *Oriental Magazine*, A. Soma de Koros in the *Journal of the Asiatic Society of Bengal Transactions*, Heins in his *Tracts of India*, Hoernle in the *Bower Manuscript*, Max Muller in his work on *Hindu Wisdom*, Maedonnell in his *History of Sanskrit Literature* and other reputed orientalists.

We hear of Greek philosophers visiting the East: e.g., Paracelsus who owed his inspiration to India (Schroeder in his work *Pythagoras und die Inder*—quoted in Sir P. C. Roy's *Hindu Chemistry*) and actually visited India (Elliott's *Greek and Roman Medicine*); Hippocrates who owed his medical knowledge directly or indirectly to India (Castellani and Chalmer's *Tropical Medicine*). India was visited by Pythagoras, Anaxarchus, Pyrrho and others who afterwards became eminent philosophers in Greece (*Brucker's Philosophy by Infield*). From Pliny we learn that Pythagoras, Empedocles, Democritus, Plato, Ithales, Crates and Endoxus and others are stated to have travelled in the East (quoted by Royle).

On the other hand "we never hear of Hindus travelling for knowledge beyond the precincts of their own country." Sir William Jones has affirmed it "as improbable that the Brahmins should have borrowed from other nations, specially the Greeks, whom they despised as 'yavanas'—while in astronomy the Hindus borrowed from the Greeks which they distinctly mentioned. As far as medicine is concerned we find nothing mentioned anywhere about their borrowing from the Greek Scholars (*yavana acharyas*).

"The period of Ctesias and Hippocrates is at least a century prior to the time when there seems to have been considerable mental activity with cultivation of literature, amongst all the nations of the East. Then Buddhism rose in India, Pharaoh Neehao reigned in Egypt, Zoraster flourished in Persia, Confucius in China"—Charak and Sushrut as we shall show later on flourished long before the Buddhistic period of Indian history.

Egyptian civilization is considered as much earlier than Hellenic. Royle has taken great pains to prove that Egyptian and Hindu civilization were contemporaries. Sir William Jones had stated that in the *Purans* (which came after the *Vedas*) we shall in time discover all the learning of the Egyptians. Sir P. C. Roy in his *Hindu Chemistry* has shown the close analogy between the *Atharva-veda* and the *Papyrus of Leyden*. Both deal mainly with "charms, spells, magical incantations and amulets," Hindu civilization was therefore much earlier than the civilization of the ancient Greeks.

We may therefore conclude that Hindu civilization was much earlier than the Hellenic and was probably contemporary with Egyptian civilization. Egypt was called the *Misra-desh* by the ancient Hindus. The priority of Hindu civilization, the "superiority complex" idea of the Brahmins (the educated section of the ancient Hindus) who used to hate every foreigner as *yavana*, the absence of any authentic record of Hindus

going outside India to learn the wisdom of foreign lands, the fact that early Greek Scholars visited the East, including India, and lastly that Hippocrates flourished much later than Charak and Sushrut—all these facts conclusively prove that *Ayurved was not at all influenced by ancient Greek thought*.

There is apparently some resemblance between the two systems of medicine. Both are based on their "physical philosophy" and their "humoral theories." On making a comparative study we find that "the analogy is more superficial than real" as the following will show:—

Physical philosophy of the Greeks.

The original of all things is the *monad*. From the *monad* sprung the *duad*. From the infinite *duad* arose the world. Everything in the world is composed of four elements, viz., earth, water, fire and air (Pythagoras).

Physical philosophy of the Hindus.

The origin of all things is *purush*. From *purush* arose *Prakriti*. From *Prakriti* arose the world.

Everything in the world is composed of five elements, viz., earth, water, fire, air and ether.

Aristotle was the only Greek philosopher who conceived of the existence of five "elements" like the Hindus. He must have borrowed the idea directly or indirectly from the ancient Hindus. In Greek medicine however only the four "elements" are recognised.

Humoral theory of the Greeks.

There are four humours, viz., black bile, yellow bile, blood and phlegm. There are three airs or vapours, viz., in the chest, in the head, and in the abdomen.

Humoral theory of the Hindus.

There are two humours, viz., *pitta* and *kaphya*. There are five airs or vapours, viz., in the head, in the neck, in the chest, in the upper abdomen, and in the pelvis.

This is of course no place to discuss whether the so-called humours are really humours or hormones, as Dr. Brock in his book, *Galen on Natural Faculties*, considers them in the case of Greek medicine, or as Indian Scholars consider them in the case of Hindu medicine. Further, the so-called "airs" or "vapours" in both the systems are nerves and their forces, or otherwise (*vide* the writer's article on the subject in the *Indian Medical Gazette*, February 1923).

The writer is strongly of opinion from the internal evidence mentioned above that in the very early days Greek medicine was not much influenced by Hindu thought as well. It is very likely that the ancestors of the entire human race, when they migrated from Central Asia carried the germs of medical truths like humours, airs, etc., with them in their migrations. So far as India is concerned the fact is corroborated in finding the rudiments of the humoral theory in the *Rig-Veda*. Later on each nation developed its physical philosophy and humoral theory according to its racial genius.

Considering from internal evidence that the analogy between the two systems is more superficial than real and does not seem to bear a close examination, we cannot but fall back on the "theory of common origin and independent parallelism of growth" of those systems of the Greeks and the Hindus and that there was no borrowing by either. The same conclusion has been independently arrived at by a great European orientalist—Goblet d'Alviella in his *Classical influence in literary and scientific culture in India*, *Bulletin de L'Academie Royale de Belgique* (quoted in Sir P. C. Roy's *Hindu Chemistry*).

(ii) *The Scientific Spirit reached a higher stage of development in Greece than elsewhere.*

In this connection Colonel Gill made a slight mistake in confounding Charak the physician with Sushrut the surgeon.

To discuss this point we must state in brief the development of Ayurved, during successive periods:—

(a) *The Vedic period (4000—2500 B.C.).*

This is the "primitive" and "mystic" period of development of Hindu medicine. The art of medicine

consisted of the use of a few simple herbals. *Rig-Veda* (primitive period) deals mainly with charms, spells; magical incantations, amulets, etc., in a later *veda*—*Alharva-Veda* (mystic period).

(b) *The Ayurvedic period* (2500—600 B.C.).

This consists of two periods, the "philosophic" period of Charak and the "anatomic" period of Sushrut.

During this period great wars were fought as described in the two great epics of *Ramayana* and *Mahabharat*, when surgery reached its acme in India.

According to Dr. Muthu (*Brief Survey of the Antiquity of Hindu Medicine*) in this period which he calls the "epic period," there were "distinguished surgeons on the staff of the contending armies. The army surgeons were fully equipped with every necessary medical and surgical appliances, regularly accompanied the army in the field and undertook both minor and major operations."

Another outstanding figure later on in this period was Vagbhatta who epitomised the medical knowledge up to his time in his *Astangahrudaya* (making copious extracts from Charak the physician and Sushrut the surgeon), as Hippocrates had done from Egyptian and ancient Greek medicine. His masterly treatise became so very popular in Southern India, "that the very names of Charak and Sushrut were forgotten in many parts of the Deccan" (Sir P. C. Roy's *Hindu Chemistry*).

In comparing Hippocrates and Vagbhatta it must be noted that while in the treatise of the latter there is little original, the writings of the former are full of original ideas, for with him ancient Greek medicine entered the "philosophic stage and thus he was aptly called the 'Father of medicine in the West.'"

(c) *Buddhistic period* (600 B.C.—600 A.D.).

This period is gradually marked by the restriction of dissection and the decline of anatomy, as a result of the tenet of *ahimsa* (non-injury to man and animals) of Buddhism. "As a result both surgery and midwifery declined; the former was left in the hand of the village barbers and the latter in the hand of the village *dhais*."

But this period "marked the revival of medicine and chemistry, which were taught in the world-famous universities of Nalanda, Taxilla, etc. During the reigns of Chandragupta and Asoka, hospitals for men and animals were more extensively provided."

During this period chemistry, which developed in India "as a handmaid of medicine," was increasingly studied, and mineral and metallic drugs were increasingly used.

During this period the central figures were the famous physicians and alchemists Patanjali, Nagarjuna, Nandy and others.

It is ridiculous to believe that during this period "when there seems to have considerable mental activity with cultivation of literature amongst all nations of the East," marks according to Colonel Gill the decline of the "scientific spirit" of research and enquiry in the domain of Indian medicine. For this is the period of Buddha in India, Zoroaster in Persia, and Confucius in China.

During this period, a century after Buddha, Hippocrates flourished in Greece. His knowledge of medicine bears close analogy with that of Indian medicine at the time handed down since the days of Charak.

We find that medicine is based on physical philosophy and theory in both countries.

The recipes were simple, consisting of a few simple herbs and occasionally an admixture of readily available minerals.

(In fact the knowledge of the use of metallic and mineral drugs did not advance as much in Greece as it did in India, for the Arabs who learnt medicine mainly from the Greeks did not advance beyond this stage in the use of minerals as did the ancient Hindus.)

Further we find a close analogy of the knowledge of some departments of medicine, e.g., personal hygiene (compare air, water, site, of Hippocrates) prognosis, examination of the patient, dietetics and so forth in both systems.

(d) *The Transitional period* (600—1100 A.D.).

The period marks "the parting of ways in the progress of Hindu medicine. Hitherto it consisted of simple

recipes of vegetable drugs with a few readily available products of the mineral kingdom" handed down from Charak.

"With the advance of knowledge of medical chemistry, more metallic and mineral drugs were used and their claims could not be ignored."

Accordingly we find two schools of physicians, one belonging to the older school of Charak using mainly vegetable drugs, and those belonging to the new school using more mineral and metallic preparations.

Of the two outstanding figures in these periods one is Vrinda, whose work *Siddha-yoga* describes the bold use of preparations of minerals (metals and non-metals). He is probably the father of the *Siddha* branch of Ayurved of Southern India and Ceylon. It may be noted that in the South we find two classes of Ayurvedic physicians, *vaidys* proper and those who follow the *Siddha* system.

The other is Chakradutta who in his book quoted from the pathology of Madhah the medicine of Charak and the *Siddha-yoga* (metallic and mineral preparations) of Vrinda. The work of Chakradutta became so famous that it became the textbook of medicine of Bengali Ayurvedists.

(e) *The Tantrik period* (1100—1300 A.D.).

Buddhism had been expelled from India and there was a revival of the Brahminical cult of a distinctly lower order.

The simpler religion of Nature—worship of the Vedas, the high metaphysics of the Upanishads were lost and India wanted to have a royal road to nirvana (salvation). The cult of *Alharva-veda* was in the ascendant and medicine degenerated into "magic and spells." Dravidian civilization mixed with non-Aryan; superstition prevailed everywhere, specially in the East coast of the Peninsula, from Bengal to Madras, the home of the Tantrik cult. Demonology became triumphant for the time being. Alchemy was at its height and exaggerated claims were made about the efficacy of metallic and mineral drugs. A combination of mercury and gold was found to be the elixir of life. Religion degenerated into certain forms and conventions.

People began to believe that "man could intimately know the 'absolute' by a faculty called 'ecstasy' (partial suspension of animation). It was a combination of philosophy and religion and covered a good deal of mysticism, magic and spiritualism." The followers of the system became believers in some exercises, which later on developed into "*Hata-yoga*, Tantrik exercises" of the Hindus.

They entered as Kingsley wrote in another connection "the fairy land of ecstasy, clairvoyance insensibility to pain, mesmerism, *samadhi* (suspension of animation, complete and voluntary, of which we have authentic records)—"these modern puzzles used successfully by those bygone seekers of wisdom."

Even this dark age was not without its silver lining. The "scientific spirit" of research was not absolutely lost. During this period the study of the pulse began, though the ancient Hindus had had some idea of the "circulation" in the days of Charak and Mahabharat.

During this period the nervous system was intimately studied anatomically, physiologically, and metaphysically. The importance of the sympathetic system in relation to organic action and the brain as the seat of higher intellectual and metaphysical functions were recognised. Certain exercises (*hata-yoga*) were devised to control the involuntary sympathetics, by which the organs could be controlled at will and the state of *samadhi* attained. (For details *vide* the writer's article on the "Nervous System of the Ancient Hindus" read at the *All-India Medical Conference*, Calcutta, December 1928.)

During this period medical chemistry was advanced and its study continued.

(f) *The Iatro-chemical period* (after 1300 A.D.).

"During the Tantrik period, a vast mass of chemical information was accumulated, which was pressed into signal service during this period. The fantastic and exaggerated and extravagant ideas, impossible of realisation of the former period were recognised and had subsided into something more practical and tangible."

"The numerous preparations of mineral drugs, though they could not secure immortality or revive the dead, were found to be helpful accessories in medicine." At first they came to be cautiously used and tentatively mixed with herbal recipes, but they soon began to assert their supremacy.

The two schools gradually blended into one, the present Ayurved where mineral and vegetable drugs are used in the same recipe. Gradually it was recognized that the simple vegetable drugs are useful in simple and acute forms of diseases. The more complicated sub-acute cases yielded more readily to a combination of both. In chronic cases where the *dhatu*s or tissue systems and organs are not merely functionally affected, the *dhatu*s or minerals (mark the same word *dhatu* means both tissue and mineral) gave better results.

Among the outstanding names of this period we find Sarangdhar, whose treatise shows a blending of both the schools of treatment.

(g) *The later Mahomedan period.*

This marks the real dark age of Ayurved, with the consolidation of the Mahomedan period with their own system of medicine. Ayurved was deprived of State-aid and State-recognition and gradually declined.

But though Ayurved was deprived of State-aid and recognition, it did not lose the patronage of the Hindu zemindars and Hindu princes, as well as of the mass of the Indian population. The torch of Ayurved was kept lighted by the *raids* in tolls. The facility of independent systematic enquiry and research, the scientific spirit declined and we find only occasional research workers on Ayurveds during this period, like Bhava Misra of the United Provinces whose book became so famous as to become the textbook of Ayurvedists in Northern India. This is the best systematic treatise on Ayurved at the present day and is known as *Bhava-prakas*.

In Southern India where Mahomedan influence was least felt, the researches into chemistry continued and several books on mineral drugs known as *Rasa-granthas* were published from time to time by the *Siddha* school of Ayurvedists. Besides oxides and carbonates of minerals, tinctures were prepared (vide *Arka-prakas* from Ceylon).

Colonel Gill is therefore not correct when he says that the scientific spirit was more highly developed in Greece than elsewhere, meaning India of course; neither is he correct when he says that the "scientific spirit" which flowed from the fountain of Sushrut subsided soon afterwards and that Indian medicine was early dominated by demonology, sorcery, witchcraft, magic and so forth.

Conclusion.

A history of the development of Hindu medicine will have to be written by Indian scholars and impartial foreign orientalists. With the beginning of the present century, a wave has spread over the civilized West decrying the originality and antiquity of Indian medicine, which was unreservedly acknowledged by their predecessors up to the third-quarter of the last century. There are, however, a very few honourable exceptions.—Yours, etc.,

HAZARIBAGH,
27th March, 1929.

A. T. ROY, I.M.S.

THE TITLE OF "DOCTOR."

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I would be very much obliged if you will very kindly give me the benefit of your opinion in the following matter:—Would an assistant surgeon of the I.M.D. holding the qualification M.R.C.S. (Eng.), I.R.C.P. (Lond.), be considered wrong if he called himself Doctor in the commonly accepted meaning of the term, viz., medical practitioner, physician, etc.? By doing so he by no means infringes the by-laws of the Royal College of Physicians.

The prefix "Dr." I understand, is extended as a matter of ordinary courtesy to any medical practitioner, at least in this country, and, furthermore, I believe is even authorized by Government for Civil Sub-Assistant Surgeons.

Before I took out the above diplomas, I was always addressed as "doctor" and exception was never taken to this on my name-board.

What about the host of Indian practitioners who do not hold registrable English medical qualifications? Can they be commanded to remove the prefix "Dr." from their name-boards?

Finally, would a layman who had insulted a practitioner holding the said qualifications by telling him he was no more a doctor than the layman himself, come within the grip of the Law, in so far as the accepted meaning of the term goes, viz., medical practitioner or physician?

This I might remark is a question of immense interest for many men of the I.M.D. and an unbiased opinion from yourself would be very welcome.

During my residence in London I personally observed several medical practitioners holding only the qualification of the conjoint Medical Board, employ the prefix "Dr." on their name-plates and I am sure if this were irregular, the General Medical Council of Great Britain, who exercise constant watchfulness in these matters would have taken some action.

Thanking you very much, Sir,—Yours, etc.,

B. J. BOUCHÉ, M.R.C.S. (Eng.),
I.R.C.P. (Lond.), I.M.D.

SINGAPORE,
13th May, 1929.

(Note.—The point referred to by our correspondent is one which has been raised from time to time in our columns. Strictly speaking, the term "Doctor" should be reserved in medical practice for those persons with a registrable M.D. qualification. In connection with the publication of papers in medical journals it is better to limit the title to such persons, as here the readers addressed are professional men who are in a position to judge the professional status of the writer concerned.

In general practice in India, however, we believe that it is customary to use the title "Doctor" for all qualified medical men with a registrable degree—whether in the United Kingdom or in India. We see no harm in this general practice, since it serves to distinguish such men from unqualified quacks and the exponents of the indigenous systems. In England an F.R.C.S. would be horrified at being addressed by any other title than "Mr."; but in India we have known men with this specialist qualification deliberately to call themselves "Dr." in order to inform the layman that they belong to the medical profession.

The whole question is one of custom and usage. In medical publications we consider that the term "Dr." should be strictly reserved to those who have an M.D. qualification; but, in general usage and in lay papers and newspapers, we see no harm in differentiating a registrable man with a registrable medical qualification as "Dr."—EDITOR, I. M. G.)

EDUCATIONAL CINEMA FILMS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—Several newspapers in India have published notices about the existence of the Scientific and Educational Film Society which has been registered in Calcutta under Act XXI of 1860 as an educational body having no lucrative object but having for aim to put at the disposal of all schools and colleges in India a series of 20 scientific and educational film shows per year.

In Bengal our attempt to introduce this powerful educational factor has proved successful by the fact that 50 schools have our educational film shows regularly.

We have therefore decided to extend our work over the whole of India and as we obviously can supply our films to only a limited number of schools it will be necessary to establish branches having their own films and outfit all over the country.

To enable us to bring this decision to the notice of the public, we would be very grateful if you would be so good as to afford us some space in your esteemed paper, and would render us your kind co-operation in our scheme.

The establishment of a branch of the Society will involve a small necessary capital for purchasing films, machines, and the necessary outfit, and as the Society has been registered under the above Act, we will require the assistance of public-spirited citizens interested in education to help our project to materialise.

I would therefore propose that a committee of influential people be formed locally who would have the interests of our work at heart. The necessary funds should be raised locally from voluntary donations or subscriptions.

Trusting in your co-operation,—Yours, etc.,

R. G. A. ALGOËT,
Managing Director,
The Scientific and Education
Film Society.

20, HARRINGTON MANSIONS,
CALCUTTA,
27th April, 1929.

Service Notes.

APPOINTMENTS AND TRANSFERS.

COLONEL J. W. D. MEGAW, C.I.E., M.B., V.H.S., I.M.S., Officiating Surgeon-General with the Government of Madras, is appointed permanently to that post, with effect from the forenoon of the 3rd April, 1929.

Lieutenant-Colonel E. H. V. Hodge, M.D., M.R.C.P., I.M.S., Civil Surgeon, Chittagong, is appointed to act as Civil Surgeon, Darjeeling, *vice* Lieutenant-Colonel T. L. Bomford, transferred, with effect from the 19th April, 1929.

Lieutenant-Colonel T. L. Bomford, M.D., I.M.S., Civil Surgeon, Darjeeling, is appointed to act as Professor of Medicine, Medical College, Calcutta, and First Physician to the College Hospital, with effect from the 22nd April 1929, *vice* Lieutenant-Colonel J. D. Sandes, granted leave.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's Personal Staff, with effect from the 1st May, 1929:—

To be Honorary Surgeon.

Lieutenant-Colonel W. M. Houston, M.B., Indian Medical Service, *vice* Brevet-Colonel F. P. Mackie, O.B.E., M.D., F.R.C.S., F.R.C.P., K.H.S., Indian Medical Service, vacated.

Lieutenant-Colonel G. M. Millar, O.B.E., I.M.S., an Agency Surgeon, is posted as Civil Surgeon, Ajmer and Chief Medical Officer in Rajputana, with effect from the 29th April, 1929.

Lieutenant-Colonel H. M. Maekenzie, M.B., I.M.S., Officiating Inspector-General of Civil Hospitals, Punjab, is appointed permanently to that post, with effect from the forenoon of the 3rd April, 1929.

Lieutenant-Colonel L. Cook, C.I.E., M.B.E., F.R.C.S., I.M.S., Civil Surgeon, Patna, is appointed, with effect from the 20th May, 1929, to officiate as Inspector-General of Civil Hospitals, Bihar and Orissa, *vice* Colonel W. S. Willmore, M.D., M.R.C.P., I.M.S., granted leave preparatory to retirement.

Lieutenant-Colonel J. Husband, I.M.S., an Agency Surgeon, is posted as Residency Surgeon and Chief Medical Officer in Baluchistan, with effect from the 12th April, 1929.

The services of Lieutenant-Colonel H. Stott, O.B.E., M.D., I.M.S., are placed permanently at the disposal of the Government of the United Provinces, with effect from the 28th November, 1922.

Lieutenant-Colonel J. S. O'Neill, I.M.S., Civil Surgeon, from Meerut to Bareilly, *vice* Lieutenant-Colonel E. C. Hepper, I.M.S., granted leave.

Lieutenant-Colonel W. D. Wright, I.M.S., Civil Surgeon, from Gorakhpur to Allahabad, *vice* Lieutenant-Colonel H. R. Nutt, I.M.S., Civil Surgeon, granted leave.

Lieutenant-Colonel A. Cameron, O.B.E., I.M.S., Civil Surgeon, from Aligarh to Agra.

The services of Major H. H. Elliot, M.B.E., M.C., I.M.S., an Officiating Agency Surgeon, are placed at the disposal

of the Government of India in the Department of Education, Health and Lands.

Major H. Caldwell Tait, M.B.E., I.M.S., Military Medical Officer, Roorkee, to be the Civil Medical Officer of Roorkee, in addition to his own duties, *vice* Major E. A. Penny, I.M.S., with effect from the afternoon of 23rd April, 1929.

The undermentioned temporary commissioned officers are appointed permanently to the Indian Medical Service subject to His Majesty's approval:—

Lieutenant Sher Mohammad Khan Mallick, M.B. Dated 16th February, 1928, with seniority from 18th August, 1927.

Lieutenant Euruch Ardeshir Ruttanji Ardeshir. Dated 30th April, 1928, with seniority from 16th December, 1927.

Lieutenant Thaku Chulharmal Ramchandani, M.B., F.R.C.S.E. Dated 30th April, 1928, with seniority from 12th May, 1926.

Lieutenant Cheruvuri Kottieth Lakshmanan. Dated 30th April, 1928, with seniority from 21st October, 1925.

To be Lieutenants (on probation).

K. F. Alford, M.B., 4th February, 1929, with seniority 6th January, 1927.

H. J. Curran, M.B., 4th February, 1929.

H. T. McWilliams, M.B., 4th February, 1929.

P. Shannon, M.B., 4th February, 1929.

G. J. O'Connor, M.B., 4th February, 1929.

B. J. Griffiths, 4th February, 1929.

E. A. Y. Mackeown, 4th February, 1929.

H. S. Waters, M.B., 4th February, 1929.

W. P. Lappin, M.B., 4th February, 1929.

G. Milne, M.B., 4th February, 1929.

A. M. Fraser, 4th February, 1929.

D. L. Trant, 5th February, 1929.

W. Walsh, 22nd February, 1929.

LEAVE.

Lieutenant-Colonel J. D. Sandes, M.D., F.R.C.P.I., I.M.S., Professor of Medicine, Calcutta Medical College, and First Physician to the College Hospitals, is allowed leave on average pay for 6 months under Rule 81 (b) (i) of the Fundamental Rules, with effect from the 22nd April, 1929.

Lieutenant-Colonel F. E. Wilson, I.M.S., an Agency Surgeon, is granted leave on average pay for 5 months and 28 days, under the Fundamental Rules, with effect from the 12th April, 1929.

Major M. A. Rahman, I.M.S., Civil Surgeon on leave, was granted by the High Commissioner for India 3 days' extension of leave on half average pay in continuation of the 12 months combined leave sanctioned in Government Notification No. 1578[V—40, dated 8th December, 1927.

Captain G. H. Fraser, I.M.S., Officiating Superintendent, Mental Hospital, Agra, leave on average pay for 17 days combined with furlough for 5 months and 13 days, with effect from 4th April, 1929.

PROMOTIONS.

Lieutenant-Colonel to be Colonel.

C. W. F. Melville, M.B., F.R.C.S.E., I.M.S. Dated 4th February, 1929, *vice* Colonel W. O'S. Murphy, M.B., I.M.S., retired.

C. A. Sprawson, C.I.E., M.D., F.R.C.P., V.H.S., I.M.S., *vice* Colonel R. F. Baird, superannuated. Dated 16th March, 1929.

The promotion to his present rank of Major H. C. Tait, M.B.E., M.B., I.M.S., notified in Army Department Notification No. 235, dated the 25th February, 1928, is antedated from the 2nd February, 1928, to the 2nd August, 1927.

Major A. E. Grisewood, M.B., I.M.S., whose retirement was notified in the *London Gazette* of the 19th December, 1924, is granted the rank of Lieutenant-Colonel, 10th December, 1924.

Captains to be Majors.

R. S. Aspinall. Dated 19th April, 1929.

G. V. Ram Mohan, M.B. Dated 20th April, 1929.

L. K. Ledger. Dated 1st May, 1929.

Lieutenant to be Captain.

C. K. Lakshmanan. Dated 21st October, 1928.

RETIREMENTS.

Colonel W. O'S. Murphy, M.B., I.M.S., from the 4th February, 1929.

Lieutenant-Colonel R. M. Barron, D.S.O., I.M.S., from the 24th March, 1929.

RESIGNATION.

The King has approved the resignation of Captain E. Kean, I.M.S., from the 21st March, 1929.

NOTES.

LIVER EXTRACT (PARKE, DAVIS & CO.).

THE general practitioner who deals with Messrs. Parke, Davis & Co. knows that he is dealing with eminently reliable and efficient drugs, and the policy of this well-known firm with regard to liver extract for the treatment of such conditions as sprue, pernicious and other anæmias, and night blindness has been extremely sound. Their Detroit laboratories have been manufacturing liver extract for some time, but the firm decided not to put their preparation on the Indian market until they were satisfied that it would stand Indian climatic conditions.

Their final product has proved to withstand the factors due to climatic conditions, and is a great improvement in the original product. By improved methods they have been able to produce a highly concentrated extract of which 2 grammes (grains 32), are equivalent to 100 grms. of fresh liver. This is stocked at Rs. 20 per box of 24 vials subject to usual discount. Messrs. Parke, Davis & Co., Lloyd Buildings, Graham Road, Ballard Estate, P. O. Box 88, Bombay, will be glad to supply medical practitioners in India with information regarding this product.

PICTORIAL PERFECTION IN PHOTOGRAPHY.

THE advance made in artistic photography during the past few years is very noticeable. So soon as the amateur of to-day passes the snapshot stage the impulse is to produce pictures which by general consent will be considered works of art. Perfection is always a worthy objective and the photographer by striving towards that end, in time, approaches the unattainable, to the general advancement of photography.

Let no amateur photographer hold back because he thinks he has not sufficiently mastered manipulative methods and technicalities to produce really creditable pictures. Happily photography has progressed along scientific lines to such a degree and has been so simplified in its progression, that the only photographer who need remain unsuccessful is the one who refuses to take advantage of this simplification.

A booklet recently published—*Pictorial Perfection in Photography*—shows convincingly how simple it is to master the technical details which are the foundation of artistic pictorialism. To increase the beginner's interest in his hobby and give very useful information to those already familiar with the elementary principles of photography, the publishers of this booklet set forth the ease with which the amateur can avoid poor results. Every camera owner will find much to interest him, especially the sections on exposure and colour photography. The booklet is well illustrated with explanatory photographs and many pages in colour.

The whole of the thirty-six pages is somewhat of a revelation, both as to the amount of information condensed into such convenient space and to the possibilities of artistic results achieved by development. After-treatment of negatives, enlarging and development without a dark-room are dealt with at length. A section explaining the colour effects obtained by toning opens up new and fascinating methods for the production of coloured photographs.

The helpfulness of the booklet will be appreciated by everybody interested in this popular subject. This booklet will be sent post free, to any reader mentioning this paper, by the publishers:—Messrs. Burroughs Wellcome & Co., Snow Hill Buildings, London, E. C. 1.

"ATOCIN."

"ATOCIN" is a product for the treatment of rheumatism, lumbago, and similar conditions recently introduced by the Cavendish Chemical Co., 137, Regent Street, London. The following reports are quoted from *The Lancet* of the 19th November, 1927.

Atocin is indicated for the treatment of rheumatism, gout and lumbago. Whilst the introduction of salicylates was a notable step forward in combating the painful afflictions caused by the different forms of rheumatism, it left untouched many aspects of this malady. In recent years attention has been given to phenylcinchoninic acid and its derivatives—among which is *Atocin*—and the clinical results obtained appear to be hopeful. When analysed, these tablets were found to contain a substance which possessed the properties of phenylcinchoninic acid with starch as an excipient. Each tablet weighs 9.38 grs., of which amount 7.5 grs. is *Atocin*.

Atocin with Aspirin.—These tablets, while used for the same purposes as *Atocin*, are used a great deal with good results for colds, influenza and neuralgia. When examined, they were found to be compounded of 5 grs. of *Atocin*, 2½ grs. of aspirin (acetyl salicylic acid), starch being used as an excipient. Free salicylic acid was absent.

A STOPPER FOR VACUUM FLASKS.

DIFFICULTIES are frequently experienced in pouring out the contents of insulated flasks built on the *Vacuum* principle, and in this connection our attention has been drawn by the Patris Co., 11, Thornfield Road, Bishop's Stortford, Herts., England, to a most ingenious stopper and pourer for such flasks, which they manufacture. In the ordinary type of flask drops of fluid may accumulate inside the metal case when the contents are poured out, and there cause rusting of the case. The "Patris pourer" is designed to give a steady thin stream of fluid in pouring, free from the disadvantages of pouring out the contents of the flask over a thick glass rim. *The Lancet* writes of this stopper that "it allows the liquid to flow in a steady stream; splashing is entirely prevented. The device will be appreciated by the user of the vacuum flask for ordinary purposes, and especially by the sick-room attendant, who may have to supply an invalid with a warm liquid at intervals."

Sets of samples of assorted sizes have been prepared for the Eastern markets at 6 for Rs. 5. The device appears to be ingenious; it consists essentially of a double-lipped tube of specially annealed glass with a jacket and stopper of tough cork, the complete pourer fitting under the metal cap, so that it need not be removed, except for the purposes of cleaning and sterilisation. It is made in different-sized gauges to fit the different sizes of vacuum flasks on the market.

MESSRS. BEHRING AND CO.

BEHRINGWERKE, Marburg, Lahn, Germany—the well known firm of manufacturers of anti-diphtheritic serum, anti-sera, vaccines, and other specialties—announce the issue of a booklet dealing with their manufacture of sera and vaccines in general, in which full particulars are given. The firm was founded by the famous Emil von Behring, whose work on anti-diphtheritic serum is classical.

They will be glad to supply copies of this booklet to members of the medical profession in India on application to the above address.

WATSON'S MICROSCOPE RECORD.

The Microscope Record, published quarterly by Messrs. W. Watson & Sons, Ltd., 313, High Holborn, London, W. C. 1, is a real journal (and not merely a trade publication) of outstanding merit, and of interest to microscopists and laboratory workers alike.

In the issue for January, 1929, Mr. A. E. Clarence Smith, M.A., A.I.C., deals with the problem of exposure in photomicrography, giving a copy of Hurter and Driffeld's "characteristic curve" diagram; the worker in

this particular line will find much of interest in this article. Mr. H. F. Hurrell, F.R.M.S., gives an account of fresh-water polyzoa; and Mr. A. A. C. Eliot Merlin continues his "hints to beginners." This last article is one which we commend not only to beginners in microscopy, but to the man who has been accustomed to use his microscope for years as well. It is almost incredible that medical men should take to microscopic work without any information about the optical principles of the microscope, yet the majority of medical men do so. Mr. Merlin emphasises the necessity for a centring sub-stage condenser; to the trained microscopist this is essential, but the student may very well be content with a built-in and non-centring sub-stage condenser. The Abbé, of course, is in universal use; but we agree that experienced workers may not be satisfied with it. The paragraphs dealing with fine adjustments are worthy of consideration; a fine adjustment that has to bear the whole weight of the body of the microscope and of the coarse adjustment needs to be of far more substantial construction than one which has to bear a lesser strain. In spite of the fact that present-day microscopes are almost standardised in construction, there is still a vast field for further experiments in design. Two classes of microscope are wanted; the first, a fool-proof model for students—(this has practically been evolved by almost all well known manufacturers, though a continental model which requires the use of both hands for working the mechanical stage, thus leaving none free for the fine adjustment, strikes us as about a century out of date); the second a model for the research worker who wants to get the most critical work out of his microscope. The latter will usually work by artificial light (even in the tropics), and he will require a centring sub-stage condenser, apochromatic objectives and compensating oculars. There is an immense difference between results under the two different conditions.

The Rev. D. P. Fuge contributes an introductory note to the genus *Coscinodiscus*, and Mr. Chapman Jones, F.I.C., F.C.S., HON. F.R.P.S., defines a microscopist's method of testing objectives. The Editor discusses the problem of getting the best out of the Abbé sub-stage condenser by way of illumination; it is often forgotten that the Abbé was originally invented for the purpose of producing such brilliant illumination of sections of stained tissues that the stained bacteria within them would appear brightly illuminated, whilst the image of the tissue would be so bright as to be negligible. To-day, the Abbé is used for entirely different purposes, and for critical work it compares very unfavourably with achromatic aplanatic condensers of the English type. Again, we see that the present-day microscope is by no means standardised, and that big advances may be expected in the near future.

"Notes and Queries"—chiefly answers to correspondents—complete the number. This journal (which is supplied free by Messrs. Watson and Sons on application) is one of cardinal importance to microscopists.

THE TREATMENT OF AMŒBIC DYSENTERY.

WHILST the clinical treatment of a case of acute amœbic dysentery is a straight forward matter, the eradication of a chronic intestinal infection with *E. histolytica* is quite another matter.

And in this connection Messrs. Burroughs, Wellcome and Co., have recently issued a small and interesting little brochure dealing with their preparations for use in this condition. It is a small brochure which is well worth the study of the medical profession in India, for one knows that with this firm their drugs are what they purport to be. The history and use of emetine is first dealt with; then that of emetine bismuthous iodide. A section follows on the uses of emetine in conditions other than amœbiasis—e.g., in schistosomiasis, bronchitis, and oriental sore. Kurchi bark is then considered; then Quinoxyl; and finally "Kharophen"—an arsenical preparation.

The pamphlet is studiously moderate in its claims for the different preparations described, and gives the chemical composition of the different remedies named. It will be of interest to the general practitioner as giving

him some indication of the different uses and values of these drugs, and how and under what circumstances to use them.

MESSRS. BAIRD AND TATLOCK (LONDON), LTD.

MESSRS. BAIRD AND TATLOCK, the very well-known firm of laboratory furnishers and suppliers of standard scientific apparatus, ask us to announce that they have recently opened an Eastern Branch under Mr. G. W. Gosling, at Avenue House, Chowringhee Square, Calcutta; P. O. Box 2169, Calcutta. There are very many laboratories and hospitals in India which deal with this celebrated firm, and who will be glad to know of that a local branch for India and the East has been opened.

Mr. Gosling will shortly be proceeding to England, and will be pleased to give his attention to any orders or indents placed either with the Indian branch or direct with the head office in London.

A STERILISING HYPODERMIC SYRINGE CASE.

It is a very common custom for medical practitioners to sterilise their hypodermic syringes by washing them through with absolute alcohol. The Goldstein Manufacturing Co., Buffalo, New York, however, have gone one better in designing a sterilising hypodermic syringe case which can be carried clipped into the pocket like the ordinary large size of fountain pen. This case has a screw-on cap with a clip, exactly like that of a large fountain pen; inside the barrel of the case is protected by a rubber sheath inside which the hypodermic syringe fits in order to prevent breakage, whilst the hypodermic needle is further protected by a brass shield and remains always in a bath of alcohol surrounding the entire needle. The apparatus appears to be very ingenious, for the syringe when withdrawn has its rustless needle sterilised by alcohol and is ready for immediate use. The price, fitted with a standard pattern 2 c.c. syringe, is \$4, whilst there is a special pattern for insulin syringes.

The same firm also manufacture a somewhat similar vest pocket alcohol-containing thermometer case for holding clinical thermometers. It is claimed that with this case the thermometer can be withdrawn and re-inserted 100 times with one filling of the case with alcohol, and each time is ready sterilised for insertion into the patient's mouth. This is listed at \$3.50, fitted with a one-minute thermometer.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

THE IMPORTANCE OF SECONDARY INFECTIONS IN THE CAUSATION OF FILARIAL LYMPHANGITIS.*

By H. W. ACTON,

LIEUTENANT-COLONEL, I.M.S.,

Director, and Professor of Pathology and Bacteriology.
and

S. SUNDAR RAO, L.M.P.,

*Filariasis Research Worker (Darbhanga Scholar),
Calcutta School of Tropical Medicine and Hygiene.*

Of the different lesions caused by *Filaria bancrofti* in man, filarial lymphangitis is the most common, and unfortunately the most troublesome affection. The actual mechanism by which filarial lymphangitis is brought about has not hitherto been clearly understood.

The authors have been engaged on a detailed study of the ætiology of lymphatic obstruction in filariasis during the past two years, both by a study of post-mortem material, and also from clinical experience with a large series of cases.

During the course of these studies, it was found that lymphatic obstruction in filarial disease is produced in one of the following ways:—

1. A chronic condition of obstruction brought about during the course of several years by the worms damaging the lymphatic glands during their passage through them, and thereby changing the glands into a granulomatous mass.

2. An acute inflammatory change in and around the glands which are already damaged by the worm. This inflammation is caused by pyogenic cocci coming to the glands through the blood stream from some septic focus existing in the body. These cases are like the elephantiasis nostras of Europe and the development of the obstruction is very rapid and accompanied by bursts of fever, and cellulitis or periadenitis.

Of the two types mentioned above, the inflammatory type is the most common one, forming, as we found from a study of the outdoor cases at the Calcutta School, 95 per cent. of the total admissions for filarial disease. The present paper deals only with this type of lymphangitis and shows the results of investigations carried out with a view to determining the nature of these septic foci and their location. A detailed examination of every case of filarial lymphangitis and chyluria was carried out during the past two

years and it was found that in all cases the source of infection is some definite septic focus.

In all the cases that were studied, the acute attack was invariably due to secondary organisms, viz., streptococci or staphylococci; the source from which these organisms got into the damaged lymphatics was a matter that had to be determined by us. In order to ascertain the exact source from which these pyogenic organisms invade the blood stream, a very detailed examination of all cases was made for the discovery of any septic focus in the body. In every one of the cases examined one or more foci of infection existed, these undoubtedly served as the source of supply of the secondary organisms that were responsible for the acute attack of lymphangitis.

The cases discussed here were those admitted into the Carmichael Hospital for Tropical Diseases, Calcutta, for acute symptoms of lymphangitis, abscess following lymphangitis, elephantiasis or chyluria, and these were not selected of an examination of the blood for thorough examination was made both clinically and bacteriologically. Routine laboratory tests were carried out in every case, and these consisted of a complete examination of the blood for malarial parasites, the Wassermann and Widal reactions, the aldehyde and antimony tests, agglutination against dysentery bacilli of Shiga and Flexner, and the night blood for microfilariæ. Total and differential leucocyte counts were also made. Cultures of the stool and urine were made for non-lactose fermenters and for streptococci, besides the routine examination of stools for protozoa and ova, and the urine for any abnormality. In addition to these bacteriological tests, a clinical examination was made of the mouth for the presence of pyorrhœa alveolaris and for caries of the teeth, as well as an x-ray examination of the roots for periodontitis. Examinations of the ear, nose and throat of these cases were done by the specialist. Twenty-eight cases were examined in detail in the manner mentioned above and the findings are presented in this paper. In this connection the authors are indebted to Lieut.-Colonel J. A. Shorten, I.M.S., for his help in carrying out the x-ray examinations of the teeth, and to Dr. Judah, F.R.C.S. for the ear, nose and throat examinations.

As a result of these detailed examinations for the presence of septic foci in these cases, it was found that two types of foci form the source of the secondary organisms. These are:—

1. External foci, usually temporary, as for example, a traumatic lesion or a tinea infection, with secondary streptococcal infection.

2. Internal and more permanent foci, e.g., pyorrhœa alveolaris, caries of the teeth, periodontitis, septic tonsils or intestinal ulceration.

In all the cases, the source of the secondary infection is found to exist in the mouth, either as carious teeth, periodontitis, apical infection or septic tonsils. In many of these cases, streptococci were isolated from these foci.

* Being a paper read at the Medical and Veterinary Research Section of the Indian Science Congress held at Madras in January, 1929.

In six of the above cases, the laboratory examination also revealed intestinal infection with *Entamæba histolytica*, hookworms, or streptococci, and in five of these cases streptococci or *Staphylococcus mollis* were also isolated from the bladder.

Acton and Knowles (*Dysenteries in India*—1928) have shown how lesions of *E. histolytica* infection in the gut act as a seat of septic inflammation from which bacterial emboli may occur and settle in different parts of the body giving rise to various inflammations, such as myositis, sciatica, etc. The mechanism of infection described by these authors by which secondary sequelæ are produced through the absorption of the secondary organisms from these lesions and thereby producing symptoms, applies to filarial lymphangitis as well.

External Foci.

The external foci are chiefly temporary in nature. The percentage of occurrence of this

type of focus in this series is small; out of a total of 28 examined only 9 were of this class. The chief forms of such foci are (1) skin disease like tinea of the feet with secondary streptococcal infections, or streptococcal dermatitis; (2) cuts, bruises, or abrasions that had become septic.

The discovery of the focus of secondary infection in filarial lymphangitis is of much more than academic interest. It has a definite bearing on the question of treatment of filarial lymphangitis. We have invariably found that by the removal of the focus, e.g., an apical abscess, or by the treatment of the focus, e.g., a dysenteric ulcer, the acute attacks disappear and the patients remain free of lymphangitis for years, at other times the attacks of lymphangitis are greatly reduced in severity and frequency.

In these cases the course of treatment consisted in treating these foci surgically or by local applications, followed by a course of auto-vaccines when possible, or a course of stock mixed streptococcus and staphylococcus vaccines.

SUMMARY.

Lymphatic obstruction in filarial infection has been found to be of two types: (a) a chronic type caused by the worm damaging the lymphatics and glands and usually an aseptic condition; and (b) acute inflammatory lymphangitis caused by a secondary infection with streptococci and staphylococci. The latter type is the more prevalent one, and the secondary organisms are derived from some septic focus in the body; these foci are of two kinds: (1) internal and more or less chronic, e.g., septic tonsils; and (2) external and generally temporary. The internal foci are commoner and their recognition is very important in the treatment of filarial lymphangitis, because by eradicating these secondary foci there is no further danger of acute bursts of cellulitis, etc., nor will the elephantiasis attain a great size.

The evidence in favour of our view, that most of the acute cases of lymphangitis are due to sepsis, may be summarised as follows:—

(1) A septic focus can always be found from which we can recover a pyogenic coccus.

(2) The irritation produced by the worm causes a break-down locally in the tissue defence mechanism (kataphylaxia). These sites form a suitable nidus for the lodgement of these cocci.

(3) The same coccus can be recovered from the inflammatory site as from the septic focus.

(4) Furthermore, it can usually be recovered from the urine also, showing that it must have invaded the blood stream.

(5) Eradication of the septic focus, followed by immunisation, prevents periodic attacks and the development of elephantiasis.

TETRACHLORETHYLENE IN THE TREATMENT OF HOOKWORM DISEASE.

By P. A. MAPLESTONE, D.S.O., M.B., CH.B., D.T.M.,
and

A. K. MUKERJI, M.B.

(From the Hookworm Research Laboratory, Calcutta School of Tropical Medicine. Supported by the Indian Jute Mills Association.)

FOLLOWING the success of carbon tetrachloride in the treatment of hookworm disease, Hall and Shillinger (1925), as the result of animal experiments, suggested that tetrachlorethylene (C_2Cl_4) might be even more efficacious.

The first report of its use on human beings was that of Lambert (1925). He gave the drug to three series of cases in doses of 2 c.c., 3 c.c. and 4 c.c. respectively. He tested the efficiency by giving a dose of tetrachlorethylene and counting the worms removed during the subsequent twenty-four hours. One week later he gave a dose of 3 c.c. of oil of chenopodium to the same people and counted the worms removed by this treatment, and the number of worms removed by the tetrachlorethylene is expressed as a percentage of the total number removed by the two treatments. In this way he found that 2 c.c. of tetrachlorethylene removed 36 per cent. of the worms from four patients, 3 c.c. removed 77 per cent. of worms from four patients, and 4 c.c. removed 94 per cent. of worms from five patients. His final conclusion is that tetrachlorethylene has no advantage over carbon tetrachloride from any point of view.

The next record of the use of this drug on human beings is that of Soper (1926). He examined the efficiency of the drug from the point of view of selective action on the species and sexes of hookworms, and he concludes that tetrachlorethylene offers no advantages over carbon tetrachloride in the case of *Necator*, but he suggests that it should be tried in places where *Ankylostoma* is the predominant species.

Schapiro and Stoll (1927) tried the drug at Penonome, Panama, when its efficiency was tested under field conditions. They first took a series of test cases in which several egg counts were made before and after treatment, and in nine patients who received doses of 3 c.c. of tetrachlorethylene the egg output was reduced by 93 per cent., and in five patients who received 2 c.c. the egg output was reduced by 88 per cent. In cases in the field on which single egg counts were made before and after treatment, it was found that 3 c.c. reduced the egg count by 81 per cent. and 2 c.c. reduced it by 77 per cent. Fractional doses in children under 16 years of age gave an egg reduction of 53 per cent. They also give the results of combined treatment with fractional doses of tetrachlorethylene

and oil of chenopodium, and they obtained a 75 per cent. reduction. Tetrachlorethylene was inactive against *Ascaris*, as tested by egg reduction, and they claim it is more active against *Trichuris* than is oil of chenopodium, as there was an egg reduction of 26 per cent. with the former drug against 23 per cent. with the latter, but this difference appears too slight to be of any real evidence of superiority. They consider that tetrachlorethylene merits further trial as an anthelmintic, but they express no opinion as to its efficiency compared with that of carbon tetrachloride.

Brosius, Peon, and Carroll (1927) treated twenty-four cases at Almirante, Panama. These cases were treated in hospital and their report is of considerable interest because a record of toxic symptoms arising from the drug was kept. There was dizziness in 11 cases, dizziness with abdominal pain or cramp in 6, abdominal pain or cramp in 3, nausea in 1, and vomiting of the drug in 1. Only three cases of the twenty-four exhibited no symptoms. In the stools of seven of these cases no hookworms were found after treatment, but all but two cases were negative for eggs on three examinations after treatment, therefore a cure rate of 91.7 per cent. is claimed for this series of cases.

A supply of tetrachlorethylene in soft gelatine capsules of $\frac{1}{2}$ c.c. capacity was sent to the Calcutta School of Tropical Medicine by a firm of manufacturing chemists, with a letter requesting us to try the efficiency of the drug in this form. It was tried in various ways, alone or combined with oil of chenopodium, and the efficiency of the different methods was tested by means of a single egg count before treatment and a single egg count at least ten days after treatment. With the exception of nine cases in group 3, Table I, who were under sixteen years of age and consequently received graduated doses of both drugs, all the patients referred to had the full dose of 3 c.c. or 6 capsules of tetrachlorethylene, and, when given, 1 c.c. of oil of chenopodium in a hard gelatine capsule. The only purgative used was 1 oz. of saturated solution of magnesium sulphate.

It is seen that the percentage reduction in eggs is much greater in group 2 than in group 1, although the number of cures is lower. The reason of the greater egg reduction in group 2 is probably because the purgative given at the same time as the capsules would tend to move them past the site of the worms before they became dissolved and so the drug would not be liberated in time to act on the worm to the best advantage. Although the percentage reduction in eggs in group 2 is very high, it is certainly somewhat lower than it appears in the table. This is because egg counts of two preparations of each stool only revealed a single egg in each of three slides, but eleven of the cases were positive by

Lane's direct centrifugal flotation method. In other words eight of the twelve cases were negative by Stoll's count, whereas only one case did not contain eggs as demonstrated by Lane's method. It should be borne in mind that in all the groups the number of cures has been estimated by Lane's centrifuge, and in none of the other instances which have been quoted for comparison has this method been employed. The great superiority of Lane's method over any other for demonstrating light infections is quite sufficient to explain the low percentage of cures in the writers' cases. It was the discovery of the ridiculously low rate of complete cure that even the most powerful vermifuges bring about when checked by the direct centrifugal flotation method that led the writers to make use of the percentage reduction in eggs as a test of drug efficiency.

before and after treatment available; but all the cases have been tested for cure by the direct centrifugal flotation method so this gives a basis for comparison. Although, as seen from Table I, the percentage of egg reduction and percentage of cures do not seem to be in any way dependent on each other.

As far as Tables I and II are comparable it seems that carbon tetrachloride is more efficient than tetrachlorethylene, except in the case of group 2, Table I, where capsules of tetrachlorethylene followed by the purgative gave over 90 per cent. egg reduction. Enquiry as to the price of these capsules even at wholesale rates revealed the fact that a dose of 3 c.c. of tetrachlorethylene in this form is nearly eighteen times as expensive as an equal dose of carbon tetrachloride given in water. Therefore, even if it might be a little more efficient, the price of tetrachlorethylene

TOTAL		..	82	17	20.7

It was considered that tetrachlorethylene given in the soft capsules in which it was supplied would tend to make it more efficient than when given in the free state in water or other vehicle, because the capsules dissolve in the duodenum and would thus liberate the drug at the desired site of operation in much greater concentration than when it reached there mixed with stomach contents. It is probable that this did occur, for in no case were undissolved capsules found in the stools. Therefore, so that the tetrachlorethylene should not have an undue advantage over carbon tetrachloride, which is always given in water at this hospital, a certain number of capsules were cut open and a dose of 3 c.c. of the drug was given in exactly the same way. The figures for carbon tetrachloride treatment that are given below in Table II have been taken from our hospital records, and in only a portion of one group are egg counts

in capsules would render it of no practical use on a large scale.

Cases which were treated in hospital and in which toxic effects of the drug could be watched for numbered thirty-eight who received tetrachlorethylene alone, and thirty-seven who received tetrachlorethylene with oil of chenopodium. In the first group, 6 complained of giddiness, 1 vomited, and 1 appeared drowsy; in the second group 19 showed giddiness, 4 vomited, and 3 appeared drowsy. These results are approximately the same as we get with carbon tetrachloride.

The results of our investigation are in complete agreement with those of the other workers to whose papers reference has been made, and we do not consider that tetrachlorethylene is in any way superior to carbon tetrachloride as an anthelmintic. Indeed, it seems that it might not be quite so powerful in removing hookworms as is the latter drug.

TABLE II.

Results of a single treatment with 3 c.c. of carbon tetrachloride with or without 1 c.c. of oil of chenopodium in a hard gelatine capsule. The purgative in all cases was 1 oz. saturated magnesium sulphate.

4	Carbon tetrachloride alone.	At same time	34	19	56
TOTAL	135	64	47.4

There is one factor, however, that has not yet been fully investigated, and that is the relative toxicity of the two drugs, and should tetrachlorethylene prove less toxic than carbon tetrachloride, it would be a very valuable substitute for the latter. A recent paper by Lamson, Robbins and Ward (1929) indicates that possibly tetrachlorethylene is not as dangerous as carbon tetrachloride. After a large number of experiments on animals they have come to the conclusion that tetrachlorethylene is not absorbed from the animal's intestines, and that when it does enter the circulation by inhalation, it has none of the pathological effects on the liver and kidneys that are exhibited by carbon tetrachloride.

It seems probable that a certain amount of tetrachlorethylene is absorbed from the human intestine, for the clinical observations of Lambert, Brosius *et al*, and the writers are in agreement, that similar signs are observed to those following the use of carbon tetrachloride. There have not yet been any fatalities from tetrachlorethylene, so it is not possible to say if the drug has any damaging action on the liver. The experiments of

and his co-workers suggest that if .. it would be slighter .. It is .. even .. sufficient .. intoxication, .. damage to a .. damaged, and as .. the former .. of carbon tetra- may prove a

THE USE OF FIBROLYSIN IN LEPROSY.

By NORBERT FIGUEREDO, M.B., B.S.,

Assistant Medical Officer, Acworth Leper Asylum, Bombay.

FIBROLYSIN, as stated by the manufacturers, is a compound of thiosinamine and sodium salicylate and is credited with the powers of dissolving fibrous tissue. It is said to be of some use in veterinary surgery and has also been used in general surgery to dissolve scar tissue.

With regard to its use in leprosy, Dr. Otto Krause in his paper, "How to make old leprosy cases accessible for treatment like one or two year old cases," read before the Medical Congress, held in Bloemfontein in March 1928, says

"The great difficulty with leprosy is that old cases resist where cases of one or two years' standing will yield to treatment with chaulmoogra oil or hydnocarpus oil.

"I have now found a method to convert old cases into new ones, and also to quicken the treatment of new cases.

"I started with the following theory:—Through the action of the bacillus, fibrous tissue is formed. In this tissue the circulation is bad and the bacillus has a splendid shelter in the same, the chaulmoogra oil cannot

attack it in full force. The toxin which the bacillus produces further poisons the system.

"A remedy which will dissolve the fibrous tissue will expose the bacillus to be attacked by the remedy. This I find to be 'Fibrolysin' (obtainable from E. Merck, Darmstadt, Germany) which is known to dissolve the fibrous tissue. I injected the fibrolysin intramuscularly for 4 to 6 weeks twice a week, then stopped for 1 or 2 weeks, then continued again until the desired effect was produced: at the same time the treatment with the oil was continued, sometimes by the mouth or through intramuscular injections.

"Massage quickened and facilitated the progress. The result was very encouraging, but as I have only private cases and a limited number, I would like to see the treatment carried on in leprosy institutions. In nervous cases of leprosy, the result was still more encouraging. I hold that the bacillus does not so much destroy the nerve but the sheath of the nerve, and through the formation of fibrous tissue, shrinking of the sheath occurs and the nerve is killed by pressure."

The same treatment is also referred to by Henderson and Chatterji (1928).

To explain the dissolving action on the fibrous tissue in leprosy, credited to fibrolysin by Dr. Otto Krause, a brief account of the formation of this tissue in nodules and nerves in lepers, as summed up by Dr. Muir (1928), may be given.

"Whenever a bacillary embolus lodges in the corium of the skin, there is a reaction caused in proportion to the size of the embolus and the reaction-producing power of the surrounding tissues. When the reaction is marked, a round nodule is formed. If this nodule does not persist, it may be called a temporary nodule. But if the reaction produced is very severe, fibrous tissue may be formed to a degree sufficient to prevent the spread of infection, and a more or less permanent nodule is formed. Permanent nodules are also formed as the result of lodging of fresh emboli inside the area of a pre-existing lesion. The fibrous tissue, which has already been formed, blocks the spread from the new embolism and brings about this result.

"A section through a nodule shows fasciculi and spaces containing connective tissue and round cells. Bacilli are found in the spaces between the cells, but not to any extent between the fibrous tissue strands."

"Nerve lesions are of two types. the fibrolysin dissolves the fibrous tissue round the nodule and sets free the bacilli, which are, in turn, acted upon by the chaulmoogra oil. Here, then, is one indication for the use of fibrolysin.

"Nerve lesions are of two types (2) Ascending—here the lesion is due to a spread of infection from a lesion of the corium of

the skin into the sensory nerve endings and so along the nerve trunks. Metastatic—here the infection reaches the nerve trunks as a result of bacillary embolism of the vasa vasorum of the perineurium. Further extension results from the organisms passing up the sheaths of the nerves. In both, there results a formation of granulation, and later of fibrous tissue. The true nerve elements are constricted and if this pressure continues long enough, the axis cylinders are destroyed."

The fibrolysin is supposed to act on the fibrous tissue formed in the sheath. The second indication, therefore, for the use of fibrolysin would be in cases in which the nerve sheath was undergoing fibrosis but was not completely destroyed.

In choosing the following cases, attention was directed to the stage of the disease in which the above indications were met with.

(I) Cases in which both superficial anæsthetic patches and acroteric lesions (with glove anæsthesia and trophic lesions of the extremities) were present together.

Case 1.—B. K., Hindu male, æt. 30. Duration of disease 10 years.

Lesions.—Anæsthetic patches over the chest and abdomen and back. Acroteric lesions of hands and legs. Thickening of the ulnar and peroneal nerves.

Case 2.—D. R. M., Hindu male, æt. 35. Duration of disease 12 years.

Lesions.—A few patches of superficial anæsthesia on the chest. Acroteric lesions of hands and feet. Thickening of the ulnar and peroneal nerves.

Case 3.—N. R., Hindu male, æt. 42. Duration of disease 12 years.

Lesions.—Patches of superficial anæsthesia on the abdomen and back. Acroteric lesions of hands and feet. Thickening of the ulnar nerves.

Case 4.—D. D., Hindu male, æt. 42. Duration of disease 4 years.

Lesions.—Large patch of anæsthesia on right buttock, a few patches on left arm. Acroteric lesions of hand. Thickening of ulnar nerves.

Case 5.—M. H., Hindu male, æt. 45. Duration of disease 10 years.

Lesions.—Patch of anæsthesia on lumbar region. Acroteric lesions of hands and feet.

(II) Cases in which only secondary nerve lesions were present.

Case 1.—G. B., Hindu male, æt. 51. Duration of disease 15 years.

Lesions.—Acroteric lesions of hands and feet.

(III) Cases in which secondary nerve lesions (acroteric) were present together with nodules showing acid-fast bacilli.

Case 1.—A. G., Hindu male, æt. 42. Duration of disease 7 years.

Lesions.—Nodules on face and ears. Acroteric lesions of feet, thickening of peroneal nerves.

Case 2.—R. R., Hindu male, æt. 50. Duration of disease 5 years.

Lesions.—Tubercular lesions of face and ears. Acroteric lesions of hands and feet. Thickening of ulnar and peroneal nerves.

Case 3.—S. G., Hindu male, æt. 25. Duration of disease 10 years.

Lesions.—Tubercular lesions of face and ears. Acroteric lesions of hands and feet. Thickening of ulnar and peroneal nerves.

(IV) Cases in which only skin lesions were present showing on bacteriological examination acid-fast bacilli.

Case 1.—R. R. K., Hindu male, æt. 30. Duration of disease, 2 years.

Lesions.—Erythematous patches on left arm, small nodules on face.

Note.—After a week's treatment a slight reaction was observed with rise in temperature.

The above cases were treated for four months from 27th November to 31st March, with intramuscular injections of fibrolysin twice a week and chaulmoogra oil once a week. The fibrolysin was given on Wednesdays and Saturdays and the oil on Mondays. In accordance with the procedure adopted by Dr. Otto Krause, the injections were stopped at the end of the first five weeks, namely, on December 31st, and resumed again on 7th January and continued without further intermissions to the end of the period of treatment.

Results.—Except in one case, no reactions were observed. The treatment is still being continued but so far no visible improvement can be found.

If the fibrolysin acted on the fibrous tissue, dissolving it and setting free the bacilli, and

if the chaulmoogra oil acted on the bacilli, a certain degree of reaction might be expected. For it is found (Rogers and Muir, 1925) that all drugs that are beneficial in leprosy have the power to produce reaction. In the first stage improvement generally takes place without reaction, but in the second and third stages the aim of treatment is to produce a reaction of a limited degree.

It might be asked why the chaulmoogra oil by itself failed to produce a reaction in the above cases. Here, however, it should be noted that chaulmoogra oil by itself has frequently been found to fail to produce reactions in old standing cases of the type of those selected for this experiment.

In such cases potassium iodide usually has the effect of sensitizing the patients, and then small doses of the oil have produced a reaction, although without the potassium iodide larger injections would produce none.

Lastly, as a contrast the following cases, treated with potassium iodide and with intramuscular injections of chaulmoogra oil, may be described.

Cast 1.—C. A., Christian male æt. 45. Duration of disease, 8 years.

Lesions.—Patch of anæsthesia on right index finger. Had a patch of anæsthesia on the right leg which yielded to treatment with chaulmoogra oil which was taken off and on for 6 years.

Results :—The anæsthetic patches have disappeared. The acroteric lesions are present.

It is to be noted that potassium iodide and chaulmoogra oil were given in doses varying with the degree of vitality and the general condition of the patients treated. The large doses of potassium iodide were well tolerated when the patients were made to undertake manual labour.

Conclusion.

The treatment of leprosy with the aid of fibrolysin as recommended by Dr. Otto Krause failed to produce any signs of improvement after a continuous trial of four months in nine old cases, which were not converted in the manner described by Dr. Otto Krause into new cases by the use of fibrolysin. The treatment also failed in one case of two years' standing only.

THE SUPERIMPOSED BLOOD AGAR SLOPE.*

By S. N. GORÉ, L.M. & S. (Bom. Univ.),
Assistant Director, Haffkine Institute, Bombay.

It is not an exaggeration to state that had not the solid media surfaces been made available in test tubes instead of in Petri dishes, bacteriological work in the tropics would have been hampered considerably; and an instance

of this hampering forms the subject of another paper.(1) Tubed media are much more serviceable than plated ones owing to the great liability of the latter to aerial contamination, especially in the tropics; this susceptibility becomes much greater when the medium contains blood or serum. Again, plated media cannot be stored for any length of time and have more or less to be freshly poured.

In general bacteriological work, next to nutrient agar, blood agar is the medium which is most commonly required either for the growth of special organisms or for the observation of hæmolysis or the primary isolation of bacteria.

Blood agar slopes as ordinarily made require a fair amount of labour and material in their making, and though suitable for growth purposes are not so for observing hæmolysis phenomenon owing to the thickness of the agar slopes, except near their upper end. Even then the slopes soon lose their bright red colour in about two or three days' time.

Owing to the difficulties pointed out above, great inconvenience was experienced in routine work in determining the hæmolytic property of faecal organisms in the course of the examination of the third series of sprue stools.(2) The only way then available for this purpose was to fish the colonies primarily obtained on agar or MacConkey's bile-salt agar on to blood agar plates; the primary isolation of such organisms was obviously out of the question; and even so the work appeared to be disproportionately laborious.

It was during the course of this work and due to the special stress laid by Col. Mackie on the determination of the hæmolytic

* Being a paper read at the Medical and Veterinary Research Section of the Indian Science Congress, Madras, January 1929.

character of bacteria, that the idea occurred to the author of pouring the blood agar on the ordinary agar slope instead of in the Petri dish to secure a thin uniform layer of the medium. This idea when put in practice succeeded so well that tubed blood agar was found not only to possess all the advantages of the plated blood agar but was capable of being stored and used like the ordinary agar slope.

An ordinary agar slope for being superimposed by a uniform layer of blood agar about 2 mm. in thickness requires about three cubic centimeters of the special medium, while an ordinary plate requires from twelve to fifteen. In the case of the tubed medium, the blood agar sets on an absorbent moisture-bearing agar surface instead of on the dry surface of the plate: this circumstance not only contributes to the medium remaining moist for as long a period as the ordinary agar slope, but also to the retention of the red colour of the medium for over a week if carefully made and stored.

In passing, it may be remarked that the superimposed blood agar slope has facilitated the study of the hæmolytic character of bacteria as greatly as has the author's cotton-wool plug technique in respect of two other protein characters, viz., hydrogen sulphide and indol production. (3) Above all, this simple device of rendering blood agar as readily available as ordinary agar has been instrumental in bringing to light a fact unsuspected so far, that the plague bacillus requires blood or serum for its optimum growth in surface cultures, and has removed the difficulties so long encountered in the isolation, enumeration and identification of the plague bacillus by cultivation methods. (1)

This principle of superimposing could also be applied to other special media, e.g., Soparkar's heated or Goré's (Jr.) digested blood agar medium for the isolation of the influenza bacillus described by Liston, (4) or Alexander Marshall's red blood corpuscle medium for the isolation of the gonococcus and the plasma medium for its subculture. (5)

With respect to the liability of the superimposed blood agar slopes to aerial contamination one cannot expect as great a percentage of sterility as in autoclaved media, since the blood has to be added to the melted agar when the latter is at about 45°C. and the resulting blood agar to be poured into the tubes containing agar slopes. It may be safely remarked here that while in the case of blood agar plates there would be hardly two consecutive plates which would be absolutely sterile, there would not be more than one or two superimposed blood agar slopes that would be found contaminated in a batch of about twenty to thirty tubes.

Having thus given an idea of the principle of superimposition of special media on

ordinary agar slopes, a fairly detailed description of 'pouring' the slopes of the modification of Wright's method is given below.

Directions for making Superimposed Blood Agar Slopes.

(1) The required number of ordinary agar slopes are arranged in a cardboard tray. The cotton-wool plugs are loosened and pulled out half way. The mouths of the tubes are flamed so as to render the margins sterile and burn away any cotton sticking thereabout. The slopes are so arranged that they face towards the left of the worker.

(2) Nutrient agar in 50-c.c., 100-c.c. or 200-c.c. quantities filled to about half in appropriate sized lipped flasks are kept ready sterilised in store. When required, the agar is melted by placing the flask in a wire cage contained in a small water bath which is provided with handles. A 100°C. thermometer is inserted in a straight agar tube and placed in the bath. When the agar in the flask has completely melted, the water-bath is bodily removed to a sink and placed under a tap. Water is then run into the bath until its temperature is brought down to about 60°C. The paper cap covering the mouth of the flask is now removed, the cotton plug drawn out, the mouth of the flask flamed, and the plug reinserted half way. The temperature of the bath is now brought to about 45°C. by gently running the tap water again.

(3) Defibrinated rabbit or human blood is used for making blood agar. According to the quantity of the melted agar contained in the flask and the percentage of blood required therein, the calculated quantity of defibrinated blood is taken up in a bulb pipette, and added to the agar which should be somewhere near 45°C. but not above it. As soon as the blood is added, the flask is lifted out of the wire cage and gently rotated so as to produce a uniform mixture of the blood and agar, care being taken not to allow any frothing.

(4) The flask is then held in the right hand with its plug taken off altogether, and about three cubic centimetres of the blood agar poured into each tube of the agar slopes. The agar tube is held in the left hand between the thumb and the last two fingers and while so held the tube is opened by lifting out the plug by means of the middle and index fingers. After pouring the blood agar into the tube to the height of about one-third the slope from its butt end, the plug is reinserted and the tube handed over to the attendant who puts the tube in a slanting position so that the added blood agar produces a uniform layer on the agar slope. About thirty agars are thus easily poured out of 100 c.c. of blood agar in about five minutes. It is absolutely essential that there should be no draught in the room and all doors and windows should be closed, especially during the time when the blood is added to the agar and the blood agar poured into the slopes. This reduces the chance of aerial contamination to a minimum.

(5) The superimposed layer of blood agar sets in about half an hour's time. The tubes are then taken up one by one, their cotton plugs flamed and properly inserted into the mouths of the tubes. The tubes are replaced in an inverted position in the cardboard tray and incubated at 37°C. for a day. The object of inverting the tubes is to allow any moisture to evaporate and thus provide a dry blood agar surface the next day. If this precaution is neglected the colonies tend to run together and to form a bacterial film which renders the isolation of the individual colonies impossible. In cases where water of condensation is required, the tubes should not be inverted.

(6) After incubation, any contaminated slopes should be discarded, and the sterile slopes stored in the dark. Whenever these slopes have to be used they should be carefully examined with the naked eye as well as by means of a magnifying lens for any stray contaminating colony of a type which is usually quite small, translucent and slow-growing.

Ordinary agar slopes are capable of being used both for the growth of aerobic and

anaerobic organisms, suitable conditions for the latter being secured by Wright's simple technique of chemical anaerobiosis. (6) Since the idea of superimposing blood agar on ordinary agar slopes first occurred in connection with the determination of the hæmolytic character of anaerobes by Wright's method, it may not be out of place to describe here the modification effected in his technique. In this, the rubber cap or stopper is replaced by a plasticine plug mounted on a piece of glass slide; the plasticine is hollowed out to contain the alkali solution, while the pyrogallol acid crystals are folded in absorbent cotton and inserted in the neck of the tube. This modification is made with the object of sealing the tube prior to making the mixture of alkali and pyrogallol, so that all the oxygen absorbed might be derived entirely from within the tube, as in the case of Buchner's tube. The anaerobic condition thus secured has been found to allow the growth of the tetanus bacillus—a strict anaerobe.

The Plasticine Plug Technique for Chemical Anaerobiosis.

(a) Cut off about half of the absorbent cotton-wool plug of the inoculated blood agar tube, and push in the remaining plug into the tube so that it is about one centimetre above the upper end of the slope and about two centimetres below the mouth of the tube.

(b) Make a thin layer of absorbent cotton-wool about two centimetres wide, and fold in it two salt-spoonfuls of pyrogallol acid crystals so as to form a round mass, a little wider than the tube, in the mouth of which it is then inserted, so as to remain flush with the margins of the tube.

(c) A glass slide is cut into two equal parts and on one of these pieces a lump of plasticine, about the size of a walnut, is so pressed by means of another slide that a circular platform about a centimetre high is obtained; its width should not be more than that of the glass slide. The moistened bottom of a Wassermann test tube is pressed in the centre of the mass of plasticine so as to obtain a hollow to hold about a cubic centimetre of liquid.

(d) From a drop bottle a ten per cent. caustic soda solution is dropped into the hollow in the plasticine, so as just to fill it, taking care that none of the solution is allowed to run over the margins of the hollow.

(e) Now take up the blood agar tube and press its mouth on the plasticine so that the margins of the tube cut into the plasticine and effectively seal the tube. During this manœuvre the cotton-wool holding the pyrogallol acid crystals comes in contact with the caustic soda solution which very soon penetrates the cotton and commences to act on the crystals. After a minute or two the tube is lifted up in a slanting position and rolled a little so as to allow all the caustic solution to be soaked up by the cotton. The tube is then put back in the inverted position and so placed in the incubator.

It need not be pointed out that the glass slide which is fast stuck to the plasticine plug pressed on it, not only serves as a cover for the plug, but also as a base for the tube to stand erect in an inverted position.

To secure a stricter anaerobic condition, the cotton-wool plug of the inoculated tube is taken off altogether and the tube kept in a slanting position until it is sealed as described above. Further, after sealing it should always be kept in the inverted position in order that none of the pyrogallol alkali mixture accidentally runs down the tube, since there is no cotton barrier to absorb the overflow if any.

When growth has occurred, the mouth of the tube is drawn out from the plasticine seal, the soiled cotton-wool removed, the mouth of the tube cleaned by dipping it in sterile water and wiped dry with sterile cotton; during all these manœuvres the tube is held in the inverted position. Finally, the tube is replugged with a fresh cotton plug from a sterile tube and handled like an aerobic culture.

SUMMARY

In the tropics tubed media are more serviceable than plated ones, owing to the great liability of the latter to aerial contamination; this susceptibility becomes much greater when the medium contains blood or serum.

Next to nutrient agar, the medium most generally required for surface cultivation is blood agar. Blood agar slopes, as ordinarily made are useful for growth purposes only. For the determination of the hæmolytic property of bacteria, blood agar plates are a necessity. However, plated media have to be freshly made and are not amenable to any simple procedure of anaerobiosis resembling Wright's.

These drawbacks in the wider routine use of blood agar have been circumvented by the simple device of securing a thin layer of blood agar by pouring it on agar slants instead of into the Petri dish; each slant requires about three cubic centimetres of the medium to provide a layer about two millimetres thick.

The agar slope provides an even, absorbent, moisture-bearing base for the blood agar in place of the uneven, dry glass surface in the Petri dish. In consequence the *superimposed blood agar slope* not only retains the red colour for over a week if properly made and stored, but the blood agar remains available for growth purposes for a much longer period.

The superimposed blood agar slope has placed the isolation of aerobic and anaerobic bacteria and the determination of their hæmolytic character within the easy reach of all workers, whether in the field or in well equipped laboratories. Above all, it has been instrumental in bringing to light a fact unsuspected so far, that the plague bacillus is one of those bacteria which require blood or serum for their optimum growth in surface cultivation.

AVERTIN RECTAL NARCOSIS.

By A. R. PODUVAL, B.A., M.D., C.M.,
Trichur.

THE rectal route for anæsthesia has been long under consideration. The first efforts in this direction were made by F. Roux in 1846. The undeniable advantages of the rectal route, the easiness of administration, the avoidance of choking and excitation, and freedom from complications, opened up the way for further research. Injury to the bowel wall was the great danger in the experiments of Roux and Pirogoff with ether. "Avertin" is an attempt to avoid all these dangers, and ensure a safe and sure anæsthesia.

Chemical Properties.—Avertin, a tri-bromoethyl-alcohol, is a white crystalline substance, easily sublimable, with a melting point of 79.8°C ., soluble in water at 40°C . to the extent of 3 per cent. It is likely to be decomposed by free exposure to light and air, and hence must be protected and securely kept in tinted bottles. It was first produced by Willstaetter and W. Duisberg by the fermentation of yeast on bromal, but Meerwin and Nord later succeeded in producing it in an easier way. Avertin begins to decompose at about 45°C ., producing hydrobromic acid with the formation of dibromacetaldehyde, according to the following formula:

This latter is a highly irritating substance producing even in small quantities severe injury to the intestinal mucosa which may go on to necrosis or gangrene.

Pharmacology.—The discovery of the valuable properties of avertin and its introduction into therapeutics are due to the researches of Eichholtz. The pharmacological investigations and the various animal experiments conducted by Prof. Straub, Muenchen, form the basis of the modern use of avertin as a drug for narcosis. He proved that the rectal mucous membrane is capable of taking up avertin quicker than water in which it is dissolved. According to Sevensing, the blood concentration of avertin reaches 6 to 9 mgm. per cent. during narcosis.

Excretion.—Avertin is excreted from the system combined with glycuronic acid, and in this form Professor Straub could recover 81 per cent. of the drug from the urine. Very slight traces of bromine are found in the sweat, but no traces of it could be found in the fæces or the expired air.

I do not propose to go into the results of animal experiments done to demonstrate the action and range of the application of avertin. It forms a literature in itself. Lendle fixes its therapeutic range as 1:7. In the modifications of its application, the last word has not yet been said, and experiments are still going on in Germany. But its place as an important anæsthetic has been established beyond a doubt.

My experience with avertin narcosis amounts to over 100 cases in which I myself have administered the drug, and another 500 in which I have seen it used. Every new drug introduced into the armamentarium of the physician and surgeon has to go through the ordeal by fire, and avertin is not lacking in dramatic experiences. I may here state that beyond an occasional "cyanosis" and rarer refractory case, we have not had any unpleasant symptoms, and no deaths attributable to the narcotic itself in our series.

Instead of saturating a patient with a particular form of anæsthetic, say chloroform or ether, from beginning to end, the tendency in Germany to-day is to gradually "lead on to complete narcosis" by stages, "*Zusatz narcose*." Avertin finds its best application here. Complete surgical anæsthesia with avertin is not advised; though many patients with the prescribed doses do not require any further addition of inhalation narcotic. The great advantage of avertin is that it is given by the rectum, and the patient is saved the unpleasantness of the taste, the smell and the anxiety—the psychic shock—so common in inhalation narcosis.

Procedure.—In the Eppendorf Krankenhaus the patients for avertin narcosis are prepared as follows:—

On the afternoon of the day before the operation, the patient is given a dose of "*bitterwasser*" (sodium sulphate mixture) and 0.5 gramme of veronal at bed time. The next morning the lower bowel is washed out by a copious enema of saline.

The patient is allowed $\frac{1}{2}$ to $\frac{3}{4}$ litre of tea in the morning if he likes to have it; or if it is indicated on account of the dehydration of tissues. About 1 to $1\frac{1}{2}$ hours before the operation, he is given 1 to 2 c.cm. of pantopon or $1\frac{1}{6}$ to $1\frac{1}{3}$ gr. of morphia. In special cases, just before starting the anæsthetic, or during its course we give one ampoule of Raceme ephedrin, Merck, subcutaneously for its effects on the blood-pressure and respiration.

In June 1928 the drug was supplied to us in the solid form, but later we used to receive "Liquid Avertin" (dissolved in amylene hydrate), 1 c.cm. of which contains 1 gramme of avertin. In the clinic of Professor Roedelius, Eppendorf, we were using at that time a dose of 0.15 grm. per kilogram of body-weight, but the manufacturers themselves on the basis of their reports advise a dose of 0.08 to 0.1 grm. per kilo. of body-weight as much safer. The anæsthetic is always given in a separate room, which is preferably kept dark and quiet. The required quantity of avertin is mixed with mucilage of salep, which should be absolutely neutral in reaction, making up a 3 per cent. solution. The drug and the solvent must be vigorously shaken in a glass flask, then placed in a water bath till the solution is at a temperature of 40°C .

Case.—The patient, young, healthy, well built, has a tumour on the right side of the neck in the region of the right lobe of the thyroid. Weight 71 kilograms.

For 71 kilos, we require 71×0.15 or 10.65 grms. of avertin. This quantity was mixed up with 426 c.cm. of mucilage, warmed and poured into a glass irrigator, fitted with a rubber tube and glass nozzle. The patient was asked to turn on to his right side, and a rectal tube about a foot long and about the thickness of a little finger after thorough smearing with vaseline was introduced into the rectum for about 8 inches. The rubber tube of the enema was now emptied of its contained air, and the nozzle introduced into the opening of the rectal tube and the whole solution emptied into the rectum by gravity. The enema tube was pressed and squeezed to completely empty it of its contents. A pair of forceps was now clipped on to the rectal tube to prevent the contents flowing out and the patient turned on his face, with the rectal tube *in situ*.

For about ten minutes the patient was talking as usual, but ceased talking rather suddenly. The eyelids seemed very heavy, the conjunctivæ a bit red, just like a man who wants badly to sleep. The nurse now put a piece of folded gauze over the eyes and waited.

There was a slight "cyanosis" of the face, which soon disappeared. There was no struggling, no gasping, no respiratory trouble, or any of the ordinary unpleasant symptoms connected with chloroform or ether narcosis. The patient just appeared to be sleeping, that is all. At this time the reflexes were all present, and the pupils reacted to light. In another five minutes the reflexes became sluggish, then entirely lost, the pupils being well contracted. Pinching of the skin produced no response. At this stage the patient was removed to the operation table.

This was a delightfully favourable case, in which the anaesthesia set in promptly and quickly, and there was no necessity to add chloroform or ether as inhalation. In other cases, I have noticed a slight tendency on the part of the patient to be a bit incoherent during the first few minutes; a later onset of anaesthesia varying from 20 to 30 minutes; decided cyanosis which passes away in about 10 minutes, and more quickly if the lower jaw is kept raised, sometimes a slightly shallow breathing, with increase in the number of respirations, but hardly any effect on the pulse. I remember in the whole of our series one case—a lean elderly man of about 60, suffering from cancer of the stomach, who when taken to the table after the administration of avertin, entirely stopped breathing. An injection of lobeline immediately started regular respirations. The operation was successfully completed (subtotal resection by the Hofmeister-Finsterer-Reichel-Polya method) without the addition of any further narcotic.

Some patients require a slight addition of an inhalation narcotic, such as chloroethyl or ether just before the incision. This is particularly indicated in the upper abdominal region for better relaxation. In any case, the inhalation anaesthetic can be soon withdrawn, and the amount used thus considerably reduced. It is always safer to regulate the dose, keeping to the lower limit of dosage and complete the anaesthesia by a little chloroethyl or ether. Occasionally, a refractory case is encountered and such a patient invariably has a history of alcoholism.

Various other diluents for avertin are used in different clinics. Some use distilled water, others normal saline solution with or without 1/10th its volume of milk, others normosal lotion. These seem to make no difference whatever. In all cases it is necessary to test the reaction of avertin, to be sure that it has not undergone any decomposition and that no hydrobromic acid is present. The temperature of the solution under no circumstances should exceed 40°C.

Test.—Two drops of a 1 in 1000 watery solution of Congo red are added to 5 c.c. of a 3 per cent. avertin solution in distilled water. The solution must now have an orange red colour, which must not change into blue. The change of colour into blue denotes the presence of HBr and such solutions ought to be discarded.

Several interesting modifications in the method of administration have been introduced with hardly any noteworthy effects. Goecke gives first a small dose, then increases it drop by drop up to the fixed dose. Borchardt, Grewing, Lobenhoffer, etc. place the patient in the Trendelenberg position to increase the speed of absorption.

Professor Bier of Berlin has latterly added 0.3 gm. of narcophin and 20 c.c. of a 20 per cent. solution of magnesium sulphate to the avertin solution to increase the intensity of narcosis. I have seen only about a dozen cases of this modification in the Eppendorf Krankenhaus, just before I left for India. True, most of them did not require a *zusatz narcotic*; but a few of the patients seemed rather unpleasantly pale on the table, though otherwise there was nothing wrong.

In a few cases, I have noticed the patients trying to lift their lower limbs during the course of the operation and as soon drop them back again. These slight movements do not interfere with the operation at all.

Secondary effects.—Thanks to the several thousands of reports that we have from famous surgeons all over Central Europe, avertin can be dispassionately judged on its own merits. The secondary effects of avertin must be considered in their true light, and its responsibility for producing these effects separated from faulty technique and faulty selection of patients.

1. *Injury to the bowel.*—During the early experiments with avertin, serious injury to the mucous membrane of the bowel was reported, which has since been found to be due to the formation of dibromacetaldehyde by overheating of

avertin. This is no longer to be feared if we keep within the strict bounds of the directions given (Borchardt, Hirsch, Nordmann, Schmieden, etc.).

2. *Respiration*.—The respiratory centre shows a most decided reaction to avertin. I have already mentioned the "cyanosis" seen at the beginning of anæsthesia, but in some cases patients grow decidedly blue or purple, the colour being noticeable not only on the face and lips, but on the finger nails as well. We do not know why some patients exhibit this phenomenon more than others, probably it is an individual susceptibility of the respiratory centre. In such cases, Professor Straub advises that the remainder of the enema still lying in the ampulla recti may be allowed to flow out. "In every case, after the patient is in a deep sleep, the remainder of the enema may be allowed to run out." This avoids overdosage and shortens the period of after-effects (Eichholtz). To relieve the respiratory distress, raising the lower jaw often suffices; in more protracted cases, the best drugs to use are lobeline, ephedrine or Raceme ephetonin, Merck, or caffeine, which at the same time increases the blood pressure. Heuss, Polano, Sievers, etc., advise the inhalation of carbon dioxide which in avertin narcosis is thought to be superior to every other respiratory stimulant (Borchardt). In the post-operative period, if any slight respiratory troubles are found (I have not noticed any in our series) and mechanical causes can be excluded, the condition can be best relieved by the administration of thyroxin, or grape sugar, (Bender).

3. *Blood-Pressure*.—A fall of blood-pressure as in any other form of narcosis, as well as in physiological sleep, is to be expected with avertin, though in my experience this is not constant. I have, however, noticed cases in which there has been a fall of from 5 to 40 mm. Hg., but generally it rises to the normal in a few minutes, sometimes above the level of blood-pressure noted before the administration of the anæsthetic, (psychic). Decided falls in pressure can be prevented by the injection of suprarenin or ephetonin.

4. *Heart and Blood Vessels*.—The pulse hardly ever shows any alteration in rate or volume. Injury to the heart through avertin could not be proved even by the electro-cardiograph (May and Unger), though such is a common event in chloroform narcosis.

5. *Liver*.—The liver remains unaffected (in contrast to the effect of chloroform on the liver). Reischauer mentions one case of fatty degeneration of the liver with a dosage of 0.15 grm. per kilo. of body-weight.

6. *Kidneys*.—A few cases of albuminuria have been noted by Borchardt, Nordmann, and others; this disappears in a few days. Has reports an undue tendency to venous hæmorrhage after avertin narcosis.

7. *Metabolism*.—As in chloroform, the acid-base equilibrium is shifted to the acid side after large doses.

Duration of anæsthesia.—The usual period of narcosis with avertin varies from 1½ to 2 hours, according to the dosage. In our hospital the remainder of the solution in the rectum is always removed on the table at the close of the operation, and the rectum washed out with normal saline solution. In the post-anæsthetic period a nurse must always be at the side of the patient, to prevent the falling of the lower jaw, which may produce respiratory embarrassment.

The patient awakens as from a sleep, complaining of nothing, and again drops back into a pleasant sleep for 3 to 4 hours, during which he gets over the immediate pain of the operation without any suffering. The great dangers of inhalation narcosis, such as post-operative pneumonia and bronchitis, are considerably reduced. My chief, Professor Roedelius, is in the habit of saying that these are no worse after avertin than after local anæsthesia. Exceptionally, a few cases of restlessness have been reported in the waking period, which is easily controlled by an injection of eukodal, or pantopon.

Indications and Contraindications.—The great advantages of avertin in operations about the head, face and neck, where inhalation anæsthesia is likely to interfere seriously with the comfort of the operator are at once evident. Thus in cleft-palate (Gossmann) in Basedow's disease (Butzenjeiger), in nose and throat operations, etc., it is especially recommended. As a matter of fact, it has been used in almost every case in which inhalation narcosis has hitherto been used.

As contraindications may be mentioned acute and chronic inflammations of the bowel (diarrhoea, dysentery, colitis, etc.), hepatic diseases, severe renal diseases, acidosis, serious diseases of the blood, advanced cachexia, and advanced pulmonary tuberculosis.

As relative contraindications requiring a very cautious dose of avertin may be mentioned the debilitated and the aged, those who are depleted of fluids, and the very obese. In intestinal obstruction and peritonitis, it is safer to give at first a small dose of avertin, to be cautiously increased as may be necessary, as one does not know the extent of damage to the bowel, or its capacity for absorption.

Other uses.—Beyond the domain of general surgery, avertin has been used in obstetrics (Dammerschlaff) and gynæcology, otolaryngology, pediatrics, eclampsia, tetanus, and psychiatry.

Summary.—Avertin must be regarded as a "basal narcotic" and it is always safer to so regulate the dose that the operation can be conducted with a little "zusatz narkose" of chloroform, ether, or chloroform.

The dosage of 0.15 grm. seems too high. It is better to start with a smaller dose of 0.08 to 0.1 grm. and intensify the anæsthesia when necessary.

halation. The purity of the drug should be tested.

The directions for preparation and administration of the solution must be strictly followed to avoid unpleasant effects. A glass syringe of 10 c.c. capacity may well replace the enema tatus. Avertin should always be given at a temperature between 37° to 40°C. in a 3 per cent. solution. The administration should be conducted in a dark quiet room for preference.

Swelling of the lower jaw should be looked for from the beginning until the awakening of the patient from anaesthesia.

When I joined the "Allgemines Krankenhaus" Eppendorf, Hamburg, in June 1928, Professor Roedelius of the 2nd Surgical Clinic was already performing the majority of major operations with this anaesthetic, and had already reports of nearly 600 operations done under avertin narcosis. But in the University Clinics of Germany and in Vienna, avertin was being used extensively; and on inquiry I found that at that time the manufacturers of the drug (I. G. Farbenindustrie, Leverkusen) had accumulated reports of nearly 10,000 cases of avertin narcosis. Up to date January 1929, the number of operations done under this anaesthetic in Central Europe amounts to about 20,000. These facts are important, as they serve to remove several false impressions regarding the delivery and therapeutic application of avertin. I remember several French, American and English doctors coming to Eppendorf Krankenhaus to learn the technique of avertin narcosis during the latter part of 1928. The methods of using avertin differ slightly in different clinics, and as we had generally uniform success with avertin, some of these doctors seemed very keen in learning the "Eppendorf" methods.

AN ANALYSIS OF 675 CASES OF PUERPERAL MORBIDITY TREATED IN THE ROTUNDA HOSPITAL, DUBLIN.

By P. C. DUTTA, M.B. (Cal.),

F.R.C.S. (Edin.), D.G.O. (Dub.),

LIEUTENANT, I.M.S.,

late Post-graduate Student, Rotunda Hospital, Dublin.

From January 1921 to June 1927, 11,638 patients were confined in the Rotunda Hospital. According to one of the standards of the British Medical Association, 675 of them were

morbid during the puerperium. Only two cases were admitted for treatment of sepsis which were not attended by the hospital. This gives a morbidity rate of 5.8 per cent. during 6½ years.

In the analysis, the cases have been classified into four groups:

(i) Where the fever was due to some definite extragenital cause.

(ii) Cases in which the fever was due to the retention of the products of conception.

(iii) Fever due to obvious puerperal infection, or its duration was more than four days.

(iv) Where no definite cause of the fever could be found, and its duration was not more than four days.

Group I.—There were 242 cases belonging to this group. They were—

Mastitis	78
Influenza	52
Constipation	24
Tuberculosis	13
Eclampsia	8
Cystitis	5
Pyelitis	7
Other causes	55
TOTAL				242

So 35.7 per cent. of the total morbidity was due to definite extragenital causes.

Group II.—There were 40 patients who could be included in this group, or 5.3 per cent. Three of them were associated with forceps delivery.

Group III.—167 cases belonged to this group. This included 55 cases of perineal tears, where the perineum itself was the septic focus, and 16 of these were associated with forceps delivery. There were 98 cases of operative delivery in this group in all.

Group IV.—There were 226 cases where no definite cause of the fever could be ascertained. This included 62 cases of perineal tears, 20 of whom were associated with forceps application, where the perineal wound itself was not septic. This shows that aseptic trauma is liable to cause a morbid puerperium. Altogether there were 107 cases of operative delivery in this group.

Analysis of the cases from certain aetiological points.—There were 280 primiparae, 106 of whom belonged to Group III (definite puerperal sepsis), and 174 to Group IV (fever due to unknown cause). The association of rupture of the perineum in primiparae and morbidity is remarkable. There were 125 patients with perineal tear in the series under review, and 121 of them were primiparae.

Exhaustion due to long and tedious labour decidedly predisposes to morbidity. In some cases exhaustion by itself, without any detectable infective lesion has caused a morbid puerperium. In this series, in 106 patients the duration of the first and second stages of labour together were 20 hours or over, and seven of them were fatal, roughly a mortality of 7 per cent. The mortality increases with the length of labour and increase in the acidosis of the blood. Fifty-five of these 106 patients had

undergone some form of internal manipulation during delivery and 15 had a lacerated perineum.

In these 106 cases, where the duration of labour was 20 hours or over, the length of puerperal illness was as detailed below:

Number of days ill.	Number of patients.
1 day ..	9
2 days ..	36
3 " ..	20
4 " ..	13
5 " ..	6
6 to 8 days ..	13
9 to 10 " ..	4
11 to 14 " ..	2
2 to 3 weeks ..	3

Some authorities suggest that the duration of the third stage of labour has some effect in causing morbidity during puerperium, but the conclusions that can be drawn from this series of cases do not agree with this. Only in 14 patients was the third stage longer than one hour, and this includes seven cases of operative delivery and one of lacerated perineum. None of them was fatal. The duration of morbidity, where the third stage was more than an hour was as follows:

Number of days ill.	Number of patients.
1 day ..	5
2 days ..	2
3 " ..	2
4 to 10 days ..	2
10 to 14 " ..	3

The committee appointed by the obstetrical section of the Royal Society of Medicine to investigate and report on puerperal sepsis observed albuminuria did not play any part in the onset of infection. During the period under review there were 1,131 patients with albuminuria during labour, and 103 were morbid at puerperium. In other words, 11 per cent. of the patients suffering from albuminuria during labour were morbid, whereas the morbidity rate, taken all round, was 5.8 per cent. only, that is, in patients with albuminuria the morbidity rate was nearly double. Of the above stated 103 cases 22 had undergone operative delivery. Therefore the morbidity rate of patients having albuminuria who had undergone operative delivery was 22 per cent. roughly, whereas the morbidity rate of all operation cases during the period under review was 17.2 per cent. This definitely shows albuminuria predisposes to infection.

There were nine cases of puerperal insanity during the period and only one of them had a morbid puerperium, suggesting that, contrary to the usual belief, infection is not the chief cause of puerperal insanity.

An analysis of the morbid cases which had undergone operative delivery is presented in a tabular form. The morbidity rate was 17.2 per

TABLE I.

Analysis of the morbid cases which had undergone operative delivery.

Nature of operation.	Total No. of operations done.	No. of cases with morbid puerperium.	CASES DEFINITELY SEPTIC. (GROUP III.)		FEVER DUE TO UNKNOWN CAUSES. (GROUP IV.)	
			Number.	Associated conditions.	Number.	Associated conditions.
Forceps ..	721	113	52	Mastitis, 2. Influenza, 3. Pubiotomy, 5. Manual removal of placenta, 2. Perineal tear, 15. Internal pelvimetry, 2. Induction of labour, 1. Perforation, 1. Eclampsia, 2. Cæsarean section, 1.	61	Pubiotomy, 8. Eclampsia, 1. Internal pelvimetry, 5. Induction of labour, 7.

Internal version ..	151	7	2	Manual removal of placenta, 1.	5	Nil
Craniotomy ..	21	7	5	Nil	2	Forceps, 1.
Internal pelvimetry	(Not recorded).	9	7	Forceps, 4. Cæsarean section, 1. Induction of labour, 1.	2	Forceps, 2.
Decapitation	4	4	Eclampsia, 1.	Nil	Nil
Lacerated perineum	..	125	66	Forceps, 21.	59	Forceps, 15.

There were 25 cases of malpresentation in this series; 11 of them underwent internal manipulations during delivery.

Cæsarean section was done in 98 cases; forty-one of them were morbid during the puerperium. The classical operation was carried out in 90, and 8 had the lower segment operation. In both the series the average duration of morbidity was seven days. Four cases ended fatally, and in all of them the classical operation was done.

There were 4 cases of accidental hæmorrhage, 12 of placenta prævia and 15 of post-partum hæmorrhage. In 13 of these hæmorrhage cases internal manipulations had been done.

Fatal Cases.—There were 24 deaths among 675 patients who were morbid, a mortality of 3.5 per cent. due to sepsis. In 7 of them no internal manipulation was done during delivery, and the labour was easy and normal. As already stated, there were 4 cases of Cæsarean section, and all had the classical operation done; one of them died from intestinal obstruction and three from general peritonitis. In one patient Cæsarean section was done at the end of trial labour and the baby was dead. In the second it was done 26 hours after rupture of the membranes, and in the third after failing to deliver with the forceps.

Blood culture was done in eight of the cases which ended fatally and 5 of them yielded *Streptococcus hæmolyticus*. Culture from uterine swabs was done in 12 of these cases, and all yielded some form of growth except one. Nine yielded *Streptococcus hæmolyticus*, one *B. coli* and one a mixed growth of both. One patient died from gas gangrene infection (*B. welchii*). Among the operation cases which ended fatally, there were 4 of forceps delivery, 4 of perforation and decapitation, 4 of manual removal of placenta, one of pubiotomy, one of induction of labour with stomach tube and one of rupture of the uterus.

TREATMENT.

Prophylactic.—Antistreptococcal serum was used for preventive purposes in 33 cases: 13 of them had a morbid puerperium including 4 deaths.

Puerperal antitoxic serum. This was specially supplied for experimental purposes. As the name implies it is an antitoxic serum and not antibacterial. It was used in 6 desperate cases and so far as can be judged from these few, the effect was very good.

CASES.

Case 1.—Perforation and embryotomy was done, followed by hysterectomy for rupture of the uterus. On the first evening she had a temperature of 100°F. and pulse rate 100, and was given the serum (20 c.c.). The patient was not morbid according to the standard laid down by the British Medical Association.

Case 2.—Neglected shoulder presentation causing rupture of the uterus: decapitation was done, and the uterus plugged with gauze. She was admitted in a very poor condition and submammary and intravenous saline were given. Then 20 c.c. of the antitoxic serum was injected. The puerperium was stormy from the third to

sixteenth days. The plug was removed on the eighth day. Highest pulse and temperature were 130° and 104.6°F., respectively, on the fifteenth day. Blood culture—sterile. There was parametritis and it drained through a rent in the uterus. The patient recovered ultimately.

Case 3.—First pregnancy, forceps delivery after 26 hours' labour. 20 c.c. of the antitoxic serum after delivery. Morbid for four days.

Case 4.—The patient had a rise of temperature before delivery. Craniotomy was done after 15 hours' labour. Prophylactic antitoxic serum 8 c.c. Morbid for 4 days only.

Case 5.—Second pregnancy. Too many vaginal examinations had been done outside. Prophylactic antitoxic serum 10 c.c. Morbid for 2 days.

Case 6.—Classical Cæsarean section late in labour. After operation the mother had 10 c.c. of the serum. She got 20 c.c. of collosol iodine on the third day. Later developed symptoms of intestinal obstruction; the abdomen was opened but the patient died ultimately.

Iodine.—Collosol iodine, given intravenously in 20 c.c. doses, has a fairly good effect as a prophylactic. How it acts is not definitely known. In the proportion it circulates in the blood it cannot be strong enough to act as an antiseptic. Moreover at this stage there are hardly any organisms in the blood. Organisms grow abundantly in a medium containing a far greater proportion of iodine than would be in the blood when 20 c.c. of collosol iodine is given intravenously. It does not produce any leucocytosis in the blood, nor does it increase the phagocytic power of the individual leucocyte. It may be said that iodine by stimulating the thyroid gland increases the metabolic rate and thereby enhances the patient's resistance against bacteria; and this can be produced more easily and effectively before the patient is really ill.

Curative.—In 1921, six patients were treated with intravenous injections of eusol, novarsenobillon and sodium bicarbonate. Three of them died.

Vaccines were used in six cases, with one death.

Antistreptococcal serum was used in 10 cases. In four of them the temperature came down on the day when the injection was given. There was only one death.

Antiscarlatina serum was used in five cases, and in all of them the uterine culture was positive. Two of them yielded a mixed growth of streptococci and staphylococci, two *Streptococcus hæmolyticus* alone and one staphylococcus alone. There was no death.

Collosol iodine was used from March 1925, and 78 patients were treated with it in this series. There were three deaths, including one from intestinal obstruction following Cæsarean section. So the mortality of the cases treated with iodine is about 2.5 per cent., whereas in the rest, i.e., 597 cases, who were not treated with iodine there were 21 deaths, the mortality being 3.5 per cent. roughly. The administration of collosol iodine does not appear to shorten the average period of morbidity, as compared with the series of cases who had no iodine treatment. From the analysis of these cases it does not appear that iodine has any specially beneficial effect when a case is already septic, but if administered early it certainly

does good, and to get the full benefit of the drug it should be given as early as possible.

SUMMARY.

1. The morbidity rate during the period under review was 5.8 per cent. The morbidity of the operation cases was 17.2 per cent. Only in 32 per cent. of all the morbid cases was the morbidity due to a detectable focus of puerperal infection.

2. Exhaustion from long labour predisposes to infection, probably by causing an acidosis in the system. Albuminuria also predisposes to sepsis.

3. There were 24 deaths from sepsis among 11,638 patients confined, of whom 675 were morbid.

4. Collosol iodine given early is useful.

5. Puerperal antitoxic serum appears to have a good effect as a prophylactic in cases where the puerperium is likely to be septic.

I beg to thank Dr. Bethel Solomons, Master of the Rotunda Hospital, for the facilities he afforded me while working there.

(Note.—Before publishing the above paper, we decided to refer it to the Master of the Rotunda Hospital, Dublin, Dr. Bethel Solomons. In reply Dr. Solomons writes that he consents to publication, but would point out that the statistics ranged over the end of one Mastership and the beginning of another, so that there was not uniformity of treatment. Also the Cæsarian section results quoted were before the popularity of the lower segment operation. Much of the matter dealt with will be found in the Rotunda Hospital reports.—Editor, *I. M. G.*)

LEPROUS REACTION.

By JOHN LOWE, M.B., Ch.B.,
Medical Officer, Leprosy Hospital,
Dichpali, N. G. S. Railways.

LEPROSY is usually a chronic disease but at certain stages there may be acute exacerbations which are usually temporary, passing off after a few days or weeks. These acute exacerbations are what are known as leprous reaction or leprotic fever. This phenomenon is well known to leprologists. Leprous reaction is of great importance and calls for further study. The following is an account of observations of leprous reaction made during the treatment of several hundred cases of leprosy.

Type of case in which leprous reaction is seen.

Generally speaking the greater the number of *Mycobacteria lepra* there in the system, the greater is the tendency to leprous reaction. Reaction is rarely seen in the early case of nerve leprosy, but the passage from the A1 stage to the B1 stage may be marked by leprous reaction. During the B stages of skin leprosy, reaction is much more commonly seen, but as the A2 stage is approached, reaction becomes more and more rare.

Clinical signs of reaction.

One of the most striking things about leprous reaction is the amazing variety of the clinical manifestations. The commonest of these manifestations are here enumerated and briefly described. Many of these may be present in one patient, and in other patients only one or two of these manifestations may be found clinically.

(a) *General*.—Fever, malaise, sleeplessness, pains in nerves and in joints.

(b) *Lesions of the skin*.—These are, first, an inflammation of the previously existing skin lesions and, second, the appearance of new skin lesions. The old lesions, nodules and thickenings become inflamed, erythematous and swollen. Suppuration and ulceration of the skin lesions is sometimes seen. The new lesions may take many forms. The commonest is the small round erythematous lesion situated in the deeper layers of the skin. These may be very numerous and scattered all over the body, but are most commonly seen on the extensor surfaces and on exposed parts. Another common form is the slightly thickened erythematous border to a depigmented patch. Erythematous macules with definite borders, and diffuse erythema with slight thickening of the skin are sometimes seen. Rarer skin lesions are papules and pustules. Sometimes the reactionary lesions are not visible and can only be detected by deep palpation as they are situated in the very deep layers of the skin. These subcutaneous reactionary lesions may take the form of discrete nodular thickenings, or there may be diffuse thickening of the skin and subcutaneous tissue giving an appearance and feel like scleroderma. A recent case of leprous reaction showed no lesions in the skin but the subcutaneous tissues of the arms and legs were thickened, hard and painful.

(c) *Lesions of nerves*.—Commonly there is acute inflammation of nerves, especially the ulnar nerve. A nerve which was previously only slightly thickened may swell up as thick as a finger. This may give rise to excruciating pain. Frequently there is an increase in anæsthesia in the distribution of the affected nerve. Sometimes nerve reaction gives rise to nerve abscess.

(d) *Lesions of the nose*.—There is frequently an increase in the nasal symptoms. Nodules may swell and ulcerate and epistaxis is common. Frequently the nose may be completely blocked by swelling and ulceration of the lesions and by the discharge.

(e) *Lesions of the eye*.—Irido-cyclitis is very commonly seen.

(f) *Lesions of the larynx*.—If nodulation is present in the larynx, reaction sometimes causes swelling of the nodules and respiratory obstruction, and tracheotomy may be necessary.

(g) *Lesions of the internal organs* are not common in leprosy, but when they do occur they are nearly always associated with leprous reaction.

The lungs.—In one recent case the lungs were affected with what was apparently a leprous broncho-pneumonia. Large numbers of acid-fast bacilli were found in the sputum, the temperature rose to 104°F ., respiration was very rapid, and there was patchy consolidation of the lungs. This was associated with reactionary lesions in the skin and in the nerves. The whole condition cleared up in about three weeks.

The testis.—Leprous orchitis is commonly seen in leprous reaction.

The liver.—An acute leprous hepatitis is occasionally seen. A recent case had leprous reactionary lesions in the skin associated with extreme tenderness and enlargement of the liver, which extended down to within two inches of the umbilicus. As the reaction subsided the liver enlargement disappeared. There was no jaundice.

The spleen.—Tenderness and enlargement of the spleen have been seen in one or two cases of leprous reaction.

The kidneys.—The kidneys may be affected, causing an acute leprous nephritis with general cedema and suppression of urine. The signs may be the same as those found in other forms of acute nephritis. Leprosy bacilli are often found in the urine. Death may occur or the nephritis may disappear with the subsidence of the reaction.

(h) Lesions of joints.—Joint pains are very common in leprous reaction and are caused by an acute arthritis. Frequently there is effusion of serous fluid into the joint, particularly in the knee. As the reaction subsides, the fluid becomes absorbed, but if reactions are severe and repeated, adhesions and limitation of movement may result.

Pathological examination of leprous reactionary lesions.

Unfortunately we have only been able to examine a few reactionary skin lesions removed by biopsy. The changes found are those usually seen in the leprous skin but in addition there are often small areas of hæmorrhage and there may be much invasion by polymorphonuclear leucocytes. Epithelioid lepra cells are usually numerous and some of them may contain lepra bacilli, but generally speaking lepra bacilli are comparatively few in number and many of them are short or beaded and do not show the ordinary bacillary form.

Blood examination in leprous reaction.

The blood shows nothing very characteristic. The red cells are usually about normal in number, though there may be some anæmia. The white cells are usually increased to about 12 to 15 thousand per cubic millimetre but there is no marked increase in any one particular cell. Usually the lymphocytes are in slightly greater proportion than normal. When suppuration occurs as the result of leprous reaction, there is an increase

in the white cells up to 25 or 30 thousand and the polymorphonuclears are particularly affected.

In some severe cases of leprous reaction lepra bacilli may be found in the blood by Crow's technique.

The rate of sedimentation of the blood corpuscles is increased in leprosy, especially in the B2-B3 stages, but in leprous reaction a still further increase in the sedimentation rate occurs, the increase being roughly proportional to the severity of the reaction.

Conditions associated with the onset of reaction.

In some cases leprous reaction occurs without any apparent exciting cause. In many cases, however, careful investigation will reveal some condition which apparently has an influence in bringing on the reaction. Generally speaking anything which tends to lower the patient's resistance may act in this way. The commonest of these factors may be summarised as follows:—

(a) *Habits and diet.*—Reaction is rare among patients who lead active healthy lives and eat good food. It is much more common among those leading sedentary lives and taking a poor diet. Semi-starvation in destitute lepers is also a common cause of reaction. An interesting observation recently made is that during the season of *Ramzan* when Mohammedans should not eat or drink anything between sunrise or sunset, leprous reaction has been frequently seen in Mohammedan patients. They have observed their religious rule and as this season in India is very hot this observation has frequently caused much suffering. At night instead of sleeping they have been eating and drinking, and at the end of a month of this trying regime with its absence of rest, leprous reaction has occurred.

(b) *Intercurrent disease.*—During the rainy season, when malaria is prevalent, malaria is commonly associated with leprous reaction. So common has it been that in every case of leprous reaction seen at the rainy season, we have examined the blood and have found malarial parasites in many cases. Other intercurrent diseases acting in the similar way are syphilis, smallpox, typhoid, influenza, etc. Pregnancy and confinement may cause leprous reaction. Recently all the patients in our institution have been vaccinated against smallpox and several have had a reaction as a result.

(c) *Treatment.*—Most of the various forms of leprosy treatment at present in use show some tendency to produce leprous reaction. This tendency is most marked in the potassium iodide treatment, which has as its basis the principle that mild leprous reaction may be beneficial. Treatment by thyroid extract which has now been reintroduced also shows a fairly marked tendency to produce leprous reaction. The hydnocarpus preparations occasionally produce leprous reaction but this tendency is not marked. The heavy metals and their salts, if given in large doses in leprosy, frequently cause action.

The nature of leprosy reaction.

From a study of clinical manifestations leprosy reaction appears to be a toxæmia which is associated with liberation of lepra bacilli and their dissemination throughout the body.

The bacilli.—These may be the result of the multiplication of the bacilli in the body or else they may be bacilli which have previously been shut up in lepra cells and which are liberated during reaction. In either case the predisposing causes previously mentioned seem to initiate the process of either multiplication or liberation of lepra bacilli. Exactly which process occurs and how it is brought about we do not know.

The toxæmia.—There are three possible sources from which the toxin may originate. First they may be exo-toxins produced by the lepra bacilli, but lepra bacilli normally show practically no toxin production. The leper patient may have his whole body teeming with lepra bacilli, yet if he is not in the reactionary phase he will show no toxæmia. Are we therefore to conclude that lepra bacilli normally produce no toxin, but in reaction toxin is produced? The second possible origin of the toxin is by the destruction of the lepra bacilli in leprosy reaction with the liberation of endo-toxins. There is some evidence that lepra bacilli are destroyed in leprosy reaction. In reactionary lesions the bacilli often show short beaded or spore-like forms, but we have no proof that these are dead or degenerated bacilli.

A third possible origin of the toxin may be explained as follows:—The toxin may be the result of the union of an antigen (lepra bacillus) with the immune body or anboceptor produced by the defensive mechanism of the tissues. In other words, leprosy reaction may be an allergic phenomenon produced as the result of the sensitizing of the tissues to the lepra bacillus. If this is so, the toxins are not produced directly by the lepra bacillus but indirectly, the liberation of the lepra bacilli into the blood-stream acting as the exciting cause. There is some evidence that such sensitization does occur. In potassium iodide treatment, probably from the breaking down of lepra cells, lepra bacilli are liberated, the number of lepra bacilli liberated being roughly proportional to the dose of potassium iodide given. Cases are frequently seen in whom before sensitization 240 grains of potassium iodide can be given without causing reaction, but after sensitization even small doses cause reaction.

Of these three possible sources of toxin, probably the third is the most important, and leprosy reaction is probably an allergic phenomenon.

The results of leprosy reaction.

All leprosy workers are agreed that severe reactions are usually harmful as they have a marked weakening effect upon the patient. Concerning the result of mild reactions various authorities have expressed different opinions. The Philippine workers consider that even mild reactions are often harmful and are to be avoided. On the other hand, Muir considers that in

some cases mild reaction is beneficial and he induces mild reaction by carefully regulated doses of potassium iodide. He considers that reactionary lesions are usually temporary and the subsidence of reaction is often accompanied by diminution in the infection. After treating about 200 patients with potassium iodide by Muir's technique I have formed the opinion that reactionary skin lesions are usually temporary, but reactionary nerve lesions and their results are often permanent. In addition reaction always has a bad effect on the general condition of the patient. In some cases reaction is followed by a diminution of the lesions, but I do not think that the proportion of patients in whom this occurs is sufficiently great to justify the use of potassium iodide as a general treatment for leprosy. I believe that of the remedies at present in use for leprosy, the best are those which show the least tendency to produce leprosy reaction, that is the hydno-carpus preparations, of which I prefer the ethyl ester.

The importance of reaction in the spread of leprosy.

It has been suggested that the period of reaction is a period of high infectivity and two possible causes of this are as follows. First, an infective case certainly discharges more bacilli from the body during the reactionary phase than during the quiescent phase. Increase in nasal discharge, suppuration of nodules, etc., increases the infectivity of the patient. Secondly, it has been suggested that the bacilli in the reactionary phase are more virulent. Definite proof of this is not available, but it is possibly so. A leprosy worker has suggested that attempts to cultivate the leprosy bacilli might be successful if the material for culture were taken from a patient in the reactionary phase.

Treatment of leprosy reaction.

Slight reaction usually passes off in a few days without treatment. The more severe leprosy reactions need careful treatment. The patient should be kept in bed and given light diet as long as fever continues. Plenty of fluid should be taken. As reaction is often associated with constipation a good purge should be given. Intravenous injection of 0.02 of a grain of potassium antimony tartrate in 1 c.c. normal saline should be repeated every other day. If the reactionary skin lesions do not subside fairly quickly they should be painted with trichloroacetic acid, 1 in 2 or 1 in 3 parts of water. Severe neuritis may be relieved by injections of adrenalin 3 minims of 1 in 1000 solution, or by oral administration of ephedrine 6 grains. These measures relieve the pain for a time, but if neuritis is very severe and persistent and there is much swelling of the nerve, then in such cases the nerves should be exposed by operation and the sheath incised and stripped off the nerve for the whole area of thickening. This stops the pain in nearly every case. Irido-cyclitis should be watched for and treated by atropine, hot fomentations and weak

antiseptic solutions and the eye should be kept covered. Nasal lesions should be treated by irrigating with warm weak antiseptic solution. By these means reactions can usually be controlled and cut short and most of the reactionary lesions will disappear. Sometimes, however, reactionary nerve lesions are persistent. The effect of potassium antimony tartrate on leprosy reaction is often most marked, but if a patient gets repeated reactions treatment with potassium antimony tartrate the drug seems to lose its efficacy.

In addition to treating the reaction, treatment of any predisposing cause to reaction, e.g., malaria, syphilis, etc., is most important.

[*Note*.—We have shown the above article to Dr. Muir, who comments on it as follows:—

(1) During leprosy reaction the bacilli may be diminished in number, but it is quite common to find very large masses of bacilli still persisting. If the bacilli have been few in number before the reaction they will be found few in number during the reaction.

(2) It is not uncommon to find 25 or 30 thousand leucocytes, even without suppuration.—*Editor, I. M. G.*]

PERTHE'S DISEASE.

By NISANATH GHOSH, M.B.,
Teacher, Berry-White Medical School,
Dibrugarh, Assam.

PERTHE'S disease is a disease with about half a dozen synonyms viz.:—pseud-coxalgia, coxaplastia, osteo-chondritis deformans, Legg's disease, Perthe's or Calve's disease, quiet hip disease, etc.

In spite of its numerous names it is not

features and what other diseases it resembles.

Perthe's disease belongs to the osteo-chondritic group which has come into prominence since radiology has come into existence. It affects the hip joint of young children at almost the same age as does tuberculous disease. It commences in the epiphysis. There may be a history—perhaps indefinite—of injury, usually trifling. The trouble complained of is often slight limping, as in early cases of tuberculous hip disease. Slight limitation of movement may also be seen. Thus in many respects it may resemble tuberculous disease of the hip joint in children.

But prognostically, pathologically and radiologically it is quite different from tuberculous disease.

The prognosis, unlike that in tuberculous disease, is good. Recovery is the rule.

The chief pathological changes are as follows:—

The bone cells in the bony nucleus of the epiphysis become dead or decalcified. So the epiphysis gets flattened, owing to pressure exerted on it by the body-weight of the patient. Later on repair takes place and new bone is deposited in the deformed epiphysis. This deformed head of the femur does not fit into the acetabulum and osteo-arthritis changes may follow.

Unlike tuberculous disease, Perthe's disease never leads to suppuration and never gives rise to serious constitutional symptoms.

very well known to the general practitioner in this part of India at least. On the other hand, it eludes detection by the average doctor, just as a veteran criminal with half a dozen names and surnames throws dust into the eyes of the average policeman.

To escape from such pitfalls in diagnosis we must know what it is, what are its chief

RADIOGRAPHIC FINDINGS.

The views about the pathology of Perthe's disease are mainly based on radiographic findings.

The radiogram of an affected joint does not present the same foggy or ground-glass-like appearance of tuberculous hip disease. In the early stage the bony nucleus of the epiphysis shows irregular density and the epiphysis itself

is compressed. Later on the epiphysis looks dense, flattened and fragmented (never hemispherical). There may be widening of the femoral neck and irregularity of the upper lip of the acetabulum.

DIAGNOSIS.

Errors in the diagnosis of this disease are often due to one or more of the following causes:—

(i) It resembles tuberculous hip disease in many respects, as well as a displaced femoral epiphysis.

children the possibility of Perthe's disease should never be lost sight of, as will be seen from the case noted below:—

Case.—On the 31st March, 1928, a boy of about ten years of age was brought to me for x-ray examination of the left hip joint, on the suspicion of tuberculous disease. He had a slightly limping gait for the last one and half years or so. The thigh on the affected side was a bit wasted—perhaps due to limited use. The general health was quite good and there was no constitutional disturbance. The facts which should have attracted the attention of every clinician in this case are:—a disease of one and a half year's duration with no other local troubles but trifling pain and a limping gait without

(ii) The possibility of its occurrence is often forgotten, though it is not an unusually rare disease.

(iii) A certain diagnosis of Perthe's disease is impossible without radiography.

Of these three the second one is very important as it escapes our attention so often. In the diagnosis of all cases of hip joint troubles in

any change in the length of the limb, without deformity, limitation of movement, abscess formation, enlargement of the iliac glands, etc., and also without any constitutional symptoms or impairment of the general health.

All the negative findings mentioned above, together with the radiographic appearances to be described and shown presently, excluded the possibility of tuberculous disease as well as of a displaced epiphysis.

X-ray examination in this case showed a dense, flattened and compressed epiphysis of the head of the

femur on the affected side (*cf.* the diagrams herewith reproduced).

Major Hayworth, M.C.S., etc., Superintendent of the X-Ray Institute of India, Dehra Dun, to whom a radiogram of this case was sent for favour of his opinion, remarks as follows:—

"I think there can be little doubt that the film you send for my opinion is of a case of Perthe's disease.

I shall be much obliged if you will send me a film of this case good enough to reduce for a lantern slide.

I have no example of this disease for demonstration purposes."

The above-mentioned remarks from an eminent radiologist not only confirm the diagnosis but testify to the comparative rarity of the disease as well.

Before concluding it may not be out of place to touch upon the etiology and treatment of this disease.

Etiology. This is not definitely known. The generally accepted theory is that a trifling and often unnoticed injury causes a defective blood supply, leading to decalcification and partial absorption of the bony nucleus of the cartilaginous epiphysis of the head of the femur. Owing to loss of bone and calcium (partial or complete), the cartilage gets flattened from the superimposed body-weight. Later on repair takes place, the blood supply is restored, and irregular bone and calcium deposit occurs in the already deformed epiphysis.

Treatment. The affected limb is to be kept free from the body-weight by some contrivance, and if there is much pain rest in bed may be necessary. Briefly these are the lines to be followed.

ISOLATION OF THE ANTINEURITIC VITAMIN.

By ASHUTOSH MUKHERJI.

Research Worker, Chemical Laboratory, Presidency College, Calcutta.

In their paper, "Isolation of the anti-beriberi vitamin," Jansen and Donath (1) have isolated the antineuritic vitamin from rice polishings using 20 per cent. acid alcohol as the extracting fluid and relying on the selective adsorption on Fuller's earth for the initial separation of the antineuritic vitamin from a large quantity of inactive material. The vitamin after liberation with baryta was further purified by the silver fractionation method of Kossel and Kutscher (2), followed by precipitation with phosphotungstic acid and platinum chloride and final alcohol-acetone fractionation.

In the present investigation we have been successful in obtaining a solid crystalline antineuritic residue from rice polishings, following more or less the method outlined by Jansen and Donath up to the platinum

purification, thus confirming their results. The final alcohol-acetone fractionation has been avoided in the present investigation, and the method successfully modified by repeating the platinum purification followed by crystallisation from water.

In all investigations attempting the isolation of vitamin B, by Funk and his collaborators (3) down to Jansen and Donath, dilute alcohol has been used to extract the vitamin. Although it is known that the antineuritic vitamin is readily soluble in water, it is remarkable that no one should have attempted to extract the vitamin by means of acid water, particularly so when we peruse the most notable work of Osborne and Wakeman (4) in which they attempted to concentrate the vitamin from yeast by means of boiling water. Jansen of course used the alcohol not to act as a solvent, but to counteract the influence of micro-organisms.

Technique.

It has therefore now been attempted to modify Jansen's technique by using acid water instead of dilute acid alcohol for the initial extraction of the vitamin from the rice polishings, using substances cheaper than alcohol for preservative purposes, thus considerably reducing the working cost. On the laboratory scale, where arrangements cannot be made for the recovery of alcohol from large volumes of water, the cost of the large volume of alcohol that is necessary must be an important consideration.

With this end in view 100 kgs. of fresh rice polishings (in two lots of 50 kgs. each) from the local rice mills have now been extracted with water containing 0.25 per cent. of sulphuric acid and saturated with thymol by adding the requisite quantity of an alcoholic solution of thymol aided by vigorous stirring. A little quantity of toluene and a few drops of chloroform were also frequently used to prevent the growth of moulds.

The rice polishings were washed in wooden casks on a countercurrent principle after the fashion of Jansen for about four days, after which the pH of the resulting liquor was adjusted to 4. One kgm. of "acid clay" was then added for every 30 kgs. of the rice polishings, and after a vigorous stirring for about a day the liquor was decanted and the vitamin liberated from the acid clay by means of baryta. The filtrate was then quickly acidified with sulphuric acid till an acid concentration of 5 per cent. was reached, after which all bases were precipitated with a solution of phosphotungstic acid in 5 per cent. H_2SO_4 . The vitamin was again liberated from the phosphotungstate by means of baryta, and after acidifying with H_2SO_4 , an excess of silver nitrate was added. The resulting precipitate was filtered off and the pH of the filtrate was slowly raised by the addition of baryta solution. The precipitate that formed between the limits pH 4.5 and pH 6 was filtered and decomposed by dilute HCl, and the filtrate from the silver chloride after decolorisation with "Norite" (the proprietary vegetable charcoal used by Jansen) was evaporated to dryness *in vacuo* over quicklime.

The residue left weighed about 3 gms. from 100 kgs. of the rice polishings. Jansen by using dilute acid alcohol obtained at this stage 5 gms. from 100 kgs. of rice polishings.

The feeding experiments were also conducted at this stage on munnia birds exactly after Jansen's method

and it was found that at a dosage of 30 mgms. per bird per day the birds were protected from polyneuritis, whereas the controls that were fed on a diet free from vitamin died between the seventh and the eleventh day.

The residue, after being thoroughly dried (in which process it loses much of its treacly nature and becomes a hygroscopic powder), is extracted in absolutely anhydrous alcohol and the platinum double salt

Jansen and is shown in the accompanying photomicrograph.

The absorption spectrum of the vitamin solution has also been taken, using the copper arc as the source of light, and it is found that there is a marked absorption in the region 3900 oA to 3300 oA and all rays shorter than

is precipitated by means of an alcoholic solution of platinic chloride. The platinum precipitate is then filtered, washed with dry absolute alcohol, suspended in water and decomposed with H_2S . The solution after filtering off the platinum sulphide, is evaporated to dryness *in vacuo* over quicklime. The platinum purification is then repeated. After repeating the process once again, the vitamin can be obtained in a crystalline form by the slow evaporation of its aqueous solution. The crystalline shape of the vitamin as thus obtained is seen to be absolutely identical with that obtained by

3248 are also absorbed. The doublet 3248 and 3274 of the copper arc, however, show quite vividly as is seen from the lower photograph. Whether the above absorption bands are characteristic of the antineuritic vitamin cannot be settled at present before we prepare the vitamin crystals from sources other than rice polishings and succeed in getting the same absorption spectrum.

My best thanks are due to Lt.-Col. H. W. Acton, I.M.S., Director, School of Tropical Medicine, Calcutta, and also to Dr. S. Ghosh, M.Sc., for their kind suggestions in connection with this work.

Conclusions.

- (1) Jansen's results have been confirmed.
- (2) The method of isolating the anti-neuritic vitamin has been modified by using acid water in place of acid alcohol.
- (3) Thymol has been found to be satisfactory in preventing the growth of moulds.
- (4) The yield when acid water is used is comparable to that obtained by dilute alcohol.
- (5) A preliminary study has been made of the absorption spectrum of the vitamin solution.

UNUSUAL DISPLACEMENTS OF THE EPIPHYSIS OF THE PATELLA.

By J. H. BARRETT, D.M.R.E.,

CAPTAIN, I.M.S.,

Quetta.

THE striking point about these two cases is not so much the fact that the actual ossifications were of extreme rarity, as the fact that these rare ossifications showed

definite displacement. My object in placing these cases on record is on account of (a) the possibility of the true nature of the case being missed, (b) the evaluation of the patient's story as to when he sustained an injury may be verified radiographically, (c) the medico-legal aspect, as well as the service liability in the case of the patient being invalided.

Ossification of the normal Patella.

The patella normally ossifies by a single centre, which appears in the second or third year, or at the latest the sixth year. Occasionally the bone is developed from two centres, placed side by side. Ossification is complete at puberty.

Rare ossification.

A third type of ossification occurs, and has been described by various writers. Previous to the year 1919 there was practically no literature on the subject, and the case records are still very small. Dr. C. T. Holland was probably the first radiologist to point out the value of recognizing the condition from the diagnostic and medico-legal point of view. He described one case (1921) and quoted another from Mouchet (1919). In these cases there was no displacement of the epiphysis, neither was the possibility of such an unusual occurrence mentioned in their writings. In order to demonstrate what the displacement of these rare epiphysis looks like, I reproduce drawings from Holland and Mouchet, and also from one case of my own. In these three cases no displacement has occurred. It will be best to examine these

The legs of the other foetus were brought out, but we had the same difficulty in delivering this too as the abdomen was also very big. We punctured the foetal abdomen below the umbilicus, in the hope of getting it reduced, in case there was foetal ascites. Only an ounce or two of straw-coloured fluid drained out. The size of the abdomen remained the same. With considerable difficulty this was also delivered. The circumference of the abdomen was 16 inches. The patient was having hæmorrhage, and as she was still under the anæsthetic I thought it best to remove the placenta manually. On passing the hand into the uterine cavity no definite placenta was felt but the whole cavity was lined by a soft velvety membrane, which felt very much like a vesicular mole. I scraped this as much as possible with the finger tips. The amount of this was about a bucketful (about 1 gallon).

After this she was given an intra-uterine douche with weak lysol solution. The uterine cavity was swabbed with 5 per cent. solution of tincture of iodine. The vagina was packed with iodoform gauze.

Examination of Fetus, 1st Fetus.—To find out the reason of this abnormal size of the foetal abdomen, we opened it and found that it contained a tumour exactly like the other two removed from the uterine cavity.

It was attached by a thin rudimentary mesentery to the posterior wall of the abdomen; and next, close to the mesentery, attached to the tumour was a bunch of very small intestines, looking like a coil of greyish coloured string. All the other organs were very small excepting the liver, which was about the normal size. The ribs and clavicle were cartilaginous and so the arms looked as if they were attached to the back.

2nd Fetus.—On opening the second foetus, we found a similar tumour in the abdomen, attached in the same way and looking exactly like the first one. The tumour was 12 inches in circumference. The foetus was quite œdematous. There were no eyes, but only fissures without openings. In place of the nose there was only a ridge. There were lips, but no openings of the mouth. The skin was more than half inch thick and there was no muscular tissue underneath.

The patient made an uneventful recovery and was discharged cured on 31st March, 1929. She reported last on May 1st. She is quite well.

A DISTENDED BLADDER SIMULATING A FULL-TERM UTERUS.

By CAPTAIN C. C. DAS GUPTA, M.B.,
C. M. O., Gopalpur Group of Tea Estates,
P. O. Gopalbagan, Jalpaiguri.

ON 12th January, 1929, I was asked to see a coolie woman, aged 25, multipara, said to be pregnant—full term, complaining of suppression of urine for 48 hours.

Past History.—Previous deliveries normal. Amenorrhœa for about 4 months. She previously passed urine normally.

History of Present Illness.—For the last two days she had not passed any urine. She noticed her abdomen growing bigger and bigger, causing her great discomfort.

Physical Examination.

Inspection.—I found the patient reclining on the mud floor with her head supported by a woman. Her legs were extended. She was in great agony. The abdomen was enlarged up to the xiphoid cartilage.

Palpation.—Abdomen was tense and tender. Foetal parts not palpable.

Percussion.—Distinct fluid thrill present. Liver and spleen normal.

Auscultation.—Foetal heart sounds and uterine souffle not audible.

Differential Diagnosis.

(1) Pregnancy, full term:—Foetal parts not palpable. Foetal heart sounds and uterine souffle not audible. Amenorrhœa of 4 months' duration only.

(2) Ascites:—Though fluid thrill was present, the sudden onset without any previous history of urinary trouble was against this.

(3) Enlarged bladder:—Stoppage of urine for 48 hours, attended with gradual enlargement of abdomen and pain suggested this.

A catheter was passed and a few pints of urine drawn off. The patient obtained instant relief and was able to move about.

Her abdomen was again palpated. The uterus could not be felt.

The abdominal swelling had almost disappeared.

Conclusion.—The retention of urine was probably due to spasm of the urethra. In introducing the catheter no stone or foreign body was felt.

The attending doctor had administered some homeopathic medicine to hasten delivery. He mistook her condition for delayed labour and did not believe her menstrual history.

A CASE OF ELEPHANTIASIS CURED BY ARRHENOL.

By MD. ABDUL QUIYUM, L.M.P.,

Medical Officer,

District Board, Darbhanga.

A MAHOMMEDAN male, aged 19, attended the Jainagar dispensary as an out-patient, during my incumbency, with swelling of his left leg.

On questioning, he narrated that about six months previously, he had had an attack of fever associated with intense pain in the left leg with a reddish, painful, linear mark extending throughout the limb. This lasted about a fortnight, but disappeared on application of some embrocation from a local sympathiser. Then, after a month or so, he began to notice a painless swelling of his limb which continued to increase for six months; the limb grew to double the girth of the other sound leg.

On examination I found that the swelling was solid, painless, and not pitting on pressure to any notable degree.

From the above history and the present condition of the patient I made a provisional diagnosis of filariasis. As arsenic has been said to be of much value in the treatment of such filarial cases, I chose arrhenol, an organic preparation of arsenic. The following morning I injected him intravenously with a solution of arrhenol (gr. ii to 1 c.c. of distilled water) and gave the following mixture.

R	Tr. Ferri perchlor.	..	min. v
	Glycerine	..	5i
	Magn. sulph.	..	5ii
	Spt. chloroformi	..	min. xv
	Aquam	..	ad 5i

One dose thrice daily.

The intravenous injection of arrhenol was given every alternate day. To my great surprise, the swelling began to decrease just after the second injection. On finding some improvement I augmented the strength of the solution to grs. iii to 2 c.c. and continued the injection at the same intervals. The swelling went down marvelously, day after day, till after the last, the sixth, injection the leg recovered its normal size, almost equal to the healthy fellow limb in all respects. The patient was apparently cured to all aspects, but his blood was not examined to give a positive proof of a radical cure.

Indian Medical Gazette:

AUGUST.

EXERCISE IN THE TROPICS.

THE object of exercise is not the production in the individual of a state of complete exhaustion, nor is it the excessive development of the whole muscular system, or of any particular group of muscles—the muscular giant whom one sees depicted as a symbol of health is not necessarily a “good life,” in the insurance sense of the word—but the production of adequate and symmetrical development of all the muscles, and, by the maintenance of the circulation of the body fluids and the increase in the metabolic rate, the ensurance of the proper functioning of all the organs and tissues of the body.

The absence of exercise from the daily routine must mean that the muscles remain ill-developed, that the organs become congested and fail to function properly, and that the resistance of all the tissues of the body to invading pathogenic organisms is very low.

On the other hand, over-exercise in a hot climate throws a great strain on the heart and other organs, such as the kidneys, which, after most of the available fluid has been lost through the sweat glands, have to excrete waste products in a highly concentrated form; it leads to nerve and endocrine exhaustion; and the excessive increase in the metabolic rate causes the liberation of toxins from the organs, especially the liver, and other tissues of the body.

Exercise, as such, is necessarily a product of civilisation. The whole existence of the lower animals living in the wild state depends upon chasing or being chased, and domestic animals—with the exception of those extreme products of domestication, the dog and the horse—even if they are not beasts of burden, are usually compelled to cover considerable distances in collecting their food. The only glimpse of apparently purposeless muscular exertion that one sees is in the very young, the skipping lamb and the gambolling kitten, whose food is provided for them without any appreciable effort on their part, but this exuberance is soon submerged in the sterner realities of existence.

Our early human ancestors who had to hunt or fish for the food did not require any other form of exercise to keep themselves healthy. At the present day the labourer, the peasant and even the skilled mechanic do not find it necessary to take artificial exercise. As we ascend the social scale the first member of society we encounter whose health would be improved by indulgence in games or sports is

the clerk, who sits all day on an office stool; as far as the Indian is concerned, this is also the class of individual who has the least opportunity for such indulgence and who takes the least advantage of such opportunity as he has. It may be poverty which prevents him from playing games, but this poverty also makes it necessary for him to walk to his work each morning and back at night. His walk in the morning must be definitely beneficial to him, but it is very doubtful if he obtains much advantage to his health from his walk home in the evening on an empty stomach after a long and tiring day's work. On the contrary, he is probably much too tired to digest properly his evening meal. The better-paid clerk, who can afford a tram or bus fare to his work, and the clerk who lives near his office take practically no exercise at all; if they can afford a carriage or car they will probably take a drive in the evening, but they will not go for a walk. This is not laziness, it is habit. The wives, on the contrary, of this class of clerk have to do most of the house-work and do not suffer in the same way from lack of exercise. A very large percentage of the members of the well-to-do merchant class and the higher grade Indian officials, again, take no exercise whatsoever; their wives also, who can afford to pay a number of servants, do little house-work and suffer equally with their husbands from the ills associated with a sedentary existence.

On the other hand, the majority of students take part in games, such as football, cricket and hockey, and in other sports, such as running and swimming. A very few of them retain their interest in games when they have graduated—or failed, as the case may be; a small number take up tennis, and an even smaller number ride or play golf, but the large majority give up games altogether and, as we have said above, take no exercise except that which their daily duties entail.

The case of the European—our remarks are more applicable to the British-born—in India is different. From childhood he has drummed into him daily the importance of games and exercise. At school he is compelled to play games, whether he likes it or not, and with increasing self-confidence he soon overcomes any dislike he may have had for them. When he goes to college he continues to play his school games or takes up other games. If he is taught that exercise is important at home, it is impressed upon him when he comes out to India that his life is actually dependent on his taking sufficient exercise. So he plays tennis, or rows, or rides, but as he is kept busy in his office until 6 o'clock on each night of the week, he has to crowd all his exercise into the week-end. He is a young man with a healthy appetite, so he probably eats too much and possibly also drinks a little too freely, and soon he acquires a “liver.”

His friends say "Ah, that is through not taking sufficient exercise." So next week-end he takes twice as much exercise and on Monday morning he arrives in his office an irritable, pessimistic and exhausted wreck. In time he finds that in order to keep fit it is necessary to take exercise during the week, but he still over-exercises during the week-end. He eventually becomes a slave to his exercise; he feels quite sure that he will be ill if he misses it for a single day. If he does miss it he certainly feels ill and possibly is ill. The worst exercise fiend is usually a somewhat portly man who quite obviously eats too much. He tries to balance excessive assimilation by increasing metabolism. If this man would eat half the amount he usually eats and would take half the exercise he usually takes he would be a very much fitter man and might even reduce his figure—and thus achieve his Mecca.

A definite rule for exercise which is applicable to everybody cannot be laid down. Some men seem to require more exercise than others, but this is very largely a matter of habit, and probably nearly anyone whose work does not confine him rigidly to one chair throughout the day could accustom himself to a very much more modest exercise routine than that of the average European of the present day, say one hour of tennis or half an hour of squash during the week, and two afternoons of tennis—of not more than 3 sets each if it is the hot weather—or two rounds of golf during the week-end. If he finds that he gets "livery" then he must look to his food for the cause and regulate his diet. For the man who never moves from his office chair the addition to a short daily walk would certainly be beneficial.

We have perhaps drawn slightly exaggerated pictures, but there is very little doubt that the European in India does on the whole tend to take too much exercise, whereas the Indian of the middle or upper class definitely takes too little.

THE PARASITOLOGY OF MALARIA: AN APPEAL FOR INFORMATION.

DURING the last six months the writer of this note, in conjunction with Mr. R. Senior-White, Malariologist to the Bengal Nagpur Railway, and Assistant Surgeon B. M. Das Gupta, Assistant Professor of Protozoology, Calcutta School of Tropical Medicine, has been engaged in the preparation of a memoir dealing with the parasitology of world malaria.

In January 1929 the detailed results of five years of blood examination of all suspected cases of malaria in the out-patient department of the Calcutta School of Tropical Medicine

became available for analysis. A study of these results led one to a study of the literature, and what was originally intended to be a brief report has now swollen to the dimensions of a large memoir. Some thirty-five of the most important journals dealing with tropical medicine for the years 1900-1928 have been searched, and abstracts written of some six hundred papers. In short, the attempt has been made to review the parasitology of world malaria, as far as papers published in readily accessible journals deal with the matter.

The result of these studies is to reveal an amazing state of affairs. Wherever there is a French colony the information is full, detailed, complete, and published in readily accessible journals. In fact our knowledge of the parasitology of malaria with reference to the French colonial empire is fairly complete. The same remark applies to the Dutch East Indies, where the problem has been very thoroughly studied for Java and Sumatra at least.

But when it comes to the British Empire, the information is scanty in the extreme. There are important memoirs dealing with malaria as observed in certain areas during the Great War—Great Britain (among returned troops), Macedonia, Palestine, and Mesopotamia; full information is available in the journals for Ceylon, for Australia, and for some of the West Indies. For the rest, there is hardly any information at all to be had. For India, only some thirty-five reports deal with the subject. The malaria maps of both Burma and the United Provinces, for example, are both completely blank. Cyprus, Malta, and Trinidad are all blank.

Now one knows that throughout India—and for that matter throughout the tropical possessions of the British Empire—there are hundreds of laboratories which are engaged daily in the study of blood films for malaria parasites. Yet this information is apparently not published in the chief journals dealing with tropical medicine. It has been partly published in local and departmental public health reports, locally published and not available to the general reader; much of it, in fact, must be in the form of manuscript reports which have never been printed at all.

This renders an attempt at a general survey necessarily incomplete. Yet we realise that the work has been done; the investigations have been made; the information must be there, though not readily available. We have seen unpublished manuscript examples that are everything that we require.

We have once previously utilised these columns in a request for information. We now desire to do so again. It is unnecessary to add that any information supplied will be fully acknowledged in the event of publication. The points on which information is desired with regard to the parasitology of malaria in the British Empire

(and especially in India and adjacent countries) are the following:—

(i) The place or places at which the observations were collected, and the name of the observer (for publication of acknowledgments).

(ii) The time of the year at which the observations were made.

(iii) The class of persons observed; e.g., children in a malaria survey, or patients admitted to hospital.

(iv) The actual parasitological findings; e.g., number of films examined, number found positive, number of infections with *Plasmodium vivax*, *P. malariae*, and *P. falciparum*, respectively.

(v) Whether thin films or thick films, or both were examined.

(vi) If observed, the ratio of gametocytes to other parasite forms encountered.

(vii) Any other parasitological findings, such as relationship of infections to age, race, sex, occupation, caste, duration of the infection, etc.

There must be many of our readers in a position to supply such information, and Lieut.-Col. R. Knowles, I.M.S., Calcutta School of Tropical Medicine, Central Avenue, Calcutta, would be most grateful for any information sent in.

Medical News.

THE JOURNAL OF NUTRITION.

THE subject of nutrition is to-day receiving more and more attention in medical circles, and the appearance of this new journal is therefore very opportune. Its first number was published in September, 1928. It is to be issued bi-monthly; the subscription is 21s. per annum (including postage), and the sole British agents are Messrs. Baillière, Tindall & Cox, 8, Henrietta Street, Covent Garden, London, W. C. 2.

The *Journal of Nutrition* is published by the American Institute of Nutrition, and is under the editorship of Dr. Eugene DuBois, assisted by a very strong editorial board. The number for September, 1928, contains much matter of interest, and the new journal is clearly of high scientific status. Dr. H. M. Evans of the University of California deals with the effect of inadequate vitamin B dietaries on sexual physiology in the male—an experimental study. The same author also deals with the relationship of vitamin E to growth and vigour. From the Nutrition Laboratory, Columbia University, Rosé and MacLeod deal with supplementary values among foods. Simmonds, Becker and McCollum from the Johns Hopkins University contribute an article on the distribution of vitamin E. Barnett Sure, from the University of Arkansas, deals with the rôle of vitamin B(1) in anorexia in the white rat. Dr. M. Elizabeth Marsh of the University of Rochester deals with the character of energy metabolism during work, giving an account of experiments on seventeen subjects made with the bicycle ergometer. A special feature of the journal will be its editorial reviews, which will include most useful bibliographies. The editorial for September, 1928, deals with vital economy in human food production, and reviews the progress made from the days of Lavosier to the present day studies in the Pennsylvania Institute.

The *Journal of Nutrition* is a most welcome addition to medical and scientific research literature.

INTERNATIONAL MEDICAL POST-GRADUATE COURSES IN BERLIN.

THESE are arranged with the help of the medical faculty of the University by the Lecturers' Association for medical continuation courses and the Kaiserin Friedrich-Haus. Part of the courses take place permanently, part only in October 1929 and March 1930.

I. Permanent Courses.

(a) Of monthly and semi-monthly duration dealing with all kinds of branches of medicine.

(b) Courses as guest-assistants in clinics, hospitals and laboratories during 2 to 3 months and longer for gentlemen desiring to do practical work under systematic supervision.

II. Courses in October, 1929.

(1) Group course: "Progress in internal medicine with special regard to stomach and intestinal diseases" (from October 1st—12th), fee RM. 75.

(2) Course for neurology, psychiatry and psychology (from October 14th—19th), fee RM 50.

(3) Postgraduate course in the domain of children's diseases (from October 14th—26th), fee RM 100.

(4) Course dealing with the chemical and physical foundation of medicine (from October 21st—26th), fee RM. 50.

(5) Postgraduate course for throat, nose and ear-specialists (from October 7th—19th, relatively 26th), fee RM 100.

(6) Single courses on all special fields of medical science including practical work.

III. Courses in March, 1930.

For March 1930 the following courses are contemplated:

A course on the different branches of internal medicine.

A course on the progress in the domain of surgery.

A course on skin and venereal diseases.

An x-ray course.

A course on obstetrics and gynaecology.

The courses are held in German, but numerous professors are able to lecture in the English, French and Spanish languages.

The information bureau of the Kaiserin Friedrich-Haus für das Ärztliche Fortbildungswesen, Berlin, N.W. 6, Luisenplatz 2—4, is instrumental in procuring suitable lodgings, gives information as to cost of stay, arranges the attendance in clinics at operations, etc., and upon request sends detailed syllabuses.

SPECIAL ARTICLES.

THE SPLEEN.*

By S. L. BHATIA, M.C., M.A., M.D. (Cantab.),
M.R.C.P. (Lond.),

MAJOR, I.M.S.,

Professor of Physiology and Dean,
Grant Medical College, Bombay.

THE spleen is an extremely elusive organ, and its functions have always been somewhat of a mystery. It has been known since ancient times that it could be removed from the body without fatal results. The spleen of runners used to be removed to make them more speedy. Malpighi records some interesting experiments, showing that splenectomy in dogs is followed by voracious appetite and polyuria. Recent work, however, does not confirm this. As the spleen was not found to be necessary to life, it used to be regarded as an organ of no great importance, but we know now that it plays an important part in the economy of the body. It is the

* Being a paper read at the November 1928 meeting of the Bombay Branch of the British Medical Association.

largest lymphoid structure in the body, and is concerned with blood cell formation and blood destruction; it acts as a reservoir for the red corpuscles and has important functions in connection with metabolism (especially of iron), immunity, tumour formation, etc.

The characteristic features of the histology of the spleen are the large size of its blood vessels, and presence of plain muscle fibres in the capsule and trabeculae. The lymphatic vessels are present just beneath the capsule only, in spite of the large amount of lymphoid tissue in the Malpighian follicles. There is a plexus of non-medullated nerve fibres accompanying the splenic artery and its branches. The large amount of plain muscular tissue causes rhythmic contractions, producing variations in its volume. The course of the blood circulation through the organ is interesting.

Branches of the splenic artery enter the trabeculae and give off branches which enter the pulp and run as central arteries of the Malpighian follicles. Here capillaries are given off, some of which end in the follicle, others connect directly with the venous sinuses. The central artery itself enters the pulp, where it becomes an end-artery, breaking up into the penicillii of Ruysch,—branches which have a peculiar stopcock arrangement known as *hulsenarterie* or sheathed arteries. The spleen is the only organ where such an arrangement exists. These branches either terminate as fenestrated end-chamber vessels, through which the blood enters the pulp, or connect directly with venous sinuses, which also have a characteristic structure. Their walls are incomplete. They are lined with large spindle-shaped cells loosely arranged, bound together by a delicate basket work of elastic fibres. The blood, after coming in very intimate contact with the cells in the pulp, enters them through apertures or tube-like branches. From there it drains into the veins in the trabeculae, which join and enter the main splenic vein. This arrangement is well suited for storage of blood and for cellular metabolic changes. The spleen pulp contains a large variety of cells, namely lymphocytes and lymphoblasts in the Malpighian follicles, cells of Aschoff's reticulo-endothelial system, splenocytes, erythrocytes, polymorphonuclear leucocytes, platelets, and pigment granules which may be extra- or intracellular, etc.

Developmentally, the spleen is composed of mesenchyme covered by thick mesothelium, and arises from the mesoderm in the dorsal mesogastrium in the fifth week of foetal life. It is later broken up by blood vessels and trabeculae from the capsules forming the reticular tissue and cells of pulp cords. Infiltration of lymphocytes into the tunica adventitia of arteries gives rise to the Malpighian follicles. The sinuses are formed from veins. From the reticular and endothelial elements of the spleen in foetal life erythrocytes and leucocytes are formed. This function is taken over by the bone marrow after birth. Both in prenatal and postnatal life the spleen is intimately related to the hæmopoietic and vascular systems in the body. Its important relationship with the vascular system as a reservoir of red corpuscles has been brought to light by the recent work of Barcroft and his associates at Cambridge.

In the end of 1921, Professor Barcroft, Professor Meakins and Mr. Doggart went to the Andes to study alterations in the hæmoglobin caused by high altitudes. When their ship, *S. S. Victoria* of the Pacific Steam Navigation Company, passed from the Atlantic into the Caribbean Sea, they observed that their blood volume was increasing. Not only the quantity of fluid, but the hæmoglobin content of the blood mounted up also. These observers wanted a base line of normal data for the blood at sea-level for comparison with their observations in the Andes mountains, but they found the results of their observations puzzling.

Thus writes Barcroft: "up went the blood volume day by day; up went the hæmoglobin, and this went on till we reached the Panama Canal, when a change took place and the tide of hæmoglobin, so to speak, commenced to abate. By the time we reached Callao, both the blood volume and the hæmoglobin in circulation were above of normal figures, but much below the Panama minimum. What was the explanation? Was it some

error in instruments, or was it a real phenomenon, and if the latter was true, what was its explanation?" They observed that the curve of their blood volume ran almost parallel to that of the mean temperature of their cabins, rising as they approached the tropical heat of central America, falling as they entered the cooler zone on the West Coast of South America. The mystery therefore was: "Whence came this outpouring of blood with rise of temperature." Is there any hidden store of blood in the body which can be drawn upon in case of emergency? Barcroft's investigations show that this hidden store is in the spleen, which may be regarded as a reservoir or bank so far as hæmoglobin in the body is concerned.

The most useful method of approach adopted by Barcroft to investigate the functions of the spleen is to withdraw it from the abdomen and fix it externally on the abdominal wall under aseptic conditions. Its blood supply remains intact. This extracutaneous spleen was demonstrated by Barcroft at Stockholm in 1926 at the 12th International Physiological Congress. He brought two dogs on whom this operation had been performed some weeks beforehand. One of them was run over by a motor car and died, but the other gave a most impressive demonstration of the fact that the size of the spleen diminishes as the result of exercise. This I had the opportunity of seeing. I saw similar demonstrations at a meeting of the Physiological Society in 1927. The spleen in the living animal is much bigger than the post-mortem organ. In anoxæmia it contracts and diminishes in volume. The reduction also occurs during carbon monoxide poisoning and hæmorrhage. The contraction occurs only if the nerve supply is intact. With rise in external temperature, there is dilatation of the skin vessels to facilitate heat loss. The spleen then parts with its store of blood to supply this additional vascular bed. With the fall in temperature, the skin vessels constrict, and the reserve supply of blood is again restored in the spleen. It may be regarded as an erectile tissue, which is capable of marked increase and diminution in its volume. During rest it is deep red in colour. During exercise it becomes pale. In a recent paper Barcroft has investigated the effect of pregnancy and menstruation on the size of the spleen. The extracutaneous spleen of the dog shrinks to about half its volume during the period of "heat" and to a somewhat greater extent during pregnancy. It reaches its smallest size a few days before the birth of pups. This shrinkage is due to the necessity of supplying blood to the uterine area. This knowledge of the reservoir function of the spleen is one of the most important additions to our knowledge with regard to this organ in recent years.

As regards actual blood cell formation, there is no doubt that owing to its large amount of lymphoid tissue, it plays an important part in supplying lymphocytes to the blood. In foetal life, it is actively engaged in forming red cells. In the adult normally it does not perform this function. It however has an indirect influence on blood formation through a stimulating action on bone marrow.

The spleen plays an important part in the destruction of red blood corpuscles by virtue of its reticulo-endothelial cells, which form an iron-free pigment, bilirubin. This is discharged into the blood. The blood platelets, too, are destroyed in the spleen.

The free iron resulting from the destruction of red blood corpuscles is stored in the spleen. It is the richest storehouse of iron in the body. This may be carried to the bone marrow and made serviceable for the formation of fresh hæmoglobin. After splenectomy the storage of iron is interfered with and there is increased excretion through the kidneys. This aspect of splenic function is much emphasised by continental observers.

The spleen forms hæmolytic antibodies and plays an important part in immunity against tetanus, diphtheria, kala-azar, typhoid, malaria, etc. It is generally free from tumour formation, and probably provides a defensive mechanism against the development of foreign tissues.

There is some evidence to show that it produces an internal secretion from broken down red blood corpuscles,

which reduces the resistance of all erythrocytes. As a hormone, after modification in the liver, it stimulates the formation of new red cells by the bone marrow.

It is closely related to all members of the hæmopoietic system.

The effects of splenectomy are not constant. Speaking generally, there is anemia of the secondary type, from which there is a slow recovery. There is diminution of red blood corpuscles and percentage of hæmoglobin. Hæmorrhage after splenectomy is less well tolerated. There is some over-growth of the red marrow by way of compensation. There is asthenia and diminished capacity for exercise. A temporary increase in platelets and also in the number of leucocytes, especially of the polymorphonuclear variety, is found. The red cells become more resistant to hæmolysis by hypotonic saline solution. Many of its functions are taken over by other members of the hæmopoietic system, but there is no doubt that without the spleen the animal is considerably handicapped.

A DISTRICT SCHEME FOR CHOLERA CONTROL.

By CAPTAIN J. M. PEREIRA, L.A.H.L.M. (Dub.),
Civil Surgeon, Santal Parganas.

THIS scheme was started five years ago as an experiment, with very meagre equipment, which I managed to get up myself, and as the venture proved particularly successful, we were permitted by Government to adopt it as a permanent measure in our district for the following reasons:—(a) The outlay, to begin with was comparatively small; (b) the recurring charges reasonable; (c) the method of first information was quickest, unlike the usual filtering through a chowkidari system; (d) the staff necessary to carry the scheme consisted largely of personnel already in District Board employment, and the organisation on the whole struck the authorities as practical.

With the usual medical organisation of each district, consisting of: (a) the outlying rural dispensaries; (b) the sub-divisional headquarters dispensaries; (c) the district headquarters and hospital.

I have divided the cholera areas to be combated into three heads; all the rural dispensaries under (a) the "first line of defence"; all the sub-divisional headquarters dispensaries under (b) as "the second line of defence"; and the district headquarters as the "base and reserves." From this it may be seen that an endeavour is made to link up the entire scheme by an organisation already existing, and the administrative control under which the success of the scheme depends is already there as a powerful nucleus to set the machinery going. The details of the scheme are as follows, and must be considered under:—

- A. The division of the district into areas of control.
- B. Equipment.
- C. Staff.
- D. Information or Intelligence.
- E. Initial cost and recurring charges.

A. *The division of the district into areas of control.*—As the outlying rural dispensaries may be considered the smallest unit of the district medical organisation, these units which are in direct touch with rural conditions I place as my "first line of defence," and equip them with one unit of equipment called a "cholera unit box." The medical officer, dresser and staff are already there, and a radius of five miles is allotted to this unit to look after. This brings roughly eighty square miles under the direct control of a medical man and his staff. The duties he is called upon to do during any recent outbreak more than compensate for his absence from hospital for half a day, and the economic loss that may result from his absence for one morning from his out-patient table is out-weighed by the preventive measures on cholera duty that morning.

B. *Equipment.*—The unit of equipment consists of a box called a "cholera unit box" size 15 inches X 13 inches X 9 inches high, containing material to sterilise

with chlorogen 40 drinking water wells, disinfectants to do about ten village houses, drugs to treat 25 cases, in addition to material for contacts, soap, towel and brush, and a hundred doses of cholera vaccine. The contents of the box are so arranged and the directions so given that apart from cholera inoculation, any intelligent layman can handle it rationally. This may be seen from the following copy of the instructions which are pasted into the lid of the box.

Cholera Unit Box.

Contents.

Cholera mixture (essential oils)	..	6 ozs.
Tr. Iodine	..	6 ozs.
Potassium Permanganate	..	1 oz.
Chlorogen	..	3 bottles.
Phenyle	..	1 bottle.
Towels	..	1
Nail brush	..	1
Soap cakes	..	1
Onuce glass	..	1
Minim glass	..	1

Directions for use.

A. Treatment. Essential oils mixture.

(1) Oil of cloves, oil of juniper, oil of cajuput of each one part, spirits of ether, two parts, mix, shake bottle well, 20 drops in an ounce of cold water, given by mouth every 20 minutes, till there is improvement. Later the dose may be given every half, one, or two hours.

(2) Solution of potassium permanganate must be given freely as a drink, all the time. A small crystal, in a pint of cold water, just enough to pink it.

(3) Warmth must be applied with hot water bottles to the feet and stomach.

B. *For contacts of patients.*—10 drops of tincture iodine, in an ounce of cold water, thrice daily for two days, especially the patient's attendants.

C. Disinfection and sterilisation.

(1) Drinking water supply. Wells. About three ounces of chlorogen to an ordinary sized well. Mix in a bucketful of water, throw it into the well. Mix thoroughly.

(2) Patient's room, vomit and motions to be disinfected with strong solution of phenyle of strength one ounce to a bucketful of water.

(3) Tank water must be boiled and cooled before use, or sterilised with chlorogen; strength half a teaspoonful to a bucket of water (2-gallon capacity).

Considering that practically every sub-division of a district has only one outlying dispensary, it will be seen that as the result of dividing areas into centres of control in our first line of defence around each outlying dispensary, there will necessarily remain certain plots that do not come within any sector. These naturally have to be catered for, and have been allotted to the Sub-Inspector of Vaccination, who is an officer of the vaccination department in this district and stationed in each sub-division. With the vaccinating season ending in March, this officer has nothing to do till October, a period which coincides with our epidemic season, and I have allotted him definite duties in this interval. These officers with their area represent the second line of defence, and in addition to the duties allotted to the first line (excepting inoculation) are in charge of material equal to ten cholera units (in addition to his own unit for his own use), mainly intended to subsidise the first line when they run short. The additional staff of the second line consists of a whole time sweeper to help the Sub-Inspector of Vaccination. In practice and within the last two years, I have omitted to include cholera vaccine in my second line, as this is expensive and the renewal of unused time-expired material was wasteful. I have since found it just as quick to send vaccine from headquarters as the result of motor transport being available throughout the district.

Third line of defence or base reserves.—The staff here is mixed and maintained by the District Board and the Public Health Department. The equipment of the entire organisation at the base is fully paid for by the board, and with cholera vaccine now issued free of

charge by Government the recurring charges have been greatly reduced. The board pays for an epidemic medical officer, chaprassi and sweeper maintained throughout the year, and the public health department pay for four men trained in cholera epidemic work for the season. The base equipment primarily consists of (a) refills for the entire organisation, (b) material and equipment for the epidemic medical officer referred to, and for the four men of the Public Health Epidemic Staff. The medical officer's equipment calls for special mention and consists of a section of the base which we term the "flying column." The medical officer in charge is liable to be sent out on duty anywhere and at any time that he may be required. The equipment of the "flying column" is as follows:—

List of Drugs and Equipment in the Flying Column.

1. Chlorogen	12 bottles.
2. Phenyle	1 gallon.
3. Cholera Mixture	20 ozs.
4. Tr. Iodine	2 lbs.
5. Spt. Vin. Recti.	1 lh.
6. Cholera Vaccine	1,000 c.c.
7. Kaoline 5 lbs. in each box	2 boxes.
8. Hand stove	1.
9. Pot. Permang. crystals	8 ozs.
10. Towel	1
11. Nail brush	1
12. Record Syringe with 2 spare needles	1
13. Ounce glass 4 ozs. capacity	1
14. Rogers' saline apparatus complete	1 set.

Contains the following:—

(a) Saline Tabloids	4 tubes.
(b) Pot. Permang. pill, 100 in each box	2 boxes.
(c) Tabloid Hg. Perchlor, 8½ gr. in each box of 50	1 bottle.
(d) Adrenalin boxes (Amp. of 6 each)	2 boxes.
(e) Pituitrin boxes (Amp. of 6 each)	2 boxes.
(f) Camphor-in-oil (Amp. of 6 each)	2 boxes.
(g) Atropine-sulph. 1/100 gr.	1 tube.
(h) Dressings	1 cake
(i) Carbolic soap	1
(j) All-glass hypodermic syringe 1 c.c. with 4 needles	1
(k) Minim glass	1
(l) Suture and needles, surgical (2 half and 2 straight)	4
(m) Suture silk	1 hank.
(n) Straight knife	1
(o) Graduated transfusion flask	1
(p) Silver cannula with rubber tube	1
(q) Dressings forceps	1
(r) Pipette with teat	1
(s) Scissors, one pair	1

The "flying column" equipment contains material sufficient, (a) to inoculate a thousand persons, (b) to sterilise with chlorogen a hundred wells, (c) material (Essential oils' mixture) to treat a hundred cholera patients, and disinfectants, etc., for contacts and houses. It has in addition complete equipment for transfusion work, and the usual surgical and medical paraphernalia needed in such cases. The entire equipment is packed in a box of separate compartments, to save breakage, and render its contents easily accessible, size 27 inches X 17 inches X 14 inches high.

The four epidemic men referred to are each equipped with a cholera unit box without vaccine, and there are four extra cholera unit boxes reserved as spares. These men are intended as workers primarily for the second line of defence, but are available anywhere.

Each of the base staff is provided with a serviceable water bottle, and hurricane lantern, and the epidemic medical officer has in addition a quick-light stove, a mosquito net, a rope and bucket. The entire staff is inoculated at the beginning of each season. The remaining portion of the base equipment include half a

dozen rakes and shovels for village cleaning, a McKenzie's spraying pump, tools, etc., for packing and sending out parcels.

Intelligence.—In this district we have educated the school gurus to a sense of responsibility and requested their help in working this plan. As a first line of information they are invaluable to the first line sector, and there are great possibilities if a local organisation can be worked up in village schools with the help of cholera informers, organised from selected schoolboys, chosen from various areas of each village. A system of rewards for the first information, and a system of coloured postcards, for cholera and small-pox separately, printed with address for each sector, and distributed to gurus will be an asset. The same system may be extended to the chowkidars, to stimulate their apathy to their pecuniary advantage by a system of rewards.

Below I append figures showing the progress in the total number inoculated each year, and it is a pleasure to add that I have on several occasions received written requests from villagers asking for inoculation and for the help of an epidemic doctor.

Population	Year	Number of inoculations performed.
1,798,639,	1924	575
	1925	1,378
	1926	3,368
	1927	9,236
	1928	18,782

A statement from each out-going unit on their return showing work done under various heads, e.g., inoculations, patients treated, wells disinfected, etc., is kept in the office, giving us a precise record of the output of each year.

The staff worked at headquarters of the campaign consists of a graph, on a skeleton map of the district, which hangs in my office, marking out centres of control in the first and second line of defence, and a circle round each centre precisely divides one sector from the other. On first information, small flags are pinned to the affected areas, depicting the general way of advance, and these when read together help to form a definite plan of attack. This is found particularly useful after mela's, fairs, etc., along lines of communications.

Initial cost and recurring charges.—The initial cost will depend on the size of the district and may be gauged from the cost of one fitted cholera unit box and the flying column. A list showing the cost of the special equipment maintained at *sadr* headquarters is also attached.

	Rs. As.
Cost of one cholera unit box	21 0
Cost of flying column equipment	300 0
Cost of McKenzie's spraying pump	60 0
Cost of water bottle	10 0
Cost of waterproof haversack	10 0
Rakes for cleaning villages at the rate of	2 4
Cost of manufacturing each cholera unit box	6 0
Cost of manufacturing flying column equipment case	14 0

With 21 centres in the first and second line and a liberal base supply, the initial expenditure with staff amounted to Rs. 5,000 and the recurring charges to about Rs. 2,000 annually.

Current Topics.

Some Ophthalmic Emergencies in General Practice.

By A. MAITLAND RAMSAY, LL.D., M.D., F.R.F.P.S.

(*The Practitioner*, April 1929, Vol. CXXII, p. 225.)

THE first duty of the practitioner is to inquire fully into the history of the accident, because by that means he is likely to learn a great deal regarding its nature.

A good clinical history is always a great help towards a correct diagnosis. For example, an injury will vary according to the character of the object with which the eye was struck—a stone, a fork, a knife, a pellet from a toy pistol, to name only a few of those most frequently responsible. While the history of the case is being taken the child should be laid on its back in a good light, and told to keep both eyes shut. If a few drops of 2 per cent. solution of cocaine be placed in the hollow at the inner canthus they will find their way into the conjunctival sac with every slight movement of the lids, and the eye will be anesthetized by the time the doctor is ready to examine it. Cocaine will be of little use, however, if the child be very nervous and frightened, and in these circumstances a general anæsthetic will be required. It is very unsatisfactory to try to examine the eye while the child is screaming and struggling.

The skin should be inspected in the first instance and the tension of the eye estimated by gentle palpation with the finger before making any attempt to separate the lids. If the tension be greatly reduced the eyeball has almost certainly been perforated, and it is well to be aware of that fact as soon as possible in the course of the examination. With antiseptic precautions the lids should be separated to get a good view of the eyeball. It is hardly necessary to say that all rough and awkward manipulations must be avoided, and if a retractor for the upper lid be not available, a serviceable substitute can be improvised by bending a hairpin. The conjunctival sac should be explored carefully. It is very unfortunate to overlook a foreign body in the retrotarsal fold or beneath the upper lid. Aided by a good light, the cornea must be examined for any abrasion of its surface. If nothing more than a superficial abrasion be discovered, all the treatment necessary is to instil a few drops of 10 per cent. to 20 per cent. solution of argyrol and to apply a compress and bandage. Argyrol is advised, not on account of its reputed antiseptic properties, but because its solution is so heavy that it finds its way into every part of the conjunctival sac and acts as a thorough scavenger. If septic infection of the abrasion be avoided, the epithelium of the cornea will be reproduced very rapidly and no scar will remain.

When the accident is more serious it is convenient to divide the cases into two groups—those in which there is no perforation, and those in which perforation has occurred.

(1) *When the eyeball has not been perforated.*—The chief signs to look for in making a diagnosis are as follows:—(a) The anterior chamber is full; (b) the pupil is circular and responds to the stimulus of light; (c) the tension of the eyeball is normal. First aid must be given without delay. Instil argyrol and apply a compress and bandage. In this group of cases, however, the injury to the cornea is usually extensive and deep, consequently there is considerable danger that sight will be affected as a result of opacity or of irregular astigmatism of the cornea. Moreover, there is always a risk of sepsis, consequently it is prudent to keep the patient in bed. Rest is essential for the smooth healing of all injuries. In other parts of the body recourse is usually had to the support of a splint, and the same principle applies to injuries of the eye for which atropine is the physiological splint. It can be used in 1 per cent. solution and is usually instilled after the argyrol. The timely use of a mydriatic is the best preventive treatment of iritis, which is one of the most dangerous complications of this group of injuries. As a rule, no further treatment will be necessary, but, whenever the injury appears so severe that sight is likely to be damaged, the family doctor will be well advised to ask for a consultation with a specialist before any complications arise.

(2) *When the eyeball has been perforated.*—It is essential to obtain a good view of the eyeball. When the eye is properly seen the diagnosis is not difficult if attention be paid to the following signs:—(a) The anterior chamber is empty; (b) the pupil is contracted and irregular in outline, and does not respond to the stimulus of light; (c) the iris is usually prolapsed

through the wound in the cornea; (d) the lens may be wounded. It is important to take note both of the outline and of the general appearance of the pupil. A prolapse of the iris may be difficult to see and can easily be overlooked; but even although the actual prolapse may not be seen, it is a sure sign if the pupil has a pyriform shape. This special alteration in the outline of the pupil is due to the iris having been drawn into the lips of the wound of the cornea. If further examination shows that instead of being jet-black the pupil presents a grey reflex, the diagnosis of traumatic cataract can be made with confidence.

In these circumstances the eye is in grave danger, and the family practitioner, after rendering first aid, ought to rid himself of any further responsibility by transferring the case to a specialist at the earliest possible moment. The prognosis, however, will depend upon the first-aid treatment, which ought always to be as simple as possible. There should be no unnecessary handling of the eye, and copious douching, the use of strong antiseptics or of lotions containing lead must be avoided. A 10 per cent. solution of argyrol may be used freely, and if there be a prolapse of iris towards the centre of the cornea, 1 per cent. atropine should be instilled, but if the prolapse be at the periphery of the cornea, 1 per cent. eserine ought to be employed. The object of the treatment in both instances is to replace the iris into the anterior chamber by pulling it free from the lips of the wound in the cornea. A prolapse of iris is always a source of grave danger, but the family practitioner should never try to excise it. The operation is not so easy as it may appear, and to ensure success the operator requires to have considerable experience of ophthalmic surgery and also to possess suitable instruments. The skin of the eyelids and side of the face should be painted with a 1 per cent. tincture of iodine, a compress and bandage applied to the eye, and the patient put to bed to await the arrival of the specialist, or sent to him forthwith for further treatment. It is quite likely that the child's parents may express the wish to wait for a day or two before consulting a specialist, but the family practitioner ought not to approve of delay. Serious complications may occur very unexpectedly, and when they supervene the eye may be lost, even although the subsequent treatment has been directed by the highest skill. There is always danger ahead, because it is in perforating injuries that sympathetic inflammation is prone to attack the uninjured eye with the tragic result that sight may be lost in both eyes.

A case of acute glaucoma.

No excuse is necessary for including acute glaucoma among the emergencies of general practice. In many instances it comes as a bolt from the blue. The patient—very often a woman about fifty years of age—goes to bed apparently in her usual health, but is awakened in the early hours of the morning by agonizing pain in the head accompanied by feverishness, nausea, persistent retching, and bilious vomiting. The symptoms are so alarming that the family practitioner is called in haste, and unless he knows well what he is about he may easily do more harm than good. When he arrives at the patient's bedside it is quite probable that no one will mention the eye; all attention has been concentrated on the general symptoms, so that even although failure in sight has been noticed it has been tacitly assumed to be due to biliousness. The true nature of the condition may very easily be overlooked, and if the practitioner be deceived the result will be deplorable. In such circumstances the possibility of acute glaucoma should always be kept in mind. It is not by any means a common disease, and a practitioner may be in practice for many years before he is called to a case. Nevertheless, every country practitioner ought to know about glaucoma, and be able to recognize the disease when he meets it. If he does not allow himself to be taken unawares there is not much difficulty in the diagnosis. The most important factor is to remember to examine the eye. It is when the practitioner omits to think about glaucoma that its presence escapes him.

The patient shrinks from the slightest touch, and may say that his eye feels too big for its socket. On palpation it feels hard as a stone. The bulbar conjunctiva is congested and œdematous; the cornea is steamy and so insensitive that it can be touched without the patient's knowledge; the pupil is dilated, irregularly oval shaped and irresponsive to light; the anterior chamber is shallow and sight is seriously impaired.

At this stage of the examination the practitioner must be on his guard not to misinterpret the significance of these signs and symptoms. The hardness of the eye, the dilated pupil, the shallow anterior chamber, and the loss of sight ought to be sufficiently diagnostic to prevent acute glaucoma from being mistaken for any other disease. Unfortunately, however, the unwary frequently confuse glaucoma and iritis, with deplorable results. It is common knowledge that in iritis the vigorous use of atropine is imperative; but it is not so well known as it ought to be that if a mydriatic be instilled into an eye suffering from glaucoma the symptoms will be so gravely aggravated that the prospects of recovery are very materially lessened. Few errors in diagnosis and treatment are followed by such disastrous results. The subject is so important that repetition may be excused, and to sum up briefly let me say:—

(1) When the family practitioner is summoned to an urgent case, in circumstances such as have just been described, he ought always to bear glaucoma in mind, and be quite sure he has excluded that disease before he commits himself to any other diagnosis.

(2) Until it is certain that there is nothing wrong with the eye, the possibility of acute biliousness or migraine being the cause of the attack ought never to be considered.

(3) While retching and vomiting are usual accompaniments of acute glaucoma, these symptoms are so exceedingly rare in iritis that their presence should be sufficient to put the practitioner on his guard and make him examine the eye with great care. If he does so he will never confuse glaucoma with iritis.

After he has made a diagnosis the practitioner need not have much difficulty about the treatment. As a result of the increased intraocular pressure the patient is suffering agony and rapidly losing sight. The indications for treatment are to relieve pain and to contract the pupil. Morphia, our sheet anchor in so many emergencies, is invaluable in acute glaucoma. It should be given in full dose by hypodermic injection, and its sedative action can be assisted by fomentations and by leeching. It is also very important to get the bowels to move freely as soon as possible, and nothing is more effective than calomel followed by a saline draught. To contract the pupil and to reduce the tension of the eye the most convenient remedy is eserine 1 per cent. solution, repeated every two hours. The patient should be kept warm in bed and encouraged by the hope that the symptoms will be relieved after a sound sleep. Although it is wise to speak to the patient in a very reassuring manner, the practitioner, before he leaves the house, ought to tell the relatives that the condition of the eye is serious, and to warn them that on the following day an operation may be necessary. Sleep is Nature's cure for glaucoma, and if the patient has had a good night the eye will probably be much better when he awakens in the morning. If, at his morning visit, the practitioner finds the pain relieved and the pupil contracted he can safely continue the treatment; but if, on the contrary, he finds the general symptoms acute and the pupil dilated he should not hesitate to ask for a consultation with a specialist. He cannot accept responsibility for delay. The circulation of the intraocular fluids has become strangulated; and, if the increased pressure be not relieved promptly, serious impairment of sight, terminating in many instances in blindness, will inevitably result. The hopelessness of the situation can, however, be removed by operation provided action be taken in time. The state of the eye in acute glaucoma has been compared to a strangulated hernia. The analogy is apt, and if it be remembered the family practitioner will never on his own responsibility counsel delay because he will readily understand

that relief to strangulation is as imperative in the eye as it is in the bowel.

The Methods of Investigating a Urological Case.

By C. A. R. NITCH, M.S., F.R.C.S.

The Practitioner, April, 1929, Vol. CXXII, p. 205.

THE great advance in diagnostic methods in recent years has been the most important factor in elevating urology to the precise and accurate science it has now become. A correct diagnosis can be made only by obtaining a full and complete history, by making a careful note of the relevant facts and following this by a thorough general and local examination, and when necessary by urethroscopy, cystoscopy and radiography as well.

The modern student is taught to regard urology as an exact science and to tackle its many problems by scientific methods. The majority of the profession have also come to realize and value the methods of making an accurate diagnosis which are now at their command, but there are still some who, for example, treat cystitis empirically from the outset instead of ascertaining its cause by the aid of the microscopy, bacteriology and cystoscopy. Oxaluria, the colon bacillus, and a foreign body in the bladder all produce more or less similar symptoms which can be relieved temporarily by drugs, but the problem can only be solved by scientific means. Again, a patient with hæmaturia is still too often treated immediately with hæmostatics instead of being subjected to a searching examination with the object of ascertaining the exact source and cause of the hæmorrhage. A papilloma of the bladder, when small, can be destroyed with one touch of the diathermy electrode; but if the painless hæmaturia which is its only early symptom is treated medicinally, the growth will have increased and probably also multiplied by the time the practitioner realizes that his favourite drug has failed him.

Vaccines are often of great value, but they are quite useless when administered to a case in which the exact cause of the infection has not been discovered.

In every disease diagnosis is the key to treatment, and in a urological case this key can only be fashioned by a preliminary methodical examination based on a formulated plan. The greater part of this examination lies easily within the scope of the general practitioner and can be carried out without any special instruments; when completed he will be in a position to decide on the necessity or otherwise of further instrumental investigation.

PLAN OF EXAMINATION.

- (1) Nature of complaint.
- (2) Family history and past history.
- (3) The symptoms and their method of onset.
- (4) General examination.
- (5) Local examination.
- (6) Examination of the secretions and excretions.
- (7) Instrumental and radiographic examinations.

(1) NATURE OF COMPLAINT.

The patient should be allowed to state in his own words, the nature of his complaint and the important short signs and symptoms he has noticed. Do not cut him short unless he is unduly loquacious, for valuable information is sometimes concealed in a mass of verbiage.

(2) FAMILY HISTORY AND PAST HISTORY.

Inquiries should be made regarding the health, age and, if not alive, the cause of death of all near relatives, particular attention being paid to syphilis, tubercle, lithiasis, diabetes, Bright's disease and mental and nervous disturbances. Also the possibility must not be overlooked of contagion from syphilis, gonorrhoea or tubercle in a member of the family living in the house.

It is important to ascertain if the patient has lived abroad and suffered from any illnesses peculiar to the district. Bilharziasis is endemic in Egypt and certain parts of Natal; lithiasis and "gravel" are common in India, and hydatids in Australia.

The age of the patient has an important bearing on the diagnosis, as certain lesions of the genito-urinary tract are peculiar to the three main periods of life.

In infancy and childhood one must be on the lookout for congenital malformations and their effects, for vesical calculus and microbic infections. Renal tuberculosis is by no means uncommon but is often associated with gross lesions in other parts of the body. Pyuria in children which does not soon respond to treatment requires careful investigation, for it may be due to congenital stricture of the urethra, to the persistence of valvular folds in the prostatic urethra, to vesical calculus, or to stenosis of the ureter producing pyoureter and pyonephrosis.

As age advances renal tuberculosis becomes increasingly common and, in addition to the many other diseases of the urinary tract, the effects of the gonococcus on the urethra, prostate and seminal vesicles come into prominence. In old age, enlargement of the prostate, vesical calculus, malignant disease and the consequences of urethral stricture claim priority.

Careful inquiries should be made regarding any acute illness the patient may have had as a child, particularly the specific fevers, for they are often followed by nephritis. Orchitis and oophoritis occur as a complication of mumps more often in the adult than in the child.

Any venereal history must carefully be investigated both as regards the form of the disease and the method and duration of treatment. Energetic irrigation may have driven a gonococcal infection into the prostate and seminal vesicles, where it lies more or less dormant for years but always ready to light up and cause puzzling symptoms when given the proper stimulus. An inflammatory urethral stricture is often long in following its cause. It is hardly necessary to point out that a negative Wassermann reaction is of no value and that the spirochæte may suddenly wake into activity as long as twenty years after the original infection.

Inquiries should be made into the habits and occupation of the patient, his relaxations, and his indulgences in food and alcohol, for all these details have a bearing both on the condition of his arteries and his kidneys and his suitability for a possible operation. The man of sedentary habits and city dinners requires careful investigation and treatment before a serious operation such as prostatectomy. Some, from either nervousness, necessity or habit, refrain from emptying the bladder for many hours, with the result that it becomes permanently overdistended and never empties properly. Such a bladder readily becomes the seat of a chronic and incurable infection. In women the urinary history during pregnancy and the puerperium should be elicited.

When the family and past histories have been obtained the patient should be allowed to describe his symptoms in detail, their onset and their course.

(3) THE SYMPTOMS AND THEIR METHOD OF ONSET.

The symptoms as described by the patient are often very unreliable and may confuse the examiner by drawing his attention from some important detail which the patient regards as trivial, but they are of great value when used as indicators to judicious questions and proper physical examination. In some instances the symptoms are typical and frankly diagnostic; while in others they may be misleading, as, for example, urethral pain and strangury which focuses the attention of both patient and surgeon on the bladder when the real cause is either uterine displacement, hæmorrhoids, a pelvic appendix, a calcified tuberculous gland irritating the nerves of the bladder, or prolapse of the bladder wall through one of the hernial rings. Again, renal pain is sometimes referred entirely to the healthy kidney, particularly in tuberculosis and calculus, or it may be referred to some part of the abdominal wall and accompanied by such acute intestinal symptoms that the actual pathological condition is entirely missed. The chief symptoms and signs described by the patient will be either pain, a swelling, a urethral discharge, or disturbances of micturition and changes in the appearance of the urine.

Pain may be local or referred; when local and stationary it is always indicative of some pathological

change; when referred it generally requires careful and often special investigation to make certain that it originates in the genito-urinary tract. Certain types of pain are peculiar to different parts of the genito-urinary tract and are best described according to their site and origin.

Urethral pain during micturition is due to inflammation; before micturition, to obstruction from a stricture, a stone, a foreign body or a growth. Referred pain along the urethra occurs both during and at the end of micturition in cystitis and is generally described as scalding. Pain at the tip of the penis is usually caused by irritation of the vesical neck and sometimes by a stone impacted in the lower end of the ureter, but it may be due to inflammatory and other changes in the posterior urethra, prostatic calculi and malignant disease.

Perineal pain, if not of anal or rectal origin, is strongly suggestive of an inflammatory or other lesion of either the prostate, the posterior urethra, the seminal vesicles or the base of the bladder.

Groin pain is generally due to inflammation of the cord or testis, but is sometimes felt in carcinoma of the prostate, in prostatitis and spermatocele.

Suprapubic pain is seldom a pronounced symptom in urinary diseases, but is sometimes present in carcinoma of the prostate, in chronic cystitis with distention, and when the upper part of the bladder is the seat of an inflamed diverticulum. It may be referred from a distance, and in one case was the sole symptom of a gall-bladder packed with stones—a problem that was only solved by abdominal exploration after an exhaustive examination of the urinary tract.

Renal and ureteric pain are characteristic when local and associated with symptoms peculiar to the conditions from which they arise, but when referred they may be very misleading. I once saw a man who suffered from attacks of sudden agonizing pain located precisely to the upper end of the scar of a herniotomy wound accompanied by exquisite tenderness at the same spot. There were no other symptoms of any kind. A skiagram of the kidney revealed the cause in a spiked oxalate calculus.

Renal pain is generally located to a triangular area having its base along the erector spinæ between the last rib and the crest of the ilium and its apex at the lower border of the ribs anteriorly. From this triangular area the pain may be referred along the course of the ureter to the inguinal region, the testis or labium, the urethra, the anterior part of the thigh and leg and the heel. Occasionally it is referred to the opposite healthy kidney, the diseased one being painless. Tenderness in the angle between the last rib and the erector spinæ is typically renal.

Ureteric pain is either felt along the line of the ureter or is referred to the groin and testis or labium. When the lower end of the ureter is implicated the pain may be felt at the base of the bladder, along the urethra, at the external meatus or in the perineum. Renal and ureteric colic are generally accompanied by muscular rigidity, vomiting and abnormal intestinal movements, and may simulate acute appendicitis or intestinal obstruction. If it be remembered that the patient with colic rolls about in agony and the patient with an acute abdomen keeps still, a mistaken diagnosis is not likely to occur.

Another diagnostic aid of great value is Rovsing's sign. This serves to distinguish between a renal and an acute intraperitoneal lesion on the right side. It is elicited by firm massage of the descending colon with the flat hand; if this causes pain in the right iliac fossa it signifies localized peritonitis, usually due to acute appendicitis; if, however, the massage does not cause pain in the right iliac fossa, the lesion is probably renal or ureteric, but may be intraperitoneal. A renal or ureteric affection will be confirmed by tenderness on pressure in the angle between the last rib and the erector spinæ. The great value of this sign is well illustrated by the following case:—

A boy of 14 had severe pain in the right side of the abdomen and muscular rigidity suggestive of acute appendicitis, but he also had frequency of micturition, pyuria and swarms of *B. coli* in the urine; there was

slight tenderness in the costo-muscular angle. Was this a case of acute pyelitis only, or of pyelitis complicated by acute appendicitis? Rovsing's sign was positive and was the deciding factor for an immediate operation, when a perforated gangrenous appendix was found adherent to the ureter at the brim of the pelvis.

Pain at the end of micturition accompanied by an intense desire to urinate is again typical of cystitis and trigonitis. A pricking pain referred to the external meatus suggests a vesical calculus or foreign body, especially if aggravated by movement and change of position. Severe shooting pain in the bladder and urethra may be due to organic disease of the spine or the central nervous system. Renal pain relieved by recumbency and either relieved or increased by change of position points to a mobile kidney, a renal tumour, intermittent hydronephrosis and horse-shoe kidney.

Disturbances of micturition figure largely in urological cases and must be subjected to detailed inquiries after the patient has described the chief peculiarity. He should therefore be asked about abnormal frequency (pollakiuria), urgency, excessive or diminished secretion (polyuria and oliguria), and painful or difficult micturition (dysuria).

Alterations in the urinary stream and loss of power occur in obstruction at the neck of the bladder and in the urethra, and in diseases of the nervous system. When sudden, it is generally due to an impacted stone or portion of growth; when gradual and progressive, to enlarged prostate, stricture or tubes.

Frequency of micturition in general may be due to habit; to changes in temperature, especially in those who have lived in the tropics; to nervousness; to the polyuria of diabetes, chronic nephritis; and diuretics such as tea, coffee, alcohol, etc.; to irritating conditions of the urine produced by blood, by the sudden discharge of pus from an infected kidney or perivesical abscess, by drugs and by oxalates, phosphates and uric acid crystals; to diminished capacity of the bladder by pressure from without, or by inflammation of its walls and lining membrane; to stone, new growths and foreign bodies, in all of which cystitis is the usual cause of the frequency; to diseases of the prostate, seminal vesicles and posterior urethra; to hernia of the bladder, cystocele and uterine displacements; and reflexly to worms and other anal and vulval sources of irritation.

Though frequency often occurs in nervous diseases it is seldom pronounced in tabes, the disease in which the bladder is most often affected. There may be slight initial frequency and urgency, but generally there is progressive loss of power with diminished desire to micturate, ending in sudden complete retention or incontinence from overflow.

Frequency may be diurnal, nocturnal or both. *Diurnal frequency* occurs in nervousness and sexual neurasthenia, in vesical calculus, and in mild inflammation of the bladder, prostate and urethra. *Nocturnal frequency* is pronounced in enlarged prostate, renal tuberculosis and severe cystitis and prostatitis. *Frequency by day and night* is due to acute inflammation of the lower urinary tract (cystitis, prostatitis, posterior urethritis, etc.), to reflex irritation such as worms, and to organic polyuria. *The frequency of enlarged prostate* is characteristic. Though present during the day it is not sufficient to attract attention. At night the patient sleeps for several hours and then wakes to urinate at more or less frequent intervals till he rises in the morning. *Frequency and urgency* indicate irritation of the posterior urethra and vesical neck.

Dysuria is symptomatic of obstruction or atony. The commonest obstructive causes are stricture, diseases of the prostate, impacted calculi, chronic inflammatory thickening of the vesical neck and congenital malformations. It is useful to remember that the patient with a stricture strains throughout micturition, with a vesical calculus at the end and with enlarged prostate at the beginning.

Painful micturition denotes inflammation or irritation of the urethra and bladder.

Oliguria is a symptom of cardio-vascular and organic renal disease.

The patient must next be asked if any changes in the appearance of the urine have been noticed and how and when they have occurred. The chief abnormal constituents are pus, blood and crystals.

Pyuria.—Pus in lumps and flakes at the beginning of micturition comes from the urethra or prostate; if, in addition, a further quantity is voided at the end of micturition it is almost certainly from the prostate or seminal vesicles. Purulent urine is passed in all varieties of cystitis, and is generally accompanied by terminal pain, but pus from the kidneys may be passed in large quantities without any symptoms of cystitis. An intermittent purulent urine indicates sacculus of the bladder, perivesical suppuration, obstructive pyonephrosis, or that form of renal tuberculosis which is alternately open and closed. In the aged, sudden pyrexial cystitis with its accompanying pyuria is very suggestive of vesical carcinoma.

Hæmaturia.—As the patient will naturally ascribe any red coloration of the urine to blood the practitioner should inquire carefully into its character, possible cause, onset, duration, presence of clots, etc., and should bear in mind the possibility of the pigmentation being due to hæmoglobinuria or to excessive indulgence in sweets stained with eosin. He should ask if the patient has resided in any part of the world in which bilharziasis is endemic; also realizing as he does the innumerable causes of hæmaturia, he must endeavour to eliminate by appropriate questions such causes as hæmophilia, purpura, scurvy, chronic nephritis, arterio-sclerosis, foods or fruits causing oxaluria, and medicines containing hexamine.

Blood from the kidney is usually intimately mixed with the urine and gives it a brown or red tinge; blood from the bladder is generally bright, and on standing forms a red precipitate at the bottom of the glass.

Hæmorrhage at the commencement of micturition is from that portion of the canal in front of the compressor urethra; terminal hæmorrhage may come from the posterior urethra, the verumontanum, the prostate, the seminal vesicles, or from a papilloma at the internal meatus.

Painless hæmaturia of sudden onset in a young subject may be due to rupture of a renal arteriole, in an older patient to arteriosclerosis or Bright's disease. In some cases of chronic interstitial nephritis hæmaturia is the initial symptom and may be so profuse as to endanger life. Painless intermittent hæmaturia is characteristic of papilloma of the bladder. Constant slight hæmorrhage is very suggestive of vesical carcinoma.

Hæmorrhage due to oxalates and uric acid is sudden in onset and usually accompanied by renal pain, but sometimes only by slight irritation of the bladder. The association of sudden hæmaturia with lumbar pain generally signifies a renal origin, but this is not always the case, for urteric calculus or a papilloma at the vesical orifice of the ureter can cause identical symptoms.

Profuse renal hæmorrhage without previous symptoms of stone occurs in papilloma of the renal pelvis, angioma of a papilla, surgical tuberculosis in which it is sometimes the first symptom, malignant growth and aneurysm of the renal artery.

From the foregoing it will be realized that the cause and source of hæmaturia can only be discovered by radiography and by the aid of the urethroscope and cystoscope, that these diagnostic aids should be employed as soon as possible, and that no operation should be performed until the site of the bleeding has been located by these means.

Crystals of calcium oxalate and uric acid, when unaccompanied by hæmaturia, will probably only attract attention by the irritation they cause, and in the case of uric acid by their colour. In some cases of phosphaturia the urine is cloudy only after meals.

Persistent haziness is generally due to colon bacilluria; occasional haziness combined with frequency in a young adult is very suggestive of renal tuberculosis.

(4) GENERAL AND (5) LOCAL EXAMINATION.

The appearance and bearing of the patient will already have been noticed, but special attention should now be paid to the complexion, the mental attitude, and to

signs of wasting or dehydration. The tongue should be inspected and the mouth examined for septic foci. The patient must be questioned about his appetite and desire for fluids. The blood-pressure should be taken and the condition of the arteries noted. The knee jerks and pupil reflexes should never be omitted, for the number of cases that have been operated on from neglect of this simple precaution is by no means negligible. The chief clinical signs of a defective renal function are thirst, disinclination for food, particularly meat, a dry tongue and a sallow complexion. In my opinion these signs are often more valuable than chemical tests, and therefore particular attention should be directed towards them. The hernial regions should next be inspected, and the heart and lungs examined if necessary.

The patient then lies on a couch and the whole abdomen is carefully palpated. If the bladder is distended (and whenever possible the patient should always be told not to pass urine before examination) the patient should empty it as completely as possible, provided the symptoms do not point to the urethra or prostate when either the three-glass test or an estimation of residual urine will be required at a later stage. After micturition, palpation will show if the bladder has been more or less completely emptied. The kidneys are then carefully examined bimanually, and any abnormalities in their position, mobility, size, shape and sensitiveness noted. The presence or absence of tenderness on pressure in the angle between the last rib and the erector spinæ should be tested. The inguinal glands should be examined, for amongst other regions they drain the urethra, penis and skin of the external genitals; they are sometimes enlarged, and often hard and shotty in established carcinoma of the prostate. The lymphatics of the testicles enter the iliac and lumbar glands; enlargement of them will have been detected in a thin patient during the abdominal examination.

The external genitals must now be carefully inspected and examined. A malignant renal growth sometimes gives rise to a varicocele which differs from the common variety in not disappearing with recumbency. Gross malformations and variations in size and shape will be detected easily, but lesser developmental defects and pathological lesions may require a careful search. The external meatus should be inspected with a view to noting both its size and the presence or absence of a discharge. A discharge may be profuse and obvious, or scanty and only rendered visible by massaging the urethra or by scraping it gently with a platinum loop. In every case a smear should be made for microscopical examination. Thickening along the course of the urethra is characteristic of long-standing stricture or of a peri-urethral abscess in connection with it.

If the scrotum be devoid of a testis the perineum, groin, inguinal canal and pelvis must be carefully searched, for the examiner should not be content until he has located the missing organ.

A scrotal swelling should be tested for translucency. Primary or idiopathic hydroceles are generally large, secondary hydroceles are always small. Special attention should be paid to the epididymis, and if there is any nodulation, thickness or enlargement the vas should be examined and later the prostate and seminal vesicles. Thickening of the globus major alone may be due to an encysted hydrocele of the epididymis (spermatocele) or to tubercle of hæmic origin. Enlargement of the globus minor is usually tuberculous or infective; when tuberculous it is generally secondary to a focus in the seminal vesicle or prostate, which in turn may be secondary to renal tuberculosis; when infective it is due either to urethritis or to prostatitis and vesiculitis.

The patient is now told to pass into an empty specimen glass all the urine he can, but if his predominant symptoms have been urethral or prostatic the three-glass test should be carried out. Urine is passed in a continuous stream into two glasses, one after the other, taking care not to empty the bladder. The prostate and vesicles are then massaged and the bladder emptied into a third glass. Glass No. 1 contains the washings of the whole urethra, glass No. 2 contains the bladder urine, and glass No. 3 contains bladder urine together

with normal and abnormal secretions squeezed out of the prostate and vesicles. A smear can easily be made from the urethra and from deposits in the urines, and either sent to a pathologist or stained with carbolthionin and examined at once if the practitioner possesses a 1/12 inch oil immersion lens. Intra- and extra-cellular diplococci, stained deep blue, are almost certainly gonococci; but should it be important to confirm this the slide, together with a fresh smear if possible, should be sent to a pathologist for decolorization and Gram-staining.

The practitioner cannot be too careful or cautious in investigating the cause of urethritis in an adult and in making notes and preserving documents relating thereto. In females the cervix should be inspected through a speculum, and discharge from it examined microscopically. When the history and symptoms point to simple prostatic obstruction a gum-elastic bi-coude catheter is passed immediately after the bladder has been emptied naturally, in order to ascertain the amount of residual urine if any.

The male patient is next placed in the genu-pectoral position and the anus carefully examined for piles, excoriations, etc. A rectal examination which should be bimanual, is then made with a well-lubricated gloved finger. Having first ascertained the presence or absence of internal piles and any growth or abnormality of the rectum, the prostate is carefully palpated. In young men it is sometimes so soft and thin that the back of the pubis is felt with hardly any intervening tissue, and at first touch gives the impression that a hard prostate is being palpated; but the absence of steep sides to the lateral portions makes the diagnosis easy, and if there is the least doubt it can be cleared up at once by another rectal examination after the passage of a catheter.

The prostate should be carefully examined for mobility, elasticity, hardness or softness, nodules or diffuse thickening, and local or general tenderness. The definition of the margins of the lateral lobes, the presence or absence of the vertical interlobar sulcus, and the mobility or attachment of the overlying rectal mucous membrane must also be investigated.

The normal adult prostate is felt as a slight, smooth, moderately movable prominence covered by freely movable rectal mucous membrane and separated into two lateral lobes by a shallow vertical median sulcus. This sulcus becomes deeper in benign scicile enlargement involving the lateral lobes, but, of course, is not altered when the enlargement is mainly intra-vesical; it is usually obliterated in malignant disease.

The chronically inflamed prostate is firm, only slightly movable, and generally has some tough nodular inflammatory deposits in one or both lateral lobes. Hard nodules surrounded by more or less normal prostate are very suggestive of tubercle and quite characteristic if the epididymis is also affected. A single calculus is difficult to diagnose by touch alone and requires confirmation by x-rays; but multiple calculi, which are usually small, can be rubbed on each other and feel like grains of uncooked rice in a bag. An abscess is tender and is felt as a soft area in the midst of the generally enlarged tough prostate. Pressure may cause a sudden gush of pus from the urethra. The malignant prostate is seldom much enlarged and is sometimes quite small; it is stony hard, irregular and nodular, and firmly fixed. The median sulcus is absent and the sulcus generally felt at the edge of the normal lateral lobe is replaced by a firm flat band apparently joining the prostate to the pelvis. This band is composed of lymphatics and cellular tissue infiltrated with carcinoma cells. Occasionally the infiltration can be felt spreading upwards on the posterior wall of the bladder. The examiner should remember that carcinoma of the prostate gives rise to early metastases in bones, favourite sites being the lumbar and sacral vertebræ and the pelvis, and so whenever possible he should have these regions x-rayed. Occasionally the primary growth is "slight," and the metastasis is the first indication of its existence.

Below the prostate on each side of the mid-line Cowper's glands can be felt, if enlarged, by grasping

the tissues between the finger in the rectum and the thumb on the perineum. The seminal vesicles spread almost horizontally outwards from the upper border of the prostate. When healthy they can hardly be felt, even bimanually; therefore if they are palpable they are almost certainly pathological. The commonest causes of enlargement of the vesicles are chronic gonococcal infection and tubercle. In the former, pus casts and infected fluid can be expressed by massage, but they are not obtainable in the latter as the thickening is due to caseation and fibrosis.

Hæmatospermia is a common symptom of tuberculous vesiculitis, but also occurs in chronic inflammation of the verumontanum. In a thin subject it is possible to feel a stone in the lower end of the ureter, pressure often causing a pricking sensation along the urethra. A thickened ureter can sometimes be felt bimanually in both male and female, and when discovered is almost pathognomonic of renal tuberculosis.

(6) EXAMINATION OF THE SECRETIONS AND EXCRETIONS.

The apparatus required for consulting-room examinations consists of a microscope with a 1/6 inch and a 1/12 inch oil immersion objective, a movable stage, a platinum loop, a small bottle of carbol-thionin or methylene blue, slides and cover slips, and the usual reagents for testing urine.

When the patient complains of a urethral discharge or a gleet, a drop is collected from within the urethra with a sterile platinum loop and a thin smear is made on a slide. This is dried, stained for a few minutes with carbol-thionin, washed with tap water, dried by heat and examined with a one-twelfth objective. Organisms are stained deep blue, and if they are diplococci and are both in and around the cells they are certainly gonococci. If the discharge is very scanty the three-glass test is carried out and the debris stained and examined. Little masses of pus called "commas" come from the crypts of the urethra, thin long threads from the prostate.

If the urethra and prostate are not under suspicion a specimen of urine is collected in the ordinary way and submitted to the usual chemical examination. If there is any deposit or alteration in colour a drop should be placed under the microscope and examined with a 1/6 inch lens, when blood, pus, crystals, casts, cellular elements, bilharzia ova, etc., can all be seen and identified.

If motile bacilli are noticed they are almost certainly *B. coli* for they are the only ones that can be seen with such a low power. An acid, hazy urine containing pus cells may be due to colon bacilluria or tubercle, and should be subjected to careful examination by a pathologist. Uric acid and oxalate crystals are found in acid urine and can account for a small quantity of pus, but this cannot be accepted for a diagnosis, as both crystals and pus may be secondary to a stone in some part of the urinary tract.

Cloudy, alkaline urine may be due to phosphates, bacteria or pus. Phosphates sink to the bottom of the glass and dissolve on the addition of a few drops of acetic acid, whereas pus and bacteria are unaffected. Ammoniacal urine is due to decomposition of urine in the bladder occurring in chronic cystitis caused by obstruction or paralysis. Putrid, alkaline urine may be due to the same cause, or to a vesico-intestinal fistula, or a necrotic vesical growth, but it may also come from a pyonephrosis in which there is a large quantity of pus and retained urine.

(7) INSTRUMENTAL AND RADIOGRAPHIC EXAMINATIONS.

If the history and symptoms point to a stricture, a metal urethral sound should be passed with aseptic precautions after rendering the urethra analgesic by injection of a few drachms of 5 per cent. novocain solution. A medium size is selected, say 18 F., as this is large enough to localize the stricture and blunt enough not to injure the urethra. The bladder sound is seldom used nowadays, its place having been taken by the cystoscope.

Urethroscopy and cystoscopy require special instruments and training, and therefore a description of these important methods of examination has been omitted. It should be realized, however, that practically every

urological case may ultimately require one or both of these examinations together with a complete radiological examination. Urethroscopy is required for the diagnosis and treatment of chronic anterior and posterior urethritis, and for locating strictures, tumours, and abnormalities of the canal; it is always indicated in cases with perineal and urethral pain. The cystoscope is required to make and to complete diagnosis, and as a means of catheterizing the ureters and treating various prostatic, vesical, and ureteric conditions. Its use is indicated in every case of hæmaturia; in all inflammatory conditions of the bladder and kidneys, sometimes during but generally after the acute symptoms have subsided; in all cases of suspected stone, neoplasm, and foreign body; and in many cases of prostatic obstruction.

When the object of the cystoscopy is to discover the source of blood or pus or to ascertain the cause of obscure renal pain, or to localize shadows in the renal and ureteric regions, the examination must be carried out in a place where a good x-ray apparatus is available, for in order to elucidate the problem it will be necessary to catheterize the ureters, to take stereoscopic x-ray photographs, and to make pyelograms. My routine in these cases is as follows:—

The patient is given a good aperient 24 hours beforehand, to clear the bowel for radiography. One hour before examination 15 grammes of urea in 100 c.cm. of water are given by mouth on an empty stomach; this is used as a test of renal function and its diuretic effect also ensures a good flow of urine. As the patient must be conscious when the radiograms are taken, a general anæsthetic is not permissible; should the patient be temperamentally unsuitable for local analgesia, or should the bladder be very irritable, the cystoscopy and catheterization of the ureters can be carried out under gas oxygen anæsthesia. On introducing the cystoscope a specimen of bladder urine is collected in a sterile tube; the ureters are then catheterized and specimens of urine from each kidney collected in sterile tubes. The three urines are preserved for bacteriological and biochemical examination.

The patient is now placed on the x-ray table and stereoscopic radiograms taken of the kidneys and the pelvic portion of the ureters. The examination is completed with a pyelogram of each kidney.

When carried out in this way the bacteriology and cystology of the urinary tract is investigated, the course of abnormal deposits in the urines is discovered, the function of each kidney is estimated, all shadows in or near the urinary tract are localized, and the shape and size of the pelvis and calyces of the kidneys are ascertained. Further information can be obtained only by operation. In stricture cases a urethrogram is useful. It is made after the injection of 10 c.cm. of heavy lipiodol and shows up irregularities, periurethral abscesses, and false passages. A cystogram is useful in disclosing a diverticulum or an incompetent ureterovesical valve. In the latter the opaque fluid will distend the ureter and kidney as well as the bladder.

Notes on some Hæmatological and Serological Investigations in Leprosy.

By JOHN M. HENDERSON, M.B., Ch.B. (Glas.),
N. K. DE, B.Sc. (Cal.),
and
S. GHOSH.

(*The Indian Journ. Med. Res.*, January, 1929; p. 687.)

THE present series of investigations was undertaken with a view to determining whether any change directly attributable to leprosy could be detected in certain of the physical properties of the blood and serum and to correlate these changes, if possible, with the type and stage of the disease and the sedimentation rate of the erythrocytes.

(1) Specific gravity of whole blood.

For the determination of this property, the simple and relatively accurate method described by Rogers (1913)

was employed. This consists in making up a series of mixtures of glycerine and distilled water so as to give a range of specific gravity from 1046 to 1064. Blood was drawn from the median basilic vein into a perfectly dry and sterile all-glass syringe and one drop quickly added to each of a series of test-tubes containing about 5 c.c.s. of the glycerine-water mixtures of different specific gravities. The specific gravity of the blood is represented by the particular glycerine-water mixture in which the drop of blood prior to disintegration remains momentarily suspended in the body of the fluid. Simultaneous estimations were made and the final result was taken as the mean of the independent readings.

Thirty cases representing different types and stages of the disease were investigated.

Conclusions.—The type and stage of leprosy *per se* appears to have little effect on the specific gravity of the blood. Advanced types appear if anything, however, to be associated with a slight lowering of specific gravity.

There is some correlation between the sedimentation rate of the erythrocytes and the sp. gr. of the blood in that an increased sedimentation rate tends to be associated with a relatively low sp. gr.

(2) Fragility of the Red Blood Corpuscles.

This was estimated in the usual way by making up a series of solutions of NaCl in distilled water so as to give a range of concentrations of NaCl between 0.50 per cent. and 0.30 per cent., with a mean difference of 0.02 per cent. between any two adjacent solutions in the series. About 6 drops of blood obtained by finger-prick were received in a paraffin watch glass and of this 10 c.mm. were quickly transferred to each of a series of tubes containing the range of NaCl concentrations. Each tube was quickly inverted several times, the contents thoroughly mixed and the tubes set aside to stand for 30 minutes at room temperature. At the end of this period each tube was spun in the centrifuge for 5 minutes and the readings taken.

Twenty-eight cases representative of all types and stages of the disease were tested in this way. Without going into unnecessary detail it may be stated that we could find no very great variations from normal in the majority of cases. Any individual variations fell within the limits of experimental error.

(3) Surface tension of Blood Serum.

For the estimation of this property we employed a Traube Stalagmometer and in order to ensure uniformity of results particular attention was paid to the following points:—

(a) Cleanliness of the instrument. The presence of foreign matter and particularly of grease, profoundly alters the results. The instrument was carefully cleaned out with distilled water, absolute alcohol and ether and finally placed in the hot air steriliser, protected from dust, for half an hour.

(b) Uniformity in the size of drops. Marked differences in readings may result from differences in the size of drops. To eliminate this source of error so far as possible, the instrument was suspended vertically, its position being checked by the plumb line. The mouth of the stalagmometer was also carefully wiped with a clean cloth immediately prior to counting lest variations should arise consequent on partial drying of the column of serum immediately above the dropping orifice.

(c) Air bubbles were rigidly excluded from the column of fluid.

(d) Successive estimations were carried out at the same temperature:—37°C.

(e) All active treatment had been suspended for at least one week in the patients selected for experiment, lest alterations in surface tension might be caused by this factor.

Method.—In the absence of a regular thermostat we employed a bacteriological incubator regulated at 37°C. The stalagmometer was suspended vertically in the incubator and attached to its upper end was a long piece of close fitting rubber tubing which passed through a cork filling the thermometer opening in the roof of the

incubator. The other end of the tubing was clamped and a centigrade thermometer suspended inside the incubator.

About 10 c.c.s. of blood having been drawn from the median basilic vein into a sterile test-tube, the serum was separated from the clot and placed in a small clean glass vessel inside the incubator. Serum was then drawn up into the stalagmometer by suction through the rubber tubing until the upper level of the column of serum was just above the top mark on the stalagmometer. The column was then allowed to fall until the meniscus of the fluid reached this mark after which the rubber tubing was clamped. The vertical position of the instrument was checked and the column of fluid carefully inspected for air bubbles. The temperature having become steady at 37°C. the dropping orifice of the instrument was carefully wiped with a clean cloth, the position of the instrument again checked, the rubber tubing unclamped and the drops counted as the fluid fell between the heavy marks on the stalagmometer tube. The whole procedure was watched through the inner glass door of the incubator thus avoiding fall of temperature during the experiment. In all, 22 sera from different types of leprosy were examined and in both the reacting and non-reacting phases of the disease.

Our results may be tabulated as follows:—

(1) Surface tension of normal sera (mean of 56 observations)—63.3 dynes per cm.

(2) Surface tension of leprosy sera (mean of 90 observations)—62.4 dynes per cm.

(3) Surface tension of "reacting" leprosy sera only (mean of 42 observations)—62.4 dynes per cm.

It seems justifiable to make the following statements:—

(1) The surface tension of leprosy sera is on the whole somewhat lower than that of normal sera tested under approximately identical conditions: but the difference is not one which can be regarded as having any clinical significance.

(2) The surface tensions of sera from cases in the quiescent and reactionary phases of leprosy are approximately the same.

(3) There tends to be a fall in surface tension with acceleration of the sedimentation rate of the erythrocytes.

SUMMARY AND CONCLUSIONS.

(1) Observations have been made on the specific gravity of the blood, the fragility of the red blood cells and the surface tension of the serum in leprosy cases.

(2) The type and stage of leprosy *per se* appear to have little influence on any of these phenomena.

(3) Cases of leprosy showing increase in the rate of sedimentation of erythrocytes tend to show also a fall in the specific gravity of the blood and in the surface tension of the serum.

The Microscopical Changes Occurring in Organs after Death.

By F. P. MACKIE, V.H.S., O.B.E.,

LIEUTENANT-COLONEL, I.M.S.

(The Indian Journ. Med. Res., January, 1929, p. 827.)

In our study of the changes in the intestine of sprue cases, we realized that some of the appearance we described might be due to, or at least were coincident with, those due to decomposition.

The importance of being able to recognize post-mortem change is a problem which confronts all histologists, but particularly those working in the tropics.

We set ourselves the task of observing such changes in orderly sequence and, as human material is not easy of control, we used the organs of monkeys. A healthy monkey was killed by chloroform and the intestinal canal, liver and kidney were removed *in toto* and kept in sterile dishes. Portions of the upper part of the small intestine, the lower part of the small intestine, of the large intestine, of the liver and kidney were removed after various intervals and placed in fixative for subsequent section. The intestines were not opened or washed out before fixation.

Summary of Findings.

The microscopical changes due to putrefaction as studied in the intestines, liver and kidney are discernible three hours after death at room temperature (75°F.) and proceed in an orderly manner as far as they have been followed (24 hours). The first changes are discernible in the epithelial cells of the kidney and of the intestine, and are of the nature of granularity of the cytoplasm, swelling and indistinctness of the nuclei and slight changes in tinctorial reaction. As putrefaction proceeds, the epithelial cells and the parenchyma cells of the liver gradually break up, lose their outlines, become hazy and eventually merge into an homogeneous mass. The nuclei first become swollen and vacuolated, lose their affinity for hæmatoxylin and eventually dissolve up. Muscle cells withstand the process longer but eventually show similar changes. The connective tissues retain their characters still longer and for this reason the general architecture of the organ is retained long after the parenchymatous cells have become diffuent or are dissolved.

Intestinal bacteria begin to penetrate the intestinal mucosa about nine hours after death and putrefactive bacteria are met with in increasing numbers after this time, and their distribution is generalized equally throughout the tissues suggesting that they have probably been carried there by the blood stream and not by invasion from a local site after death.

A Simple Method of Preserving Fæces Containing Hookworm Eggs.

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
(*The Indian Journ. Med. Res.*, Vol. XVI,
No. 3, January, 1929.)

Owing to there being a considerable loss of hookworm eggs from fæces kept in tins a method of preventing this loss is essential if accurate quantitative figures are desired.

The following method has been devised, and it has been found to keep hookworm eggs satisfactorily for at least three weeks under any climatic conditions.

Wide-mouthed bottles of about thirty cubic centimetres capacity are partially filled with twenty cubic centimetres of freshly prepared antiformin in water in a strength of 2 per cent., and they are tightly corked.

Small paper measures of four c.c. capacity are made in the following manner. The plunger of a ten cubic centimetres syringe is taken and a cylindrical rod of exactly the same diameter as the plunger is made of some hard wood. A circular mark is made on the wooden rod the exact distance from one end that four cubic centimetres, taken from the scale on the syringe barrel, covers. Strips of fairly stiff plain writing-paper, that will not readily disintegrate in water, are cut; these are about ten mm. broader than the distance of the mark from the end of the rod. These paper strips are cut in lengths about five mm. longer than the diameter of the rod. A piece of this paper is rolled tightly round the wooden rod and the overlapping portion is gummed, forming a cylinder. The cylinder is put aside until the gum is dried, and it is then pushed on to the wooden rod until its edge reaches the circular mark. The projecting paper is now folded over against the end of the rod and the folded paper is held in place by a small square of gummed paper applied over the folds. This gives a paper tube of four cubic centimetres capacity.

A special box is made to hold the bottles in a given place, and to obviate the use of straw packing. The box has a false bottom about one inch above the true bottom and holes are cut in it to fit the bottles. A tray composed of two sheets of thin wood one inch apart is made, and in the upper sheet a series of holes similar to those in the false bottom are cut, to hold more bottles. A flange is placed round the inner walls of the box at such a height that the tray, when in position, will just touch the corks in the bottles in the bottom layer; the lid of the box is hinged and it is of such a height that it comes in contact with the corks of the bottles in the tray. The box is closed by a hasp and staple, and a

padlock. The holes in the tray and in the false bottom are numbered, and a piece of paper, ruled to contain a number of spaces corresponding to the number of bottles in the box, and with columns for desired particulars, is fixed inside the lid of the box with drawing pins.

Fæcal specimens are collected in the field in the usual tin pill boxes with a piece of paper gummed on to the lid of each for recording particulars. On the same day that the stools are collected a paper measure is exactly filled from each tin and it is dropped into one of the bottles, and at the same time the particulars on the lid of a tin are copied on the sheet of paper in the lid of the box opposite the space corresponding with the number of the hole in which the bottle is placed. It is necessary to tie the corks into the bottles with a piece of twine, otherwise the pressure within the bottles generated by fermentation may so loosen them that they leak during transit.

On receipt at the laboratory the loose papers which were the measures are removed from the bottles with forceps and the bottle is well shaken to make an even suspension of fæces. Six cubic centimetres of this mixture is immediately poured into Lane's centrifuge tube, which has been previously marked with a diamond at the six cubic centimetres level, and this portion is subjected to Direct Centrifugal Flotation in the usual way. Negative bottles are discarded and the residue of the positive bottles is poured into flasks, and the bottles rinsed out with the requisite amount of N/10 sodium hydroxide to give the proper dilution by Stoll's method when it is added to the flasks.

The bottle originally contained twenty cubic centimetres of antiformin solution and four cubic centimetres of fæces, so that six cubic centimetres of this mixture contains one cubic centimetre of fæces, which is the optimum amount for D. C. F., and the remaining eighteen cubic centimetres of mixture contains three cubic centimetres of fæces, which is the correct amount counting by Stoll's method. Therefore, in addition to being preserved, the fæces are accurately measured at the time of collection, which is a great saving of time in laboratory.

This method has been used successfully on several hundreds of specimens. It is very cheap because, apart from the bottles, all the necessary apparatus can be made in the laboratory.

Value of Leucocyte Counts, according to Schilling Formula, in Clinical Medicine.

By F. W. NIEHAUS, M.D.
(*The Journ. Lab. and Clinic. Med.*, March 1929,
Vol. XIV, p. 531.)

THE numerical and the differential leucocyte count is recognized as a valuable laboratory procedure; especially in infections it is regarded as an index of severity, and frequently is an important factor in deciding whether or not to perform a major surgical operation. But this measure is not always infallible, and often the leucocyte count does not furnish the anticipated information.

The method to be considered here has been found to minimize greatly these disappointments.

The first attempt to modify the conventional leucocyte count was made by Arneth in 1904, the chief point of which was a classification of the neutrophils according to the nuclear morphology. His method was rather intricate, and too ponderous and time consuming for use in clinical medicine.

Cook modified this method, dividing the neutrophils into five groups. This is a practical method, and furnishes as much information as the more complicated Arneth classification, and is still used by Ponder.

Schilling recently modified Arneth's method. His method is much simpler; in fact, with good preparations, it does not appreciably increase the time and labour of an ordinary differential, and markedly adds to its value. His classification of leucocytes is as follows:

1. *Mycocytes*.—The nucleus is round, oval, or kidney-shaped. It is relatively large, vesicular, and stains palely. It is coarsely granular, and usually has a nucleolus. The cytoplasm is pale blue. The granulations are usually delicate, and stain weakly. These are normally found in the bone-marrow, but never in the peripheral blood.

2. *Young Forms*.—Normally many are present in the bone-marrow, rarely in the peripheral blood. The nucleus is sausage or bean-shaped. It is vesicular, and does not stain intensely. There are granulations in the ends of the nucleus. The cytoplasm is like that of mature cells. At times it is distinctly light blue; the granulations are not so distinct. The cells are usually slightly larger than mature cells. This class is, in part, identical with Pappenheim's "metamyelocytes."

3. *Staff Forms*.—The nucleus is T, U, or V shaped. The cytoplasm is fully mature. These cells constitute 3 to 5 per cent. of the leucocytes of normal blood.

Degenerative staff forms are apparently mature neutrophils without segmentation. On account of a developmental inhibition, the sausage form does not divide into segments. They are differentiated from the normal staff forms and the young forms by small band-like, often bizarre, twisted and always hyperchromatic (dark, structureless) nuclear forms. The granulations either easily over stain or stain feebly and are partially dissolved. These easily break in making smears.

4. *Segmented Forms*.—The nucleus consists of 2 to 5 unequal segments. The latter are united by fine threads. Broader unions (bridges) are temporary attenuations of the nucleus, which are influenced by technique and amoeboid movements. Only the former are classified as segmented. About 67 per cent. of these are present in normal blood.

The other forms of granulocytes are the *eosinophiles* and the *basophiles*. Cells ordinarily classified as small lymphocytes are the only cells recognized as *lymphocytes*. Those white corpuscles which are usually classed as large lymphocytes, and the transitional cells, are called monocytes. The monocytes are described as at least twice the size of a red blood cell, usually much larger than a granulocyte. The cytoplasm is relatively wide, stains smoky blue to pale violet, and it frequently contains small vacuoles. The nucleus is of a medium size, or relatively large. Its shape is oval, or bean-shaped; it is placed slightly eccentric; the wall is never entirely smooth. It may even be sausage-shaped, or have plump segments.

Schilling further conceives the origin of white corpuscles from three sources namely: the granulocytes from the bone-marrow; the lymphocytes from lymph glands, and lymphoid tissue wherever found; the monocytes from the reticulo-endothelial tissue. The peripheral blood picture reflects the functional status of these organs or tissues, as influenced by their disease, or by their response to exciting agents, as infection. This is further influenced by destruction of leucocytes so that two factors are at work, namely, productive and destructive.

With pyogenic infection there is a bone-marrow stimulation to increased production, and also an increased use of neutrophils before they reach normal maturity. The greater the stimulus the less mature are the cells thrown into peripheral circulation. So that, first, the number of the staff forms, then the young forms, and even the myelocytes are found in circulating blood. Coincident with this influx of immature forms, the cells are used before reaching maturity. In classifying these cells according to the nuclear form and consistency, a marked difference in the nuclei is evident. This is designated nuclear deviation. These are usually written from left to right across a page (myelocytes, young forms, staff forms, segmented forms). As the number of cells belonging to the groups on the left is increased, this condition is referred to as deviation to left. Changes enumerated above are regenerative changes. Besides these some diseases and infections exert an influence primarily inhibiting bone-marrow. These are degenerative changes.

With this conception in mind, certain blood pictures indicate certain phases of disease or infection.

(a) Slight stimulations produce only minor changes with slight increase of staff forms.

(b) Moderate stimulus shows a few young forms.

(c) Strong excitants cause marked increase of the young and even parent forms (myelocytes).

Ordinarily, the leucocyte count is parallel with the severity of the infection, but with very grave infection a sudden fall may occur. In the latter instance the decrease might be interpreted as an omen of recovery but in reality would be the reverse. The correct interpretation would be evident by proper scrutiny of the individual cells. Undoubtedly many young forms would be present in the blood. This phase concerns only the neutrophils. When this ends favourably, with a return of nuclear deviation to the right, and decrease of leucocytosis, there is an increase of monocytes. This denotes that the infection has been conquered. The healing phase is evidenced by a lymphocytosis. Eosinophiles also disappear from the blood in severe infection, and their reappearance is the earliest favourable sign. On the other hand, basophiles appear only with severe infection, when the defensive factors are losing ground, and disappear with earliest improvement.

In all cases of acute appendicitis, there is a significant increase in the number of the younger cells. Its value was particularly emphasized in the cases which have only a slight increase in the total number of leucocytes.

Only those cases of chronic appendicitis are included which showed definite chronic inflammatory changes histologically. These are chiefly characterized by a more or less increase of the lymphocytes.

With normal pregnancy the usual leucocytosis is partially due to an increase of the immature forms.

The changes with the acute respiratory infections were very irregular. Deviation to left was coincident with the onset of a pyogenic process, usually several days after onset of illness.

In acute mastoiditis there was usually a definite increase in non-segmented forms. In several cases with low total leucocyte counts the Schilling differential was particularly valuable.

Chronic focal infection is characterized by an increase of lymphocytes.

Acetylcholine as a Depressant.

(Abstracted from *The Prescriber*, April 1929, Vol. XXIII, p. 146.)

CHOLINE, or hydroxyethyl-trimethylammonium hydroxide, $(CH_3)_3N(OH).CH_2.CH_2.OH$, is a base that has been isolated from numerous animal and vegetable tissues. Its main pharmacological actions are those of lowering blood-pressure and of stimulating intestinal peristalsis, both of which actions can be antagonized and controlled by atropine. These properties are possessed also, and in much greater degree, by its acetyl derivative.

Acetylcholine, $(CH_3)_3N(OH).CH_2.CH_2.O.CO.CH_3$, is the acetyl derivative of choline. It occurs in small quantities in ergot, but as it is very readily hydrolysed it is usually absent from medicinal preparations of that drug. It has long been known to possess the properties of choline in a much more powerful degree; indeed the general impression has been that it was too poisonous for administration medicinally.

Careful investigations during the past three or four years, however, have shown that acetylcholine, when suitably administered, is not only safe, but is a valuable therapeutic agent. It is known that the depressant action of histamine is directed mainly to the capillaries, causing flushing of the skin by dilatation of these vessels; the action of acetylcholine, on the other hand, is confined to the arteries and arterioles. Its action as a vasodilator was found to be 100,000 times as powerful as that of choline, while its toxicity was only three times as great.

So powerful is this vasodilator property of acetylcholine, that Krogh regards its action as that of a hormone; the presence of minute quantities in the blood serves, he thinks, to maintain, in conflict with

adrenaline, the requisite arterial tension throughout the system.

Further studies have revealed other details of its action. Subcutaneous injection increases the volume of the retinal artery in man. In very dilute solution it excites the uterus of the guinea-pig. It increases the tone of smooth muscle and stimulates intestinal peristalsis. It produces contraction of striped muscle, which is controlled by atropine. In most respects its action is directly opposed to that of adrenaline.

The form in which it is used is the hydrochloride, which is a white powder, very hygroscopic, and soluble in water forming a stable solution. It is administered by subcutaneous or intramuscular injection: intravenously it is dangerous, while orally it seems to have no action. The dose is 0.05 gm. the first day and 0.1 gm. the following day. If in ten days the results are inadequate, a dose of 0.2 gm. may be given twice daily, but usually the single daily dose of 0.1 gm. is sufficient.

The vasodilator property of acetylcholine being restricted to the arteries and arterioles, the drug is of use in those conditions in which its effect on the vagosympathetic equilibrium can be exerted. It is of value in Raynaud's syndrome, in gangrene arising from arteritis, and in troubles of a like nature. In ten or fifteen minutes after an injection the fingers recover their normal colour; this persists for twelve hours to three days. In arteritis with a tendency to stenosis it is often of considerable value, and in the many troubles and complications of arterial hypertension it frequently renders good service. Its action in dilating the retinal artery makes it useful in spasm of this artery. Profuse tuberculous sweats appear to yield to the influence of small doses, 0.01 to 0.02 gm. Acetylcholine holds promise of being of some value in angina pectoris and in lead colic, while its action on intestinal peristalsis suggests its use in habitual constipation.

Acetylcholine hydrochloride, synthetically prepared, has been put on the market in the form of ampoules containing 0.1 gm. of the dry salt; these are accompanied by ampoules each containing 5 c.c. of double-distilled water for its solution. The contents of one ampoule of the salt are dissolved in the distilled water for subcutaneous or intramuscular (not intravenous) injection.

A Study of the use of Parathormone in the Control of Menstrual Bleeding.

By E. ALLEN, M.D., F.A.C.S.,

and

H. C. GOLDTHORPE, Ph.D.

(*Amer. Journ. Obstetrics and Gynecology*, March 1929, Vol. XVII, p. 344.)

We have been trying for the past two years to control excessive menstrual bleeding with the parathyroid hormone. The primary rationale of this treatment is based on the increased coagulability of the blood encountered in hypercalcaemia. Added to this was the possibility that hypodermic medication with the active principle of the parathyroids might indicate to us some of the relationship between the ovarian and parathyroid secretions.

Beginning with the work of Collip, investigators have noticed the production of hypercalcaemic states with the increased coagulability of the blood in laboratory animals; particularly dogs. This hypercalcaemic state in dogs is characterized by anorexia, hæmorrhage into the gastro-intestinal tract, and death. According to Collip, this danger may be imminent when a serum calcium of 15 mg. per 100 c.c. of blood is reached. Hueper has reported depositions of calcium in excess of normal in many important organs obtained from dogs in which this hypercalcaemic state has been maintained for some time.

As far as we have been able to ascertain no case has been reported of a fatality in the human nor has any one established a level of hypercalcaemia in man. In view of the experimental evidence and lack of established

rules for dosage, we have had to be extremely careful in our experimental work on women.

It is difficult to evaluate clinical symptoms in different individuals, especially in women who are menstruating. Nausea, vomiting, headache, and a feeling of depression are a common accompaniment of the menstrual period. Therefore, we have discontinued medication in several instances where, if we had had the courage to continue, more definite results might have been obtained.

Method.

These experiments were conducted on a series of fourteen young women who complained of severe menorrhagia. All of them had been previously subjected, with only temporary if any results, to the usual hemostatic procedures, such as oxytocics, injection of foreign proteins, and operation. The foreign protein injections were given with the possibility in mind that the disturbance might be on an infective basis in spite of negative palpatory or operative findings. Eight of these patients had menstruated profusely from the beginning of their menstrual history. Subsequent observations are recorded in this paper on the four patients included in our preliminary report. Due to a change in services some of these patients have not been observed for the past nine months. However, the results include observations on most of them for at least three menstrual periods after all treatment had been discontinued.

Definite conclusions are hard to draw from such a small group of patients but we feel that the following points are of interest:

1. We obtained good results in five patients, fair results in six and poor results in three cases of severe menorrhagia treated with hypodermic injections of parathormone.

2. The optimum dosage seemed to be about forty units intramuscularly, given each day over a period of five days.

3. Most effective results were obtained by combining this medication with 120 to 180 grains of calcium carbonate or lactate by mouth per day.

4. Calcium levels bordering on the hypercalcaemic state were obtained only five times, and only by this combination.

5. Patients having this high blood calcium (13.24 to 15.5 mg. per 100 c.c. plasma) usually complained of some headache, nausea, and a rapid pulse. Bleeding ceased at these levels.

6. Intravenous injections of parathormone would seem to be contraindicated.

7. The same condition that cause the menorrhagia seems to predispose toward sterility.

8. Direct effect can be produced on the endometrium by radium and the ovaries, protected by the insertion of a lead screen through the cul-de-sac in patients where medication fails.

Acetylsalicylic Acid and Alkaline Citrates.

(Abstracted from *The Prescriber*, April 1929, Vol. XXIII, p. 144.)

A mixture of acetylsalicylic acid and sodium citrate with caffeine in the form of tablets has been introduced in Germany under the name of Amigren. It is stated that the therapeutic action of such a mixture sets in more quickly and more intensely than that of plain acetylsalicylic acid: it is assumed that resorption begins in the stomach and that the passage from there to the small intestine is more rapid.

The opinion of a number of medical men regarding the therapeutic action of this mixture during a recent influenza epidemic was that it is a most excellent mixture for influenza. By its use the blood poison is eliminated quickly from the system. In this the potassium citrate plays a part, because the action is both diuretic and diaphoretic. The action is quicker than that of acetylsalicylic acid, the patient often saying that there was a marked improvement even after the first dose. Then a small dose—say 5 grains—gives better results than one or even two 10 grain doses of

acetylsalicylic acid, and, finally, the patient does not complain of that washed-out feeling to the same extent.

The Intranasal Application of Insulin.

(Abstracted from *The Practitioner*, April 1929, Vol. CXXII, p. 267.)

THE writers have observed the effect on the blood-sugar in diabetics and in normal controls of insufflation of the nasal mucous membrane with a powder containing borax as a vehicle and varying quantities of insulin. Each powder of 25 to 30 mg. contained from 10 to 30 units of insulin. This powder was found to be quite non-irritant. Both in normal controls and in the diabetic cases a marked fall in blood-sugar took place within 2½ hours of the insufflation, thus proving that absorption from the mucous membrane of insulin had occurred. The writers do not suggest that this form of administration of insulin can replace that of subcutaneous injection in severe cases of diabetes which call for constant supervision, but they think that it may have a useful application in the treatment of the milder ambulant forms of the disease in which patients are at present allowed to give themselves the injections. The substitution of an intranasal administration for the often painful needle prick would be welcomed by these patients, and suitable dosages could, with care, be readily determined.—(H. Wassermeyer and A. Schafer. *Klinische Wochenschrift*, 29th January, 1929, p. 210).

Treatment of Neurasthenia.

(Abstracted from *The Practitioner*, April 1929, Vol. CXXII, p. 264.)

THE writer is of opinion that physico-therapy is not of much value in the treatment of true neurasthenia; neither hydrotherapy, electricity, nor heliotherapy have been found of benefit, in his experience. In neurasthenic dyspeptics bicarbonate of soda is contra-indicated, and magnesium oxide, with bismuth, is to be preferred; in some cases, dilute hydrochloric acid is of great benefit, given before meals, in water. Constipation should be combated by mild laxatives, such as psyllium seeds or liquid paraffin. The glycerophosphates are among the best drugs to employ in the treatment of neurasthenia, and the following prescription may be found useful:—

R			
Magnes. glycerophos.	..	cg. 25	(grs. iv.)
Pulv. valerian	..	cg. 10	(grs. j.ss.)
		1	
Pulv. belladonn.	..	mg. 5	(grs. ⅓)

Sig. For one cachet; to be taken twice daily before meals.

Strychnine should never be given to true neurasthenics; and opotherapy is of little benefit, except that extract of the suprarenal is helpful to patients who are very depressed; it is best given in the form of the fresh gland, powdered, in capsules.—(R. Benon, *Journal des Practiciens*, 9th February, 1929, p. 89).

Medical Research in 1928.

(*The Prescriber*, Vol. XXIII, April 1929, p. 121.)

(CONSIDERABLE interest has been aroused by the report of the National Research Council on the therapeutic value of artificial light, and considerable indignation has been evinced in certain quarters, but the following, taken from an editorial in the *Prescriber*, appears to be a fair statement of the case.—Ed., I. M. G.)

Considerable attention is given in the report on medical treatment by artificial ultra-violet light, which is now being advocated and used in a great variety of disorders. Some part of this new use of light has, the Council says, an indisputable scientific basis. It is now established that irradiation of a particular sterol known to exist in the fat of the skin actually produces the vitamin D which repairs the food deficiency of which rickets is one of the most obvious signs. But there is no scientific reason to suppose that the treatment of

rickets is better effected by irradiation of the skin than by the direct provision of the necessary food values. The use of artificial light to supply what the right food can give is merely wasteful: the same effect obtained from ultra-violet light at a cost of three or four shillings can be secured from cod-liver oil for less than a penny. As a substitute for the missing sunshine in our cities, ultra-violet irradiation is not very warmly supported by the Council. Trials among school children in London and elsewhere have yielded very contradictory results; and the general conclusion is that the power of resistance to minor ailments was not in any way increased, nor was the general health of the children improved by simple treatment with ultra-violet light. No objective evidence is provided, it is said, that results have been achieved which could not have been far more cheaply gained by proper food, and it appears that exercise and fresh air are greatly preferable to indoor sessions around a lamp. It has been definitely shown that ultra-violet irradiation, when it has caused a certain inflammatory reaction of the skin, does cause an increase in the bactericidal power of the blood, but this increase has not yet been correlated with any permanent effects of value in the body. Indeed there is no reason to suppose that artificial light does more than produce a certain counter-irritation, such as a mustard plaster produces at much less cost. Considerable work has been done with ultra-violet light in the treatment of superficial infections, but beyond a certain curative effect in the case of corneal ulcers the Council are unable to find evidence of any good results that cannot be obtained by simpler and less expensive treatment, and the expenditure of public money upon expensive installations is strongly deprecated. At the same time the Council believes in the effectiveness of natural sunlight, especially in surgical tuberculosis, though it is admitted that in such treatment other influences are bound to come into play.

Electrocution from Electrical Apparatus.

(Abstracted from *International Med. Digest*, Vol. XIV, March 1929, p. 192.)

A CASE was recently reported in which a young man was found dead in a bath with an ultra-violet ray lamp beside him. Death was attributed to shock, and an electrical expert, who examined the lamp at the request of the coroner, gave evidence to the effect that there were five ways in which an electric shock might have been sustained from the apparatus. The deceased had purchased the lamp in order to treat himself for blackheads on the back of the neck.

Another case was reported where a mischievous young boy electrocuted his younger sister by throwing an extension cord on which there was a lighted bulb into the bathtub in which she was bathing.

The fact that informed electricians invariably install fixtures in a bathroom with glass or china sockets or properly insulated chain pulls, is evidence of the fact that it has long been realized that water and electricity are extremely dangerous when they get together.

Reviews.

THE MEDICAL ANNUAL, 1929.—Bristol: John Wright and Sons, Ltd. 1929. Pp. 771, with many text illustrations and 71 plates (plain and coloured). Price 20s. net. Postage 9d.

For the medical man who has not access to a medical library and also abundant time to spend in that library, there is no better investment than the *Medical Annual*. It is far more than a mere epitome of the recent papers on any subject, it is a collection of reasoned résumés of the important advances made in each subject written by a man who is a master of his particular subject. Nobody can afford to buy a new textbook on each branch of medicine each year, but most of us can afford to buy the

Medical Annual; using this in conjunction with a textbook, one can be certain of being up-to-date.

There is little new to be said about this year's *Medical Annual*. It is quite up to the standard of its predecessor; amongst its special features are the large number of beautifully reproduced coloured plates.

Turning first of all to tropical diseases, we find that all the recent advances have been recorded. The most striking work of the year has been that on yellow fever. As the writer of this section points out, this advance has not been made without loss on our side; two of the world's leading research workers, Noguchi and Adrian Stokes, fell victims to the disease. Plasmodium has been in use for some years in malaria, though its use has been extended considerably during the year under review.

Amongst the surgical subjects the treatment of gastric pyloric and duodenal ulcer receives a considerable amount of attention. The question of the relative values of gastro-enterostomy and of excision of the ulcers in duodenal ulceration are considered. The medical man is reminded that he himself is subject to human ills by a paper in which the results of 100 operations on doctors for duodenal ulcer are analysed. They were nearly all treated by gastro-enterostomy and readers will be relieved to hear that in 90 per cent. the operation and the result were completely successful. In this section a number of new instruments are illustrated and there are also detailed illustrations of methods of excising gastric and pyloric ulcers in different positions.

Under the heading of anaesthetics there is a good summary of the work that has recently been done on Avertin, a new rectal anaesthetic. So far it has not been used to any great extent for producing complete anaesthesia, because for this the dose necessary approximates too closely to the toxic dose, but it has been used extensively as a sub-anaesthetic. Under its influence the patient goes to sleep quietly and minor operations can be performed, but for abdominal work an inhalation anaesthetic in small doses is used in addition.

L. E. N.

MANSON'S TROPICAL DISEASES: A MANUAL OF THE DISEASES OF WARM CLIMATES.—Edited by Philip H. Manson-Bahr. Ninth Edition. Revised. Cassell and Company, Ltd., London: Pp. XX plus 921, with 23 colour plates, 12 half tone plates, 401 figures in the text, 6 maps and 34 charts. Price, 31s. 6d. net.

THIRTY-ONE years ago the late Sir Patrick (then Dr.) Manson first published his *Manual of Tropical Diseases*. Since this date there have been eight new editions and a larger number of reprintings of this world-famous book. Throughout its thirty years of life it has been the standard handbook on tropical diseases for the English-speaking races. Larger books—running into a number of volumes—have been published in English and other languages, but in none of them have their producers contrived to be so comprehensive in so small a space. The earliest editions of this book had a smaller page sheet, wider margins and about half the number of pages of the present edition, and yet they contained an adequate résumé of contemporary human knowledge regarding diseases peculiar to the tropics. So great has been the advance in this branch of medicine that the present author—who modestly calls himself the editor—must have had considerable difficulty in condensing our present knowledge on the subject into the many times greater space of the present edition. We notice that the successive editions have assumed a 4-year periodicity. It seems to us remarkable that any one man can manage to keep so large a number of sections on so many diverse subjects so completely up-to-date; Dr. Manson-Bahr must have already begun the work of revision for his next edition.

It is absurdly easy for a reviewer to pick out what he considers mistakes in a book of this nature, but a review is scarcely complete without some criticism.

In the leprosy section the author makes no attempt to describe the course of the disease as it is now known. He states that the bacillus is found in the mucous membrane of the nose in the majority of early cases of

leprosy, a misstatement long ago proved as such. He denies the presence of giant cells and seems to be unaware that in certain common types of lesion they are invariably found in large numbers both in the corium and in the thickened nerves nearby. In the leishmaniasis section, there are a few statements of minor importance with which the reviewer cannot agree; for example, there is no evidence in India that "kala-azar—unlike malaria—shows a predilection for the acclimatized—the natives," nor is the remark that "Sinton first suggested in 1922 that a sandfly was the insect vector" true in any respect. Mackie in 1914 concluded a report in his extremely valuable work in Assam by saying that he considered that the sandfly, more than any other insect, would repay further investigation, whereas we have been unable to trace the Sinton (1922) reference. Figure 38 is not a good example of a case of kala-azar; it is a caricature. The reviewer has not seen, during the whole of his experience in Bengal and Assam, more than a dozen patients in this extreme condition and certainly less than a quarter of these were really cases of kala-azar, though they were usually sent to him as such. The reproduction of photographs of such exaggerated examples is common in textbooks, but is nevertheless to be deplored, more especially when they are the only clinical type illustrated, as they must inevitably give an entirely wrong impression to those unfamiliar with the disease.

We have searched in vain for a reference to justify the statement, attributed to Fairley, that "about 28 per cent. of malaria bloods in the acute stage of the disease . . . give a positive Wassermann reaction." We are sorry to see this ghost, which we thought was laid some years ago, again revived. (From the reviewer's point of view one of the most irritating features of the book is the complete absence of references.)

Although in every case the author has given a good résumé of the published works on the various diseases, there are occasions when he displays evidence of lack of first-hand experience of the disease about which he is writing. Manson's *Tropical Diseases* is a book which will always find a first place in the medical library of the student of tropical medicine, both in England and abroad; nevertheless, the information contained in it is often insufficient for the "specialist"—and every medical man working in the tropics should be a "specialist" in the few main diseases of the region where he is working—and for the research worker. At the same time we would not suggest that this book be enlarged; on the contrary, we think the author should in future only put in new matter at the expense of the old so as to keep the book down to a reasonable-sized single volume. It is time that the vast subject of tropical medicine was split up and there is an opening for books on *regional tropical diseases* with the various chapters written by experts with recent practical knowledge on their particular subjects. The man going to India, for example, could in addition to his Manson, purchase the book on tropical diseases of India; from such a book trypanosomiasis, schistosomiasis, etc., could be excluded and the extra space used up by dealing in greater detail with the diseases that do occur in India. At present, however, as far as India is concerned, such a book does not exist, and the practitioner here, or in any part of the tropics, cannot possibly afford to be without the latest edition of Manson's *Tropical Diseases*. The present edition has in every way maintained the high standard set by its predecessors and in some features it has surpassed them. The coloured plates, which include a few new ones, are excellent, the printing and paper are good, and the binding is pleasing and appears to be strong.

L. E. N.

THE DISEASES OF CHINA (INCLUDING FORMOSA AND KOREA).—By Dr. James L. Maxwell, M.D., B.S., Secretary, China Medical Association; Editor, *China Medical Journal*. Second edition. Shanghai, China Medical Association, 1929. Pp. 530, with 174 illustrations. P. O. Box 1121. Price, in China and the East, Mex. \$10.00; in Great Britain £1.

We have nothing but praise for this very well got-up and most informative book, which is the second edition

of Jefferys and Maxwell's first edition. As far as we know, information about the diseases prevalent in China is very scanty and very difficult to get at; for instance, almost the only paper dealing with the distribution of malaria in China is one by Faust in 1926, though Boeckh in 1923 mentions the introduction of epidemic malignant tertian malaria into Hoyun province by Sun Yat Sen's troops in that year. As editor of the *China Medical Gazette*, however, the author has had access to full sources of material and the result is a second edition which should be in the hands of every medical worker in China, and which will be of considerable interest to every medical practitioner in Asia. The illustrations alone will be of profound interest to medical men in the East, for there is hardly a phase of tropical medical practice which is not illustrated in the book.

The book opens with a most interesting account of medicine, past and present, in China. The indigenous systems of medicine in China do not have the vogue that the corresponding ones in India have; for we read that no well-known Chinese proverbs are that 'medicine is one of the nine low trades,' and that 'the ordinary physician kills men.' Ethical standards are completely lacking.

The main subject matter of the book is divided into two parts, dealing respectively with medical and surgical diseases. The book is remarkable throughout for its vivid descriptions of local conditions in China, of the difficulties with which medical men practising in that country are faced. We are also pleased to note that free resort has been made to such Indian journals as our own and the *Indian Journal of Medical Research* (and full acknowledgments made). Enteric fever is probably widespread in China and common in childhood, if Minett's observations in Hongkong are evidence. Typhus is common all over north China and extends as far south as Shanghai. In this connection the use of the common Chinese bread-steamer for delousing is most interesting. Leprosy is very fully dealt with; it is very common in China, but generally of mild type. The full technique of the method of treatment by infiltration of the lesions is given, and both Calcutta and Philippine Islands' reports have been drawn upon for information. Deficiency diseases are also fully dealt with, accompanied by a very striking colour plate of the rash in pellagra and photographs of cases of osteomalacia. The information on kala-azar is meagre, but on the whole fairly accurate; the author, however, terms the parasite of the disease the Leishman-Donovan body, whereas the correct name is *Leishmania donovani*; also we believe the aldehyde test to be far more reliable than the globulin test for the serum in this disease, though the latter only is described in the volume.

The section on metazoal diseases is illustrated by some very striking photographs of cases of filarial elephantiasis, and the distribution of the disease in China is discussed. The author, however, quotes the old view of Manson that lymphatic obstruction in filariasis is due to liberation of unhatched ova from the adult female worm; it is far more likely that the obstruction is due to migration of the adult worm itself towards the surface lymphatics. *Ascaris* infection appears to be almost universal in China, whilst *Ancylostoma* infection appears to be commoner than infection with *Necator*. *Fasciolopsis buski* infection is very common over large tracts of China, while infection with *Clonorchis sinensis* is reported from Kwantung and Kiangsi provinces. Contrary to what is usually supposed to be the case, tapeworm infections are relatively uncommon in China, though the aboriginal tribes in Yunnan consume raw beef and suffer from *Tania saginata* infection in consequence. Formerly an advocate of open operation in liver abscess cases, the author now relies almost entirely on emetic and aspiration. He is of opinion that broncho-spirochetosis is a clinical entity, different from pulmonary tuberculosis, and that it is quite common in China.

Insanity appears to be a terrible problem in China, for the family system is well established in the country, and in the absence of mental hospitals the patient remains with the family who control him by any means, however cruel. The Kerr Hospital at Canton is the one solitary

institution that is attempting to grapple with this terrible problem. Atriplicism is a curious Chinese disease due to eating the weed *Atriplex serrata* in times of famine; it is associated with acute oedema of the face and hands and cyanosis. Suicide is very common in China, opium and phosphorus being the poisons most commonly employed. A few years ago the opium habit was sternly checked in China, but recent years have seen a terrible recrudescence of the habit, troops even being paid in opium in place of money. Here there is a whole series of extracts from reports by different observers, which shed much light on the opium question in China. The morphia habit is also well established in the country.

The undifferentiated fevers of China are the subject of a short, but interesting chapter. Diseases peculiar to China are again a most interesting subject: China is the world's largest storehouse of freaks, and voluntary deformities are common. The artificial making of wild men is a terrible operation, described in the volume; it consists in removing the entire skin at repeated operations and grafting the skin of a dog or other wild beast in its place, the victim's larynx being also mutilated. Footbinding is now happily uncommon in China, but the condition is illustrated by a photograph and a skiagram.

Turning to surgical diseases, the book is remarkable for its wealth of illustrations of tumours and allied conditions. China in fact appears to be even more remarkable than India in its immense numbers of surgical cases of tumours which have been allowed to grow to a very late stage before surgical help is sought. Hernia is extremely common in China; untreated fractures abound, and often give rise to most curious deformities. Osteitis of all kinds is very common, and an interesting account is given of a case of complete removal of the sternum.

Eye diseases are an immense problem in China, and one of which only the fringe has been touched so far. The author is (rightly) emphatic that the general practitioner should not attempt advanced eye work, such as cataract operations; these should be left to the specially trained worker. The incidence of trachoma is variously estimated at from 10 to 50 per cent. in different parts of the country. Skin diseases have a very large place in the practice of medicine in China (and in this connection we are glad to see incorporated much of Acton and McGuire's work taken from this journal, and freely acknowledged). Molluscum fibrosum is the subject of several striking photographs. The chapter on tumours is unique; perhaps in no other country in the world could so extraordinary a collection of photographs have been got together. A full discussion is given as to the incidence any types of cancer seen in China. Vesical calculus is said to be especially prevalent in the province of Kwangtung, whilst a very striking photograph on p. 500 is one of a trayful of calculi removed from a urethral diverticulum. The general prevalence of syphilis is about 15 per cent., and probably twice that figure for troops; the disease was apparently well known in China as early as the 12th century A.D.; tabes dorsalis is rare in China, but it is stated that with the enormously increased nervous tension in the population of recent years owing to the chronic civil wars, it is markedly on the increase. Gonorrhoea in China is described in an ancient book by Huang Ti, B.C. 2736.

Finally, a word must be said as to the printing and binding of the book. For a work published in China, these are excellent. In general the very numerous illustrations are well executed.

Dr. Maxwell is to be heartily congratulated on this excellent treatise. It reads like the record of an expedition into unexplored territory, and it will be of interest to medical men throughout the East generally.

R. K.

THE STORY OF MODERN PREVENTIVE MEDICINE.
—By Sir Arthur Newsholme, K.C.B., M.D., F.R.C.P.
London: Baillière, Tindall and Cox, 1929. Pp. XII plus 295, with 9 figures in the text. Price, 18s. net.

This volume is a continuation of the author's *Evolution of Preventive Medicine*, published in 1927, and

is intended at least as much for the layman as for the professional. It gives a simple and readable account of the discoveries in parasitology and physiology of the 19th century, after which the chief epidemic diseases of the world are considered separately, with accounts of the progress made in the struggle against them. Chapters VI, XVII and XVIII, deal with filariasis and Texas fever, malaria, and yellow fever respectively; and in these there are several statements not in accordance with modern beliefs. For instance, the exploded hypothesis that filariasis can be contracted by ingesting, or bathing in, water in which infected mosquitoes have died, is referred to on p. 137. On p. 138 the malaria parasite is called *Pyrosoma bigeminum*, whilst on p. 141 the parasite investigated by Theobald Smith is referred to as a *Plasmodium*. (*Pyrosoma* is a genus of deep sea Ascidians.) No mention is made of the work of Christophers in elucidating the cycle of *Babesia bigemina* in the tick. On p. 152 the sexual form of the malaria parasite is said to be a "sporozoite," whilst the statement on the same page that "mosquitoes prefer cattle to human beings" is not so generally applicable as the author supposes. There is a good deal of carelessness in proof reading evident in this section. Beauperrthuy's name is misspelt on p. 145, at the bottom of which "mesozoites" is printed where "merozoites" is meant. On the next page "gamocytes" catches the eye. On p. 163 Laidlaw's name is also mutilated.

The second section of the book deals with physical and social conditions of health and calls for no special comment. The illustration in Fig. 9 of the medical student contracting a sore throat in his "diggings" in the early "eighties" will amuse as well as interest a later generation. The bottle on the table may or may not be beer.

The third section on "Some Physiological Conditions of Health" gives a simple and interesting account of the endocrine system, and the vitamins, with the diseases connected with their dysfunctions. The statement is made on p. 259 that rickets does not occur south of the latitude of Italy. We know that the disease occurs in Colombo.

The book closes with a final chapter on the evil of alcohol, which must especially appeal to the land of the author's adoption.

R. S. W.

FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE. TRANSACTIONS OF THE SEVENTH CONGRESS, HELD IN BRITISH INDIA, DECEMBER 1927. VOL. I.—Edited by Lieut.-Col. J. Cunningham, C.I.E., B.A., M.D., I.M.S. Pp. 865; fully illustrated. Calcutta. 1929. Messrs. Thacker's Press & Directorles, Ltd. Price, Rs. 25.

We have previously dealt so fully with this most important Congress (in our issues for March and April 1928) that here we need only point out that the first volume of the *Transactions* is now published, and that a few copies are available for sale from the publishers, in addition to the copies which are supplied to all full members of the Congress.

The *Transactions* of the Congress held in Hongkong in 1912 were published in a single volume of 399 pages; those of the Congress held in Japan in 1925 necessitated two volumes, totalling 2313 pages. The *Transactions* of the 1927 Congress at Calcutta, however, run to three volumes, of which this is the first, totalling in itself 865 pages. This alone gives some indication of how enormously the work and scope of the Association has grown. In addition to these three volumes a separate supplement will deal with the business proceedings of the Congress. The first volume has also a foreword by Major-General Sir T. H. Symons, Director-General, Indian Medical Service.

The present volume covers Sections I and II of the six sections into which the Congress was divided. It includes papers dealing with medicine and dermatology; pathology; surgery; ophthalmology; gynæcology and diseases of pregnancy; mental hygiene; radiology; dentistry; State medicine; general and special hygiene; maternity and child welfare. There is here a wealth of material for the interested reader to browse in. Note-

worthy papers in this volume are the paper on secondary infections in enteric fevers by Lieut.-Col. F. A. F. Barnardo, I.M.S.; the two by Major H. Stott, I.M.S., on diabetes in the East; Sir Frank Connor's paper on the surgical aspects of filariasis, with Lieut.-Col. K. K. Chatterji's companion paper on the same subject. In the domain of ophthalmology Lieut.-Col. W. V. Coppinger, I.M.S., deals with glaucoma as seen in Calcutta, Major E. O'G. Kirwan, I.M.S., with the ocular complications of leprosy, and Major F. F. Strother Smith, I.M.S., with trachoma as studied in India. In the gynæcological and obstetric section Dr. Margaret Balfour's paper on diseases of pregnancy and labour in India is of first class importance; Dr. Agnes Scott's study of osteomalacia in India is equally interesting; whilst Dr. Kedar Nath Das' paper on operative midwifery in the pre-Chamberlen period is most fascinating and full of recondite information. Capt. Dunjibhoy's paper on the rôle of Indian hemp in the causation of insanity in India will appeal to mental specialists in this country. Dr. Galstaun's paper on radiological appearances in anæmic hepatitis and Madura foot opens up what is largely unexplored territory. Dr. Borland McVail's account of quarantine condition in the port of Calcutta is a paper of importance to all port officers of health. Lieut.-Col. A. D. Stewart's paper on the activated sludge process is a most important contribution to public health study in the tropics, whilst Lieut.-Col. A. J. H. Russell, I.M.S., discusses the question of population and public health in India—again a paper of first class importance. Dr. Ruth Young discusses the organisation of child welfare in India and the obstacles in its way; whilst a considerable discussion also took place on the same subject in this Section.

Altogether a most notable volume, and a noteworthy addition to the ever growing literature on tropical medicine and surgery. It only remains to add that the style of printing, binding and publication, are admirable; and to congratulate Colonel Cunningham, as Organising Secretary to the Congress, on the publication of the first of the three volumes of the *Transactions*.

R. K.

NEUROLOGICAL EXAMINATION.—By Charles A. McKendree, A.B., M.D. Philadelphia, and London: W. B. Saunders Company. 1928. Pp. 280. Illustrated. Price, 15s. net.

"The purpose of this book" to quote the author's own words "is to familiarise the medical student and those interested in post-graduate specialisation with a comprehensive and systematic form of examination of the central nervous system. The abnormal reactions are interpreted as pertinent pathological expressions of interference with anatomical relations and physiological functions in such a way as to give to the student clinical pictures of pathology which he may readily understand and group under various syndromes."

The book is divided into convenient chapters covering such themes as the history, physical examination, general sensory examination, cerebral nerves, systemic examination, skeletal system, mental status, etc. Under each head, lucid and exhaustive treatment of the various connected aspects are attractively brought out with suitable illustrations. In addition to the general subject matter of the book being presented in a uniformly praiseworthy manner of due proportion and proper perspective, the chapter on "mental status" deserves special mention as comprising excellently arranged collected matter on a subject which is at present engaging the attention of the student of psychology, sociology and allied branches of study. It is now widely recognised from extensive researches that "criminal tendency" is a pathological condition of the mind, just much like any other physical disease symptom. This attitude of outlook has of course not appealed strongly to dispensers of "law and order" yet; but it is bound to find universal acceptance in the near future.

We hope that in the next edition mistakes of a grammatical nature frequently committed in the text will be corrected. Dr. H. A. Riley introduces the volume with a brilliant foreword. The get-up of the book is

excellent. We have great pleasure in welcoming this little treatise.

S. S. R.

TUBERCULOSIS AND HOW TO COMBAT IT: A BOOK FOR THE PATIENT.—By F. M. Pottenger, A.M., M.D., L.L.D., F.A.C.P. Second Edition. St. Louis: The C. V. Mosby Company. 1928. Pp. 275. Price, \$2.00.

THE author is a well-known writer on the subject of tuberculosis, and his classical textbook on this disease has a wide reputation not only in the United States but throughout the world. The present book, coming from such an authority, will carry much weight.

There is general agreement nowadays as to the principles along which tuberculosis should be combated, both in the individual and in the community, and many books have been written on this subject. It is only by the continuous education of the patient and his relations, and of the public at large that we can hope in the end to stamp out this disease. Dr. Pottenger's style is lucid and he puts forward many practical hints which will prove helpful to those who seek to fight against tuberculosis.

E. M.

FRACTURES AND DISLOCATIONS: IMMEDIATE MANAGEMENT AFTER CURE, AND CONVALESCENT TREATMENT WITH SPECIAL REFERENCE TO THE CONSERVATION AND RESTORATION OF FUNCTION.—By P. D. Wilson, A.B., M.D., F.A.C.S., and W. A. Cochrane, M.B., Ch.B., F.R.C.S. (Edin.). Second Edition, revised; London: J. B. Lippincott Company. 1928. Pp. XVII plus 789 with 1029 illustrations. Price 45s. net. Obtainable from Messrs. Butterworth and Co. (India), Ltd. Price, Rs. 33-12.

It is a pleasure to review a second and revised edition of this excellent book; that a second edition would follow was a foregone conclusion.

A detailed account of the work is quite unnecessary, as this has already appeared in the *Indian Medical Gazette* for April, 1926. The book remains the same, except that "new methods and illustrations have been incorporated." Every surgeon and general practitioner must make himself familiar with the latest teaching on fractures and dislocations, and they could not do better than to select this book for the purpose. There are 19 chapters and 1029 illustrations; the latter are admirably executed, and liberally elucidate the text.

The publishers are to be congratulated on the way in which their work has been carried out in all respects; the English reader will not be irritated by American phraseology and spelling.

F. P. C.

PRACTICAL CLINICAL LABORATORY DIAGNOSIS.—By C. C. Bass, M.D. and F. M. Johns, M.D. Third Edition, 1929. Pp. 187 with 20 plates, 134 illustrations, including colour plates and photographs. London: Baillière, Tindall and Cox. Price, 34s.

THIS is an excellent manual, which should be in the hands of every laboratory worker. It is remarkable especially for its exceedingly complete series of photographs and for its colour plates. It is divided into 17 chapters, with 2 appendices, and is a wonderfully complete presentation of the subject in small compass. The use and care of the microscope, the preparation and staining of blood films, differential leucocyte counts, platelet counts and hemoglobin estimations, blood-sugar and other special blood tests, malaria, the Widal reaction, examination of the urine, gastric contents, and faeces, of pus and exudates and sputum; leprosy, the spinal fluid, tests in diphtheria, gonorrhoea and syphilis are all detailed very fully. The appendices deal with formulae and apparatus. The book is exceedingly well printed and illustrated on glazed paper, and well bound. It may seem expensive, but we do not consider it so when the tremendous number of illustrations—134 plus 20 plates—many of which are in colour, in 187 pages—is considered.

The chief merit of the book, indeed, is its profuse illustrations, many of them photographs, of successive steps in a laboratory procedure. Thus in the matter of

blood counts we have successive illustrations of the diluting pipette, the counting chamber from vertical and lateral aspects, taking the blood into the pipette from the patient's finger, diluting it in the pipette, revolving the pipette so as to thoroughly mix its contents, cleaning the cover glass, squeezing out the diluted blood into the counting chamber, each of the five steps in cleaning and placing the special cover glass over the counting chamber, looking at the distribution of cells to see that they are uniform, and of even and uneven distribution of cells—in all no less than twenty illustrations—many of them photographs—of the procedures employed in this one procedure. This alone will give some idea of how thorough the book is, and of how valuable it will be to laboratory workers in general.

In connection with each laboratory procedure the authors have given one method, and one method only, having selected in each case what they believe to be the best. The appendices are also very helpful, for they indicate with how small an amount of equipment the laboratory worker can carry out all tests ordinarily required. The colour plates also are a special feature of the volume, and (with one exception), admirably executed.

Of specially tropical diseases only malaria and leprosy receive consideration. With regard to the former, although colour plate VI of the malaria parasites is supplemented by a series of very fair photomicrographs, yet in our opinion it is very disappointing. We doubt indeed whether a student could learn to differentiate species from it. The delicate hair-like rings of *P. falciparum* are here shown as almost massive, whilst the hæmozoön pigment in *P. malariae* is here almost wanting. Partly this may be the publishers' fault, but the plate is very disappointing. A less crowded plate with fewer but more accurate figures would have been better. In connection with leprosy no mention of examination of the nasal secretion is made, and the coloured illustration of the lepra bacilli is poor; we doubt whether a medical practitioner proceeding to the tropics could reliably diagnose leprosy from this account.

With these exceptions the book is admirable. Its account of the dark ground examination for *Treponema pallidum* is good, though the account of the morphology of the spirochæte might be extended. No less than six photographic illustrations show how to draw blood for the Wassermann or other specific reaction from the antecubital fossa. The Butler precipitin test, however, and not the classical Wassermann test or any of its modifications, is described.

On the whole, a book which has many excellent points and will be most helpful to the laboratory worker, but which, we think, might be improved with regard to tropical diseases.

R. K.

HANDBOOK OF BACTERIOLOGY.—By J. W. Bigger, M.D., Sc.D. (Dublin), F.R.C.P.I., D.P.H., M.R.I.A. Second Edition. London: Baillière, Tindall and Cox. 1929. Pp. XVI plus 452, with 2 plates and 82 text figures. Price, 12s. 6d. net.

THIS little book should prove extremely valuable as a class book for M.B. students in this country. It gives the student an excellent introduction to the subject of bacteriology. The author has balanced theory and practice nicely and thus produced a book which will give the medical practitioner an insight into the theories of bacteriology and immunity and at the same time sufficient instructions to carry out minor bacteriological examinations for himself. It does not claim to be a book for the laboratory worker. It is, of course, disappointing to find that the protozoa have only been allowed 19 pages and the pathogenic fungi 7, but this is always their fate in textbooks, whether in Europe or America, and the average examinee is not expected to know more of the subjects than will be found in these pages.

The book, which is well bound, and well printed on good art paper, is strongly recommended to both students and teachers.

L. E. N.

recognised that it is almost all of bacillary type. India has the highest incidence of any country concerned. The incidence of enteric fevers was only 1.3 per 1,000. Influenza, on the other hand, reigned almost supreme—incidence 24.1 per 1,000; and it is clear that this disease constitutes one of the most important problems for the military medical authorities. Malaria accounted for admissions of 289.6 per 1,000 in West Africa; 138.8 in India; 82.7 in Mauritius; and in the Army generally for 49.5 per 1,000. An increase in Egypt was largely due to relapses in troops sent from India to that country, but north China and Shanghai had bad reputations during the year. Pneumonia was responsible for 3.6 per admissions per 1,000, with a case mortality of 10.8. These figures are interesting as they give the death rate among a healthy and medically selected population. An anti-vaccine was on experimental trial at Woolwich. Sandfly fever varies widely in incidence from year to year; it was especially prevalent in 1927 in Egypt, Iraq and Malta. Pyrexia of uncertain origin shows very wide variations indeed from one country to another. The majority of such cases are annually reported from Egypt, and may be due to unrecognised sandfly fever or to mild intestinal infections. Jamaica appears to have a short seasonal fever of its own and Bermuda also, whilst dengue (often perhaps unrecognised) is prevalent in Malaya. Shanghai also has a peculiar "Shanghai Yangtse fever," the origin of which has not been traced so far. The same command also showed a high incidence of pulmonary tuberculosis. In Malaya the closing of brothels has led to the (usual) increase in the incidence of venereal disease. (This very important question has been a knotty problem for many years; is it better to have brothels which are officially inspected, with relatively less venereal disease; or none, with increased clandestine prostitution, no inspection, and increased venereal disease? Different countries have settled the matter in different ways with regard to their armies).

Most of the dengue in 1927 was reported from India and Aden. Malaya is also heavily infected. Mental disorders were unimportant—151 admission only, or a ratio of 0.5 per 1,000 strength. Eye diseases accounted for an admission rate of 4.9 per 1,000. Tonsillitis figures very high in the returns—admission rate 33.8 per 1,000; it is most prevalent in the Home commands. Amongst women the general admission rate was 180.1 per 1,000, and amongst children 172.0 per 1,000. In the latter class tonsillitis, bronchitis, diarrhoea and measles, figure high.

On pp. 34–55 there next follows a most interesting account of the work of the specialist departments. In the medical department special attention is being paid to the incidence of respiratory diseases in the Army, whilst the search for a really effective remedy for chronic intestinal amœbiasis still goes on. Four cases of kala-azar were treated at Millbank during the year. Vaccine treatment is especially on trial with regard to gonorrhœa, pneumonia and tuberculosis. Surgical work in the Army is now of a very high order, and many military hospitals are equipped with really first class operating theatres. Ether is the anæsthetic most generally employed. A new portable x-ray apparatus has been standardized for use in the Army both in peace and war, and this step will greatly simplify radiological examinations, for those using the apparatus will be fully familiar with the standard pattern. The special incidence of otitis media led to the issue of orders that this complaint was to be especially looked for among recruits; it is often first discovered when the new recruit turns out to be deaf on parade. In the matter of hygiene, constant improvements to barracks and water supplies are mentioned. New tables for physical training of recruits have been introduced throughout the Army generally. Mother and child welfare centres continue to be established, five new ones having been opened in the Aldershot command during the year. The Army Hygiene Advisory Committee dealt with such diverse problems as the chloramine treatment of water, the regulations for disinfection, diphtheria at the Guards' Depot at Caterham, the health of the Shanghai Defence Force, and the effect of work in tanks on the

soldiers of the Royal Tank Corps. The Pathology Department reports a year of continuous investigations of specialist problems, and a large number of new publications. Army dental centres are better equipped than before. The ratio of recruits discharged within the first six months of training shows a marked increase—chiefly due to more rigorous inspection for middle ear disease. It is interesting to note that, in order of frequency, the chief causes for rejection are middle ear disease, loss of teeth, defects of the lower extremities, flat feet, and defective vision. This gives some idea of how thorough the medical examination of the recruit has to be in times of peace if the Army is to maintain its fine physical standard. It is noted that appropriate dental treatment will often enable men who would otherwise have to be rejected to be engaged.

Section III of the report deals with the health of the Army in the various commands. Here what will interest our readers will be the section on India, pp. 83–95. The admission rates per 1,000 were for officers 24.65, other ranks 30.85, women 12.15, and children 11.91. The corresponding death rates were 3.63, 2.82, 4.39 and 14.27. Malaria, of course, heads the list as a cause of sickness—7,723 admissions in the year of soldiers, and 168 of officers. The average number of constantly sick in hospital was 30.85 per 1,000 of strength. Mosquitoes and sandflies are the chief enemies of the British Army in India in times of peace, and even much of the "inflammation of areolar tissue" which figures so prominently in the returns is due to insect bites. Peshawar returned a very high incidence rate of sickness, but at Lahore mosquito-proofing of barracks has led to a notable reduction in the incidence of malaria from 1,038 per 1,000 in 1924 to 255.3 in 1927. With regard to dysentery year by year sees a steady "change-over" in the reported prevalence of amœbic and bacillary types, and it is now realised that bacillary dysentery is far more common than amœbic. Peshawar, Delhi—recently pronounced by an authority to be the best example of a "malaria-free enclave within the Indian Empire"—and Quetta continue to report high malarial incidence. Approximately one-quarter of the sickness in the British Army in India is due to malaria; admissions for this disease amounted to 138.8 per 1,000 of strength. At Delhi the figure was 452.9 and at Peshawar 490.4. A satisfactory feature of the report is the steadily lessening incidence of venereal disease in the figures for India, though Madras, Bombay and Bangalore reported high incidence. Rangoon also figures as head of the list, with an incidence of 219.4 per 1,000 strength. The Central Dermatological Laboratory at Poona continued to do excellent work in the diagnosis of venereal disease during the year, as also to give special instruction in this subject to newly arrived junior R. A. M. C. and I. M. S. officers. In the Ceylon command dengue and gonorrhœa head the list of incidence of the different diseases, whilst the return for malaria (in this most notoriously malarious island) was completely negative. In Malaya the incidence per 1,000 for admissions was 81 for gonorrhœa, 78 for dengue, and 25 for malaria. In Mauritius malaria headed the list; in North China and Shanghai, gonorrhœa.

A very interesting account of sanitary conditions (or rather their absence) in Shanghai is given on pp. 121–132. The defence force finally reached a maximum strength of personnel of over 16,000 and accommodation had to be improvised from the beginning. The water supply from the Wangpo river was highly polluted, and this state of affairs was met by chlorination. Fly-proof bucket latrines were used, and ablution benches and hot and cold baths erected. Ice chests were plentiful and proved invaluable. Owing to the especially heavy incidence of helminthic infection among the Chinese, all Chinese employed as cooks were subjected to the most rigorous medical inspection before they were enlisted. The troops landed in the most bitterly cold weather, whilst the town was crammed to overflowing with refugees, and sanitary conditions were entirely lacking. Under such conditions an admission rate of 744.6 per 1,000 is not surprising—the British battalions from India showing more sickness

than those from Home. Then came the hot weather, when climatic conditions were reversed, and khaki drill was issued. Malaria, enteric fevers, dysentery and pneumonia were the diseases chiefly responsible for sickness. A special feature of the expedition was that the medical units went out fitted with complete dental personnel and equipment. Three specialist dental officers were on duty with the force.

We have tried to give a succinct review of this most important publication. Its interest is unique. Rigidly selected for physique, but sent to almost every climate in the world and subjected to the attacks of a whole host of diseases, the British Army health returns constitute a symposium on world-conditions of health. There is perhaps no other report (with the exception of the Rockefeller Foundation reports) which deals with so vast an area. This volume should be in the hands of every military medical officer and of every public health official in India.

ANNUAL REPORT OF THE EUROPEAN HOSPITAL FOR MENTAL DISEASES AT RANCHI FOR THE YEAR 1927. BY LIEUT. COL. O. A. R. BERKELEY-HILL, M.A., D.M., I.M.S., PATNA, 1929. SUPERINTENDENT, GOVERNMENT PRINTING, BIHAR & ORISSA.

THIS somewhat belated report has only recently come to hand, but is of considerable interest, as Col. Berkeley-Hill's reports always are.

There was accommodation for 206 patients during the year, whilst the fees for first and second class paying patients were raised to Rs. 300 and Rs. 200 respectively per month. Admission for the year totalled 70, and re-admissions 22. The latter figure is very high, and Col. Berkeley-Hill comments adversely on the entire absence of any "after-care" association for patients in northern India, with the exception of the Calcutta organisation. Voluntary boarders have steadily increased from 1920 to 1927 and numbered 23 in the year under review.

Eight mentally defective children were admitted during the year, and here Col. Berkeley-Hill touches upon one of the most important of Indian problems. The Local Governments who contribute to the upkeep of the Hospital, when consulted, replied that they considered that a comprehensive and not a makeshift plan was necessary. "The whole subject of mental deficiency in India needs a whole-time champion, and until such a one arises it is not likely that there will be much progress towards some solution of the problem" writes Col. Berkeley-Hill. "But even now the situation is not quite hopeless. During the year the Government of Bengal asked me to inspect the Children's Home at Kurseong and the Colonial Homes at Kalimpong, with a view to seeing to what extent they might be associated with a scheme for the care and treatment of mentally defective children in Bengal. The province of Madras, going still further, reached the stage of contemplating the construction of a special institute, for mentally defective children on up-to-date lines."

Criminal insanes under treatment during the year numbered 7. The total population of the hospital during the year was 262 as against 253 in the previous year. Bengal, the United Provinces, and the Punjab sent the largest number, those coming from Bihar and Orissa numbering only 12. Approximately 24 per cent. of cases are discharged cured per annum. The death rate for the year was 4.62—one death being from drowning, either accidentally or suicidally, it could not be determined which. Influenza, malaria, and digestive troubles are largely responsible for such sickness as occurs.

Occupational therapy is largely relied on by way of treatment, the patients being put to rug-making, tailoring, making woollen and paper flowers, weaving, cross-stitch work, painting, etc. There is a ready sale for the products made, and a special stall of them was exhibited at the 1927 Congress of the Far Eastern Association of Tropical Medicine in Calcutta. Proposals for building suitable accommodation for this work have

been passed. Hydrotherapy also plays an important part in treatment. Drugs, writes Col. Berkeley-Hill, only play a minor part in the treatment of mental disease; mental treatment alone is effective. The band continued to be a source of delight to patients and staff during the year; it consists of 7 members of the staff and 8 full time trained bandsmen. Musical drill is conducted to band music, and cinema entertainments, games, boating on the lake, and picnics are indulged in.

Minor improvements were effected in buildings during the year, but the water supply still causes anxiety. In June a failure of the electric supply very nearly stopped the entire water supply, and only the re-conditioning of an old steam pumping plant saved the situation. A club house for the staff was established during the year, and the library contains over 1,000 books. The co-operative stores continued to function as the main source of supply to the hospital. Receipts during the year amounted to Rs. 5,02,477; expenditure to Rs. 4,46,052 (net); and the average cost per patient during the year to Rs. 2,287—a very considerable reduction on the figures for previous years. There was no matron during the year, and one is certainly necessary. Colonel Berkeley-Hill pays a special tribute to the work of his staff; work in psychiatry in India is of a pioneer character and demands energy, interest, and initiative. He especially singles out the able services rendered by Dr. J. N. J. Pacheco, the Deputy Superintendent.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, FOURTH ANNUAL REPORT TO THE COURT OF GOVERNORS, 1927-28.

News of the London School of Hygiene and Tropical Medicine will always be of interest to our readers, and it is clear from this report that substantial progress is being made towards the completion of the new organisation of the School with regard to building, equipment, and teaching and research. The recently introduced advanced courses in bacteriology and immunology, and in epidemiology and vital statistics have been well established, and five students during the year gained the new Diploma in Bacteriology of the London University. The work in the division of epidemiology and vital statistics is largely interlocked with Professor Greenwood's work at the Ministry of Health and with that of the Statistical Committee of the Medical Research Council.

A special committee has been appointed to consider how best the old School of Tropical Medicine—now the Department of Tropical Medicine of the new School—can be fitted into the new scheme. The Seamen's Hospital Society have decided not to close the hospital in Endsleigh Gardens, and this famous hospital will continue to be associated with the new School. Hence the former suggestion for a new Imperial Hospital for Tropical Diseases has fallen into abeyance. Important appointments have been made to the chairs of biochemistry and of chemistry as applied to hygiene, which will be associated in one administrative division. The professor of public health has been appointed, and this department will also deal with physiology as applied to hygiene. A part of the capital as well as the interest of the Milner Research Fund is being applied to research work, and about one-sixth of the accommodation in the new building is being reserved for research work only. The Research Field Station at Salisbury in Southern Rhodesia is to be continued for another period of five years.

A School Council has been constituted on an academic basis, and will deal direct with the Board of Management. The Council is an advisory, not an administrative body. Dr. J. F. C. Haslam has been appointed Director, and Mr. R. L. Sheppard, Assistant Director of Library Services. Regulations relating to the conditions of appointment of whole-time staff of the School have been drawn up. The expenditure during the year was very close to that budgeted for; and the estimates for 1928-29 have been met by a Treasury grant of £25,000. An Equipment Committee

is drawing up plans and estimates, and placing orders.

The annual meeting of the Court of Governors was held at the British Medical Association's House on November 30th, with Sir Holburt Waring in the chair. The Director (Dr. Andrew Balfour) presented his report and stated that there had been an increase of 17 per cent. in the proportion of students sitting for the Diploma in Tropical Medicine and Hygiene who were successful.

It is hoped that the new and very handsome building in Portland stone which is now nearing completion in Bloomsbury will be ready for a formal opening in the summer of 1929.*

KASHMIR C. M. S. MISSION HOSPITAL. ANNUAL REPORT FOR 1928. BY DR. E. F. NEVE, M.D., C.M., F.R.C.S. ED.

THIS short annual report, with its excellent and interesting photographs, is always of interest. As far as we can recollect, it was a previous Viceroy of India the other day in a public speech who said that he had come out to India rather prejudiced against missions, but what he had seen of missionary work, and especially of medical missions in India, had made him a complete convert and enthusiastic supporter of them. Certainly medical missions in India have a magnificent pioneer record, and the Kashmir C. M. S. Hospital—run very largely by private subscriptions—is one of the most famous among the 200 odd which exist in this country.

Dr. Neve writes in an interesting manner of the necessity for the personal touch in medical mission work. Institutions do excellent work on a large scale, but it is often the personal reputation of the man in charge which brings in patients, and personal touring in the districts which brings a mission hospital into contact with the people. At various villages visited Dr. Neve tells of the crowds of patients who came to the tent dispensary; 400 at one, 800 at another. Lord Goschen (for years Chairman of Guy's Hospital), on visiting the Hospital wrote "In a large European hospital, with a large staff and specialised organisation, it should always be easy to achieve efficiency. But it is really remarkable, in this hospital, with its small but capable staff, how efficiently it is run, down to the smallest detail."

During 1928 expenditure largely exceeded income, owing chiefly to the building of a new house for nursing sisters. The income of the hospital is derived from four main sources; endowments for cots and beds; local donations and subscriptions—which have dropped from Rs. 12,000 or Rs. 13,000 to Rs. 10,000; fees from patients; and an annual grant of Rs. 10,000 from Kashmir State. Income from interest on reserve funds amounts to only Rs. 3,000 per annum, and as the total expenditure for the year was Rs. 56,724, it will be seen how very largely dependent is the hospital on donations and subscriptions. The income from fees has been much reduced by constant transfers of members of the staff to other places; this breaks up any chance of organising a general practice for the benefit of the hospital. (Although we are hearty supporters of medical missions in India, we confess that we have never heard anyone say a good word for missionary boards; there must be such organisations, of course, but they often fail to realise local conditions on the spot.)

A feature of the year unfortunately was the transfer of the Leper Hospital from control by the mission to the Kashmir State—which was effected whilst Dr. Neve was on leave; apparently without consulting him, and against the advice of the Director of Medical Services of the State. For thirty-six years Dr. Arthur Neve and Dr. Ernest Neve in turn have run this hospital in an honorary capacity, and most efficiently, the buildings being constantly added to, modern methods of treatment continuously introduced and improved upon, but "no acknowledgment whatever was made of 36 years' honorary work, including the foundation and organisation of the asylum."

* This was opened by the Prince of Wales in July, 1929.

Srinagar, "the city of the sun," has a population of 142,000, and the opportunities for medical and surgical work are enormous. Puerperal fevers, enteric fevers, and tuberculosis appear to be the three chief problems. Open air treatment is possible for nine months of the year—not only for cases of tuberculosis, but also for medical and surgical cases of all kinds. Kashmir most urgently needs a tuberculosis sanatorium; apparently the disease was almost unknown in Kashmir in 1890; "but during the last two decades it has been increasing by leaps and bounds"; and—an interesting point—nearly a quarter of the cases are of bovine origin. Osteomyelitis and tuberculous bone disease are very common. Cataract does not figure largely in the Kashmir returns, but entropion and trichiasis are important. Cancer occurs—chiefly of the Kangri-burn type—but is not very common. The detailed table of major operations shows that eye diseases (215) head the list, with bone and joint operations (208) second, and abdominal sections (84) third. "Tumours" of various sorts numbered 338, but included 133 cases of tuberculous glands. Vesical calculus cases only numbered 12.

"The best days of a man's life are those in which he renders service," quotes Dr. Neve from Abu'l Tarif; and certainly the well-known Srinagar Hospital continues to render most valuable service; it is a model of what it should be.

REPORT OF THE CHEMICAL EXAMINER TO THE GOVERNMENT OF THE PUNJAB FOR THE YEAR 1928. BY MAJOR D. R. THOMAS, M.B., Ch.B., I.M.S., LAHORE. SUPDT., GOVERN- MENT PRINTING, 1929. PRICE, 10 ANNAS.

MAJOR THOMAS' reports are always interesting, and this one is no exception to the rule. Major H. S. Anand, I.M.S., held charge of the post of Chemical Examiner from the beginning of the year until October, when Major Thomas returned from leave and took over charge.

A table shows the steady increase in work in all departments from 1924 to 1928; this is true indeed of all chemical examiners' departments in India, and in the course of time must involve the creation of new laboratories. Medico-legal cases have increased from 1,202 to 1,705 in these years, and the total number of articles examined in the year from 5,133 to 7,129. Analysis for the Excise Department has now been taken over by the Chemical Examiner's department, and the work has roughly been increased by sixty per cent. in the last five years.

Human poisoning cases dealt with numbered 681 and poison was detected in 66 per cent. of them. Arsenic was also detected in the remains of a cremated body sent for examination. The chief poisons used are in order of frequency opium, arsenic, *dhatura* and mercury. Contrary to popular belief, powdered glass comes last on the list and was responsible for only one case. Animal poisoning cases numbered 55, and arsenic was the principal poison detected. Stain cases numbered 3,046, and blood was detected in 1,086. General analyses of miscellaneous articles numbered 1,744 and included samples of liquor, tinctures, cocaine, charas and opium. Only 38 out of 52 samples of ghee examined were found fit for human consumption. An interesting experiment was carried out with regard to ammonium sulphate as a fertiliser.

In Appendix I of the report, Major Thomas comments on the way in which medical officers send in viscera for chemical examination from cases where they have no reason to suspect poisoning, and where the true cause of death, e.g., pneumonia, is clear. If there are secret reasons for sending in these viscera, the medical officers concerned keep them to themselves.

This increases the work of the department unnecessarily, and means an increased number of unnecessary examinations and a decrease in the number of cases in which poison is detected.

The report contains the following interesting case reports:—

Barium Carbonate (rat poison).

A family in the Hissar District after eating some chapattis began to vomit and purge, exhibiting the symptoms of an irritant poison. A calf that was given a chapatti also became ill. On investigation it was discovered that some officials of the Health Department, who had recently visited the village in connection with rat destruction, had left behind some of the pills and a bag of atta. A young boy found these articles and took them to his mother who cooked the chapattis. On examination of the articles barium carbonate was detected.

Nitric Acid (Aqua fortis).

A young student in one of the Lahore Colleges, finding that he had failed in one of his subjects, shut himself up in his room and was found dead. A post-mortem examination was carried out and signs of poison were evident in the viscera. There was browning of the mucous membrane of the alimentary canal and the stomach was highly congested. Nitric acid was detected.

Arsenic (homicide).

A young unmarried daughter was found by her parents to be pregnant and in order to hush up the affair they had her removed to another village. Within two days of her arrival she died. A post-mortem examination elicited the fact that she was about five months pregnant and the congestion of the internal organs pointed to death from an irritant poison. Arsenic was found in all the exhibits sent for analysis. The police reported that she had had administered some poison to produce abortion.

Strychnine (accidental).

A very remarkable case is reported from Hoshiarpur district where a medical man gave some tablets supposed to be quinine to a family. The head of the family took four tablets, he also distributed three tablets each to four members of his family. They all became ill and suffered from convulsions. The head of the family died and his viscera on examination contained strychnine. The other members fortunately recovered. The tablets that remained were analysed and proved to be pure strychnine.

Strychnine (non-fatal).

A very mysterious case was sent from Delhi where a lady stated that she ordered six packets of a powder from a well established firm of chemists. She took one powder just before retiring to bed. In half an hour she felt her muscles stiffening and she had twitching movements. She woke up some of her neighbours and the medical man on his arrival found her a picture of strychnine poisoning. Drastic treatment was carried out and she recovered. The vomit was examined and 1.2 grains of strychnine were recovered. What powder remained in the glass was also examined and approximately 2 grains of strychnine were found. On examining the remaining five powders obtained from the chemist, no poison was detected and the ingredients conformed with the standards of the British Pharmacopoeia.

Perforated duodenal ulcer simulating irritant poisoning.

The viscera of a young man were received with a history of pains in the abdomen, vomiting, diarrhoea and a post-mortem report of congestion of the stomach and intestine. The pathologist reported a perforation the size of a small button in the duodenum and on chemical analysis no poison was detected.

In a second Appendix to the report, Major Thomas gives certain most useful suggestions for police and medical officers regarding sending in exhibits. As these may be of importance to our readers, we here reproduce them. They are as follows:—

(1) All exhibits suspected to contain stains should be thoroughly dry before being packed and despatched for examination. The safest way of drying exhibits is to expose them to the sun. In cases of exhibits that become brittle on drying, they should be carefully packed in cotton-wool and then in a wooden box,

(2) Sharp-edged and pointed exhibits like swords, spears, etc., should be packed in boxes and not bound up into cloth packages. In their transit through the post they are liable to cut through the packing material and the exhibit is exposed.

(3) As far as possible no letters should be glued on to exhibits as they interfere with analysis.

(4) Exhibits in connection with cases of murder by hurt or violence may be sent direct to the Chemical Examiner. This saves time and relieves the office of the Civil Surgeon of the district of unnecessary correspondence.

(5) Endeavour to send all the exhibits in a case of murder by hurt or violence under one covering letter, thereby reducing the cost of examination, etc.

(6) Nail clippings are poor exhibits to send for the detection of blood in murder cases. No court of law could be expected to attach much weight to the finding of human blood on the nails of the accused.

(7) Stomach tubes in hospitals are frequently kept in a solution of mercury. They should be carefully washed with water before use. Traces of mercury found along with another poison in a stomach content, might produce such complications as would handicap the successful prosecution of a case.

(8) Carbon copies of reports are sometimes very difficult to read.

Correspondence.

LOBAR PNEUMONIA WITH INTERMITTENT TEMPERATURE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—Recently I have come across a case of lobar pneumonia with all the classical signs and symptoms of that disease, but with an intermittent temperature chart similar to that reported in your issue for June 1928.

From the very onset the case looked like one of malaria, with high but intermittent fever and delirium during the febrile phase. The patient had two injections of quinine bihydrochloride, but this did not affect the fever. On the morning of the third day of illness it was discovered that consolidation had set in in the base of the left lung, and this cleared up the diagnosis. The patient was treated as a straightforward case of pneumonia, and made an uneventful recovery.—Yours, etc.,

BHUPENDRA NARAYAN CHAKRABATTY,
Medical Officer.

ANGURSON CHARITABLE DISPENSARY,
P. O. PINCHIRA, BURDWAN DISTRICT,
25th May, 1929.

(Note.—We have seen similar cases with intermittent fever in cases where lobar pneumonia set in as a complication of malaria. Patients suffering from true malaria sometimes develop lobar pneumonia as a complication.—EDITOR, I. M. G.)

THE STERILIZATION OF HYPODERMIC SYRINGES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—On p. 297 of your issue for May 1929, I was interested to read the letter by Dr. Jyoti Dhur Roy on sterilization of hypodermic syringes, and your comment on the same. Of course any method short of boiling is not ideal for perfect asepsis, but I have found the following method perfectly safe and speedy in more than a thousand subcutaneous injections of various medicaments in practice.

I carry a small spirit lamp in my injection case, together with an aluminium spoon of sufficient size to boil the needle only of the syringe. The syringe with needle in situ is boiled and then kept for use in a metal case (procured from Messrs. B. P. Vara and Co., Bombay) in rectified spirit. Before giving an injection the needle only is boiled in the aluminium spoon over the

flame of the spirit lamp, whilst the syringe is sterilised by drawing rectified spirit into it and again emptying it into the metal case. Needle and syringe are then fitted together and are ready for use.

I have never seen abscess formation or even swelling in using this method, and it is in my opinion both safe and rapid. I may add, however, that I have only used it for hypodermic and intramuscular injections; for intravenous injections I always boil both the syringe and needle.—Yours, etc.,

C. S. SHARMA, L.M.P.,
Medical Officer in Charge.

KAIMGANJ DISPENSARY,
FARRUKHABAD DISTRICT,
6th May, 1929.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the query on p. 297 of your issue for May 1929, with regard to the sterilization of hypodermic syringes, in my experience chloroform is the most rapid and useful means of sterilization for any type of syringe, including the "Record" pattern. I have given a few thousand subcutaneous, intramuscular, and intravenous injections, using this method, and have seen no bad results. The method is as follows:—

Pure chloroform is taken into a clean drachm glass, and a small quantity of it is drawn into the syringe through the needle and brought into contact with the whole of the inside of the barrel of the syringe and then ejected, repeating this process about five times at most. The needle and the adjoining part of the barrel are dipped into chloroform for a few seconds; similarly the other end of the barrel and then the piston are dipped into chloroform. The chloroform rapidly dries up by waving the parts of the syringe in the air, and they are then fitted together and ready for use.

With this technique I have never seen sepsis in some thousands of injections. I have often used the same syringe to give injections to five or six consecutive patients, sterilizing it with chloroform between the injections. After the injection is given the syringe is rinsed out with methylated spirit, dried with a clean towel, and replaced in its case. Syringes of 10 and 20 c.c. capacity are sterilized in the same manner.—Yours, etc.,

INDIGENOUS MEDICINE AND DISTRICT BOARDS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I should like to protest most strongly against the employment of unregistered practitioners (*vaids* and *hakims*) by district boards and municipalities. As I am a taxpayer to both these bodies, I object to see my hard-earned money wasted in this fashion. The old excuse that registered medical practitioners are not available is no longer true in these days, when even M.B., B.S. graduates in Indian universities are willing to settle down as practitioners in rural areas on a small subsidy. There are some things that they cannot do however, and they are to dance attendance on those who make such appointments, or issue bogus certificates; hence their unpopularity.

Medicine has always been a State subject in India since time immemorial, and it is difficult to understand the present-day policy of multiplying medical schools and institutions, without finding employment for the host of graduates turned out, and—at the same time—indirectly helping quacks through the agency of district boards and municipalities.—Yours, etc.

D. BHARADWAJA, L.R.C.P., L.R.C.S. (Ed.),
L.R.F.P. & S. (Glas.).

A CASE FOR DIAGNOSIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the case of hyperpyrexia for diagnosis recorded in your issue for May 1929, p. 260,

by Drs. Pereira and D'Cruz, I suggest that the case was probably one of typhoid fever. All the symptoms and signs, viz., the temperature, slow pulse rate, headache, drowsiness, and tympanitic abdomen, point to it. I have seen cases here where the Widal reaction was reported as negative even up to the 30th day of illness, and positive thereafter at 1:100 or higher dilution. The negative agglutination test in this case appears to have been observed about the 17th day of illness. Tice, in his *Practice of Medicine* (1927), Vol. IV, p. 503, says that "while a positive result is highly presumptive of typhoid, a negative finding has no significance." There is a temperature chart on p. 484 of the same volume illustrating such a case, where the Widal reaction was negative on the 8th and 15th days and positive on the 47th day. It is possible therefore that the Widal reaction might have become positive in this case at a later stage. The hyperpyrexia and meningeal symptoms suggest complications of typhoid fever. It appears to be most unlikely that the case was one of malaria, as so much quinine was administered without affecting the fever. The blood film was also reported to show no malaria parasites.—Yours, etc.,

CH. KRISHNAMURTY, L.M.P.,
Sub-Assistant Surgeon.

CENTRAL JAIL, RAJAHMANDRY,
28th May, 1929.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the case of hyperpyrexia for diagnosis recorded on p. 260 of your issue for May 1929, I suggest that the case may have been one of cerebral abscess following chronic middle ear disease. The patient showed the following symptoms:—

Slight headache, occasional vomiting, a continuous temperature of from 99°F. to 101°F., slight drowsiness, general malaise for about six weeks, a slow pulse during the whole course of the illness, 90 with a temperature of 101°F., and 97 with a temperature of 104°F., hyperpyrexia at the terminal stage, twitching of the right upper and lower extremities, a lumbar puncture with negative results, a negative Widal reaction, and no response to quinine administration.

Let me now enumerate the points in favour of cerebral abscess following on otitis media, whether of cerebral or cerebellar type. In such cases headache is rarely absent; optic neuritis is less frequent than in cerebral tumour (in the present case the fundus was not examined); the mental changes are drowsiness, apathy, later stupor, and coma. Vomiting and vertigo are chiefly seen in cerebellar cases. The pulse is often slow, in the terminal stages rapid or irregular. The temperature in latent and uncomplicated cases is usually normal or sub-normal, but rises very high in the terminal stages with sinus thrombosis or rupture into the ventricle. Respiration is often slowed down, especially in the cerebellar types. Leucocytosis is often marked, but is not invariable.

Considering all these points, I believe that the patient probably had a cerebral abscess of the left side, resulting from chronic otitis media.—Yours, etc.,

S. P. SARBADHIKARI, L.M.S.

MIDNAPUR,
8th June, 1929.

THE TREATMENT OF ACUTE VAGINISMUS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In reply to the enquiry in the correspondence columns of your May issue, on the treatment of acute vaginismus I hasten to assure your correspondent that the only "radical" cure for this distressing complaint is psycho-analysis. There can be no doubt whatever that vaginismus is essentially a psychic manifestation of the lack of psycho-sexual adaptation to a partner and the fundamental cause of this disturbance is an incestuous father-fixation during infantile sexual development. Such a condition can only be treated by psycho-therapy, and psycho-analysis is the one and only certain and justifiable measure to unearth the complex from the

deeper layers of the unconscious. Practitioners in general, and gynaecologists in particular, are ever ready to suggest all manner of unnecessary surgical interference, with the result that Pelion is piled upon Ossa. The condition is curable and I would advise that the case be shown to a mental specialist.—Yours, etc.,

J. NORMAN PACHECO, M.R.C.S., L.R.C.P., I.M.D.,
Officiating Medical Superintendent.

RANCHI EUROPEAN MENTAL HOSPITAL,
KANKE (RANCHI),
22nd May, 1929.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—With reference to the case of acute vaginismus recorded in the *Indian Medical Gazette* of May 1929. I beg to suggest the following treatment:—

"Induction of general anaesthesia, dilatation of the introitus vaginae, and excision of the ring of tissue which is the remnant of the hymen. Haemorrhage may be profuse and it is always desirable to tie all bleeding vessels and insert a tampon filling the entrance of the vagina. This is the treatment suggested by Sajous in his *Analytic Cyclopaedia of Practical Medicines*."—Yours, etc.,

SHYAM LAL, B.A., M.B., P.M.S.,
In-Charge, District Hospital.

LAKHIMPUR, KHARI,
29th May, 1929.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—In reply to Dr. Roy's letter published in your May issue, I beg to quote a few lines from *Guerensey's Obstetrics*.

"The treatment should be conducted according to homœopathic principles. The use of the knife, formerly so freely resorted to, is now generally denounced by practitioners, while the very questionable procedure of dilating the canal by graduated dilators, although claimed to be very successful, does not appear to be necessary. Should the vaginismus be dependent upon some local difficulty or disease, that must be removed before we can hope to accomplish a satisfactory and permanent cure. Coitus should be strictly prohibited, and all excitation of the parts by motion should be avoided by enjoining perfect rest. Lavements of tepid water will be found very grateful.

In vaginismus the diet should be strictly attended to. All use of coffee, tea, spirituous liquors, stimulants and spices of all kinds should be positively prohibited. As much out-of-door exercise should be taken as possible."—Yours, etc.,

J. N. BANERJI.

116A, HARISH MUKERJI ROAD,
BHOWANIPUR, CALCUTTA,
21st May, 1929.

HÆMOPLASTIN.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—With reference to the notes by Dr. K. P. Lahiri on p. 256 of your issue for May 1929, on the use of Hæmoplastin (P. D. & Co.), I may perhaps be permitted to record my experience with this preparation.

I have used Hæmoplastin in three cases of severe epistaxis, and in two of pulmonary hæmorrhage. Whilst it proved extremely successful in the first three cases, it failed to stop the bleeding in the last two. Its effect in severe epistaxis, however, is admirable.—Yours, etc.,

MANCOTTA TEA ESTATE,
DIERUGARH, ASSAM,
31st May, 1929.

M. BAROOA, L.M.P.

Service Notes.

APPOINTMENTS AND TRANSFERS.

COLONEL J. D. GRAHAM, C.I.E., I.M.S., Public Health Commissioner with the Government of India, has been elected by the Indian Research Fund Association as the representative of the Association on the Advisory Board of the Imperial Council of Agricultural Research constituted under the Government of India Resolution No. 826-Agr., dated the 23rd May, 1929.

Lieutenant-Colonel H. E. Stanger-Leathes, I.M.S., Assistant Director of Public Health, Delhi, is appointed Deputy Director-General, Indian Medical Service, with effect from the 5th July 1929, or the date on which he assumes charge of the post.

Lieutenant-Colonel W. J. Simpson, I.M.S., an Agency Surgeon, is posted as Chief Medical Officer in Central India and Residency Surgeon, Indore, with effect from the 14th June, 1929.

On return from leave the services of Major J. M. R. Hennessy, I.M.S., are placed at the disposal of the Government of India in the Department of Education, Health and Lands.

Major J. B. Hance, O.B.E., I.M.S., Chief Medical Officer in the Western India States Agency and Residency Surgeon, Rajkot, on return from leave, resumed charge of his appointment, with effect from the 4th June, 1929.

Major L. K. Ledger, I.M.S., an Agency Surgeon, on return from leave, is posted as Agency Surgeon in Bundelkhand, with effect from the 21st May, 1929.

LEAVE.

Lieutenant-Colonel J. R. J. Tyrrell, I.M.S., an Agency Surgeon, is granted leave on average pay for 3 months and 9 days, under the Fundamental Rules, with effect from the 14th June, 1929.

Lieutenant-Colonel H. M. H. Melhuish, D.S.O., I.M.S., Director of Public Health for the Government of Bombay, is granted an extension of leave, out of India, on average pay for 2 months and 24 days, followed by leave on half average pay for 16 days in continuation of the leave granted to him in Government Notification No. S. 20/16, dated the 28th January, 1929.

Lieutenant-Colonel H. H. Thorburn, C.I.E., M.B., I.M.S., Surgeon to His Excellency the Viceroy, is granted leave on average pay for 4 months, with effect from the 30th June, 1929.

Lieutenant-Colonel R. B. Seymour Sewell, I.M.S., Director, Zoological Survey of India, is granted study leave for 5 months in continuation of the leave on average pay for 5 months sanctioned in Education, Health and Lands Department, Notification No. 29-Z.S., dated the 28th March, 1929.

Major J. B. Hance, O.B.E., I.M.S., Chief Medical Officer in the Western India States Agency and Residency Surgeon, Rajkot, was granted leave on average pay for 42 days, under the Fundamental Rules, with effect from the 23rd April, 1929.

PROMOTIONS.

Colonel to be Major-General.

J. W. D. Megaw, C.I.E., M.B., V.H.S., I.M.S.

Lieutenant-Colonel to be Colonel.

H. M. Mackenzie, M.B., I.M.S.

Majors to be Lieutenant-Colonels.

G. B. Lynn, D.S.O., M.B., I.M.S. Dated 31st January, 1929.

M. A. Rahman, I.M.S. Dated 31st January, 1929.

Captains to be Majors.

G. M. Moffat. Dated 14th May, 1929.

L. G. Pearson, M.B. Dated 18th May, 1929.

P. M. Antia, M.B. Dated 23rd May, 1929.

Lieutenant to be Captain.

Mohan Lal Ahuja, I.M.S. Dated 11th May, 1929.

RETIREMENTS.

Colonel R. F. Baird, I.M.S., from the 16th March, 1929.

Lieutenant-Colonel W. M. Anderson, C.I.E., M.D., I.M.S., from the 29th December, 1928.

NOTES.

WATSON'S MICROSCOPE RECORD.

WE have referred to this most interesting journal in these columns previously, but make no apology for returning to the subject. Whilst admittedly a "trade journal" it is full of interesting matter to the microscopist, and laboratory and research worker, and may be obtained free on application to Messrs. W. Watson & Sons, Ltd., 313, High Holborn, London, W. C. 1.

The issue for January 1929 contains several important features. A. E. Clarence Smith deals with the problem of exposure in photomicrography, and discusses the relationship of density to exposure; this is an article which will interest all those who have photomicrographs to prepare. Mr. H. E. Hurrell, F.R.M.S., discusses the fresh water Polyzoa, and the Rev. D. P. Fuge the genus *Cosinodiscus* among the diatoms; in this genus there are some 300 species and the genus is of importance in standardising microscopic measurements. A most useful essay is one by A. A. C. Eliot Merlin on "Hints to Beginners"; his remarks with regard to the Abbé sub-stage condenser are very sound; the fixed non-centering sub-stage condenser is deservedly popular, but it is *not* the ideal fitting for getting the best value out of a good oil immersion lens. The fine adjustment is a part of the microscope which is at present in a very experimental stage; lateral fine adjustments have replaced the old fashioned central ones, but it is doubtful whether the change is for the better; what is wanted is a fine adjustment which will have to bear only the weight of the triple nose-piece and objective, and not that of the whole body and coarse adjustment as well. Even the microscope mirror is probably capable of improvement, and rustless steel may one day come to replace silvered glass. The editor of the *Record* discusses how to get the best out of the Abbé illuminator, and Mr. Chapman Jones the methods of testing objectives. "Notes and Queries" is a section which shows how popular the *Record* is; we are ourselves indebted to it for an authoritative opinion that "photomicrograph" is correct, and "microphotograph" wrong. We had come to the same conclusion from a study of recent journals.

Wonderful as are present-day microscopes, with their binocular vision and many other recent improvements, yet the instrument is still in the experimental and transitional phase, and future years may see many improvements. (For example, we know one enthusiast who has been for years trying to devise an automatic mechanical stage—which would move a blood film automatically at slow speed backwards and forwards under the oil immersion objective, and could be stopped the instant that one saw a suspicious object for study. Up to the present, he has not succeeded, as far as we know.)

The *Microscope Record* is a real help to laboratory workers, and a journal which should be widely known.

NEW, AMŒBICIDAL MEDICAMENT.

A FURTHER addition has recently been made to the list of amœbicidal agents issued by Burroughs Wellcome & Co., Snow Hill Buildings, London, E. C. This medicament is described as "Kharophen," an acetyl derivative of 3-amino-4-hydroxyphenylarsenic acid and is obtainable as a "Tabloid" product. Clinical reports indicate that "Kharophen" is of value in the treatment of amœbic dysentery. It is administered by the mouth as "Tabloid" "Kharophen" gr. 4 twice a day for a course of 10 days.

The makers claim that "Kharophen" has a considerable advantage over other amœbicidal agents, especially emetine, in that it is definitely tonic and non-depressant. It is stated to have a marked hæmatinic action, and patients show a distinct improvement in their general health at the conclusion of the course of treatment, in addition to the disappearance of dysenteric signs and symptoms. The absence of undesirable action, and the general tonic effect give this substance obvious advantages in the treatment of children and debilitated patients. "Kharophen" is eminently suitable for use in out-patient

work, in dispensaries in the field, and in remote areas out of touch with medical treatment.

"Kharophen" has been used effectively in the treatment of yaws (frambœsia), both in adults and in children.

"Tabloid" "Kharophen" is issued in bottles of 25 gr. 4 products.

FIFTH INTERNATIONAL CONGRESS OF MILITARY MEDICINE AND PHARMACY, BRITISH MEDICAL ASSOCIATION HOUSE, LONDON, MAY 6TH TO 10TH, 1929.

EFFECTIVE dioramas depicting the exploits of Scott and Peary were prominent features at the stand of Burroughs Wellcome & Co., in the Exhibition held in connection with the Congress. The actual cases carried by these and other notable pioneers were in view and attracted considerable interest.

A comprehensive range of "Tabloid" and "Soloid" medicine cases was displayed. The unique construction of these outfits is the result of many years' experience and ensures the utmost compactness and portability with medicaments which retain their potency under any climatic condition.

A characteristic selection of "Wellcome" brand sera, vaccines, tuberculins, and serological products was shown. These preparations are made and biologically standardised at The Wellcome Physiological Research Laboratories. They include Schlick and Dick test products, concentrated scarlet fever anti-toxin globulins, diphtheria prophylactic, anti-gas-gangrene serum (W), etc.

Among the more recently introduced medicaments shown may be mentioned "Tabloid" ephedrine hydrochloride (prepared from genuine *Ma Huang*), "Wellcome" liver extract, "Wellcome" insulin, "Hypoloid" quinine and urethane, and "Hypoloid" sodium salicylate for intravenous injection in the treatment of varicose veins; "Quinoxyl" for amœbic dysentery, "Alepol" for leprosy, and "Avenyl" for leprosy associated with syphilis.

There were also specimens of medicinal plants exhibited which were typical of those specially grown on the Wellcome Materia Medica Farm for the preparation of Burroughs Wellcome & Co. products. Many old and well tried products were also in evidence, presented with that pharmaceutical refinement characteristic of Burroughs Wellcome & Co.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers, relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India, Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

KURCHI BISMUTHOUS IODIDE, ITS VALUE IN THE TREATMENT OF CHRONIC AMŒBIC INFECTIONS OF THE BOWEL.

By HUGH W. ACTON,
LIEUTENANT-COLONEL, I.M.S.,

Director and Professor of Pathology and Bacteriology,
and

R. N. CHOPRA, M.A., M.D. (Cantab.),
LIEUTENANT-COLONEL, I.M.S.,

Professor of Pharmacology, Calcutta School of Tropical
Medicine and Hygiene.

INTRODUCTION.

Holarrhena antidysenterica belongs to the natural order Apocynaceæ, and is a small deciduous tree with white flowers. There are many Sanskrit names for it, the better known being *kutaja* and *kulinga*. The other vernacular names are Bengali *kurchicc*, Hindi *kureya* and *dudhi*, and Tamil *kulappalai*. The seeds are called in Sanskrit *indrayava* or Indra's seeds, in Hindi *indrajaba*, and in Persian *indrajavataikh*. The reason why these seeds have been named after the god Indra is due to the following mythological story. The god Indra came to the aid of Rama before they crossed over to Lanka (Ceylon) and defeated the king and demon Ravana in a great battle. After a fight in India, the god Indra noticed the large number of Rama's soldiers, i.e., the monkey army of Hanuman, who had been slain during the fight. Indra in compassion restored them to life by sprinkling *amrita*, or the water of life, over the dead monkeys, and the drops that fell on the ground became the seeds *indrayava* from which this plant sprang into being.

The tree grows well up to 3,500 feet, and is found in all the lower hilly tracts from the Himalayas to Travancore. *Holarrhena antidysenterica* is often mistaken for another species of the same family, viz., *Wrightia tinctoria*; in fact Linnæus was originally responsible for this confusion. In 1809 Brown revised the whole of the family of Apocynaceæ and rectified this mistake. In spite of this the two plants have been mistaken one for the other. *Wrightia tinctoria* is inert, and it is largely owing to this fact that *Holarrhena antidysenterica* did not attract much attention, because more often than not the inert bark was used instead of the active *Holarrhena*. The following points will serve to distinguish the two plants. In *Holarrhena antidysenterica*, the bark is thick, dirty white or buff coloured, and very bitter to the taste. The seeds are oat-shaped and have a tuft of hair on the end remote from the foot stalk, they are very bitter and are contained in long follicles, the thickness of a quill.

The flowers are odourless. In *Wrightia tinctoria*, the bark is thinner, reddish brown in colour and of a smooth appearance; in the seeds the tuft of hair is next to the foot stalk; the flowers are white jasmine-like with a fragrant odour.

The value of *Holarrhena antidysenterica* has long been known to the indigenous systems of medicine in India as a cure for dysentery. Kanai Lal Dey (1896) was so struck with its therapeutic value that he advocated that it should be included in the British Pharmacopœia. Recently Lieut.-Col. R. Knowles (1928) reported the value of "Tabloids" of extract of kurchi bark in the treatment of amœbic dysentery. As regards the active principles of the bark, in 1858 Haines first isolated an alkaloid which he named "conessine." In 1880 R. C. Datta in collaboration with R. D. Ghosh isolated an alkaloid which they named "kurchicine" and gave 2 to 5 grains as a dose in the treatment of dysentery. Pyman (1919) isolated two alkaloids, conessine and another which he named "holarrhenine." More recently Drs. Sudamoy Ghosh and N. N. Ghosh (1928) isolated three alkaloids from *Holarrhena antidysenterica*, viz. conessine, an alkaloid differing from holarrhenine, which they named "kurchicine," and a third with a low melting point—"kurchine." Chopra, as the result of his researches from the pharmacological point of view, commenced using the total alkaloids of kurchi bark, which we will speak of as "kurchi alkaloids," in the treatment of acute amœbic infections by intramuscular injections.

This paper illustrates the value of combined team work of the bacteriological and pharmacological departments; both laboratories were working at the same subject but from totally different points of view, until their interests became identical, i.e., the discovery of a more efficient remedy. The more experience one has in the working of large research institutes, the firmer does the conviction grow that the time has now passed for isolated and detached workers. Co-operation in an institute is the only possible way to save an enormous amount of waste of time and energy, as the workers are all housed in the same building and can obtain constant help and advice from each other, as they are experts on their own subjects. Thus we were saved the trouble of working up the technique of cultivating *Entamoeba histolytica*, for Lieut.-Col. R. Knowles supplied us with these cultures. Dale and Dobell (1917) first showed the value of emetine bismuthous iodide in the treatment of chronic amœbic infections, and got constant curative results by their method of treatment. Their results hold good when dealing with young soldiers in England, but the drug is not so successful when dealing with the class of case we have to treat in India. Knowles (1928) clearly brings this point out in his paper by the numerous failures he had with all the different combinations of emetine he used in the treatment of these chronic cases.

Acton (1921) first pointed out the importance of the pH of the solute on the behaviour of *Paramacium caudatum* towards the cinchona alkaloids. At that time he performed similar experiments with emetine; these were not published, but he found that emetine like quinine was ten times more powerful in its action in an alkaline substrate of a pH of 8 than in an acid one of a pH of 6. During the War, Acton also noted the marked acidity of the stools in cases of acute amoebic dysentery when tested by litmus paper. Later Knowles Napier, and Das Gupta (1923) worked this point out, estimating the pH of the stools in these cases in detail and with more accurate methods. Naturally Acton regarded the failures in treatment by emetine as due to the alkaloid not being in a sufficient concentration in the acid contents of the large gut. The stools in these cases were usually between a pH of 5 and a pH of 6; this meant that the emetine would have to be in a concentration of 1 : 8,000 to 1 : 10,000 to be effective on the amœbæ in this substrate. We first tried to remedy the acidity of the bowel by giving by the mouth large doses of bismuth carbonate as recommended by Deeks, but we found this treatment was not successful in bringing about a complete cure. Acton next commenced to try and ascertain the reason of the increased acidity of the stools, and gradually accumulated sufficient evidence to incriminate the following organisms. Most commonly there was a streptococcal infection present, shown by the numerous fine colonies seen on the glucose Conradi plates; next in frequency a co-existing bacillary infection due to the *B. dysenterica* (Flexner or Strong); and lastly, other acid-producing organisms such as the *B. lactis aerogenes*, *B. acidi lactici*, etc. A different line of treatment was then started by him in those cases which had failed to be cured by a course of emetine bismuthous iodide. These patients were first given a course of autogenous vaccine made from the particular organism isolated from the stool—usually a streptococcus or Flexner's bacillus, and after completing three weeks of immunisation were then given a course of emetine bismuthous iodide. This modification of treatment cured every case that failed to be cured by emetine bismuthous iodide alone. The combination of a vaccine and emetine therapy is not a very practical one in India, however, as vaccines can only be prepared in the main laboratories, and hence people in the districts would always have to come to the larger towns for treatment. Chopra and his co-workers were investigating the action of the different alkaloids of kurchi bark (*Holarrhena antidysenterica*), and found that the total alkaloids of this bark were just as powerful in their action on cultures of *Entamoeba histolytica* as conessine. This was an important finding, as it meant that we could use a mixture of these alkaloids which would be easier to obtain in larger quantities and therefore cheaper than isolating one alkaloid like conessine.

They observed that the total alkaloids of kurchi

were more powerful in their action on cultures of *Entamoeba histolytica* than emetine, and moreover the total alkaloids of kurchi bark had no emetic or irritative action on the gut and did not depress the heart. Chopra then commenced to use the total alkaloids, giving them by subcutaneous injections in cases of acute amoebic dysentery. The results were more striking than with emetine, yet failures still occurred in spite of the treatment. In one of the cases of failure, the bacteriological laboratory isolated the *B. dysenterica* (Flexner), and after a course of vaccine the total alkaloids of kurchi bark were again given and the patient was cured by the combined treatment. As the total alkaloids of this bark, which we will call "kurchi alkaloids," have no emetic action, and only slightly lower the blood-pressure, it is possible to give them in much larger doses than is feasible with emetine. Acton suggested that as potassium bismuthous iodide forms an insoluble bismuthous iodine compound with all alkaloids, a kurchi bismuthous iodide could be prepared which would be insoluble until it came into the large intestine, and by increasing the dose a greater concentration of these alkaloids could be attained, sufficient to overcome the hindering action of the acidity in the large intestine. In the first case treated, we commenced with two grains and gradually increased the dose until four grains of kurchi bismuthous iodide were given twice a day. The dose is given early in the morning and the last thing at night in order to avoid ionisation occurring, as the stomach contents may be acid in reaction. The dose is well tolerated; there is no appreciable effect on the pulse rate or blood-pressure. The depressant, emetic or intestinal irritation that is usually caused by emetine was not observed by us. If cures only took place with the same certainty as with emetine, we would have a safe and efficient drug in these kurchi alkaloids, that would replace emetine in the treatment of amoebic infections of the bowel.

We here publish our first series of twenty cases in comparison with those obtained by Lieut.-Col. Knowles in his series with emetine. The results are much better for the kurchi series that have been given from 8 grains upwards a day. Time and a larger experience will enable us to fix more definitely the duration of treatment and the dose necessary to cure every case without resort to vaccine therapy. We will then be able to treat these carrier cases in the outpatient department instead of admitting them into hospital, and no longer need insist on complete rest during the course of treatment. Rest in bed will be essential in the acute and subacute cases where deep ulceration must be always present. So far as we have observed the kurchi alkaloids are as powerful in non-suppurative hepatitis as emetine, but we have had no experience with liver abscess. The value of independent research on the same disease is now apparent when viewed from two different aspects. Acton was obsessed with the dictum of his teacher, Sir James Kingston

Fowler, K.C.V.O., viz., that the failure of a specific remedy was not due to any fault of the drug, but to the person who administered it. Therefore he concentrated all his efforts to find out the cause of failure of emetine and emetine bismuthous iodide in the treatment of amœbic infections of the bowel. Chopra, on the other hand, was working on indigenous drugs, and found that the total alkaloids of kurchi bark gave better results in the laboratory on cultures of *Entamoeba histolytica* than emetine. As soon as clinical failures occurred in the kurchi alkaloid series, one worker was able to help the other with his knowledge of the cause of failure. The low toxicity of the kurchi alkaloids enabled us to overcome the hindering effect of the acidity in the larger gut by increasing the dose and thus attaining a greater concentration of these alkaloids, and so making cures more certain.

Pharmacological action.

Chopra and his co-workers (1927) worked out in detail the pharmacological action of conessine on amœbæ, etc. Previously in 1922 Brown had shown that conessine had a marked amœbicidal action in every way equal to emetine, but had no effect on the organisms of bacillary dysentery. In 1914 Burn investigated the pharmacological action of conessine, oxyconessine, and holarrhenine. He found that conessine exerts a considerable narcotic effect on frogs but has no appreciable effects on mammals. According to him both conessine and holarrhenine are cardiac poisons causing the heart to come to a standstill. These alkaloids, when injected intravenously, cause heart block and have a particularly destructive effect on the auriculo-ventricular bundle. In small doses, both these alkaloids produce a rise of blood-pressure when injected intravenously both before and after paralysing the vaso-constrictor endings with ergotoxin. This statement of Burn's on the action of conessine on the heart muscle, if it were true for the total alkaloids, would make one hesitate to administer them in large doses. Any limitation in the dose would defeat the end we had in view, i.e. to attain a concentration of these alkaloids in the large intestine sufficient to kill the amœbæ in spite of the acidity that was present in the gut content or in the surface tissues. We therefore investigated the action of these alkaloids very thoroughly and in detail, and found as follows:—

(a) *On the circulation.*—Small doses, 2 mgms., injected intravenously into the saphenous vein of a cat weighing 2 kilos., caused a persistent fall of blood-pressure, but without any alteration in the intensity or frequency of the heart beat. In much larger doses, there was slowing of the heart beat. Perfusion through the isolated heart rarely showed any effect on the frequency or force of the contraction. Doses of 2.5 mgms. in a cat of 2 kilos. showed no alteration in the auricular and ventricular contractions as seen in myocardiographic tracings. Although there is a

marked rise in pulmonary pressure with conessine and holarrhenine, the rise is only slight when the total alkaloids are injected into the animal. As the fall in blood-pressure is not due to a direct action on the heart or heart muscle, we next proceeded to study where the dilatation of the vessels occurred in the body.

(b) *The volume of various organs and structures in the body.*—We found that the limb volume, and that of the liver, spleen and kidney were all decreased after intravenous injections of the total alkaloids, indicating that vaso-constriction was occurring at these sites. On the other hand, there was a very marked increase in the intestinal volume with complete inhibition of intestinal movements; this was recovered from after a few minutes. From these results we concluded that the fall in blood-pressure is due to the dilatation of the intestinal vessels and to a lesser extent to engorgement of the lung.

(c) *Local effects on intramuscular or subcutaneous injections.*—When a 6 per cent. solution was injected into the tissues no hæmorrhages or necrosis was observed, but a good deal of œdema at the site of the injection. The œdema was most marked after 4 hours and began to disappear after 24 hours and disappeared completely in 48 hours after the injection; most of hyperæmia and œdema was caused by the acidity of the salt of the alkaloids.

(d) *On the uterus.*—The total alkaloids have very little effect on the excised uterus or on the uterus in situ except in strong concentrations which it is impossible to attain in the circulating blood. The alkaloid kurchine with a low melting point is the most powerful, causing contractions in a concentration of 1:50,000. Most alkaloids circulate in the blood at a concentration of 1:150,000 to 1:500,000. Therefore these alkaloids would have no effect if given to a pregnant woman.

Although our experience is somewhat limited, we can state the following facts from our clinical experience. There is no emetic or depressant effect when 20 grains of the kurchi bismuthous iodide are given daily for 10 days. The pulse remains normal in frequency, tension and rhythm. There is no alteration in the heart sounds, even in a case of cardiac disease. The drug does not cause irritation of the alimentary canal with diarrhœa as does emetine. If diarrhœa does occur, there is generally a reason such as a co-existing bacillary infection by the *B. dysenterica* (Flexner or Strong).

Injections into the muscles.—One- to two-grain doses of the total alkaloids give rise to no signs of bruising (hæmorrhages), as is seen with emetine, or necrosis as with quinine. Further, there are no general symptoms of mental depression.

Treatment by the total alkaloids of kurchi bark injected intramuscularly.

The total alkaloids of this bark do not cause any marked local reaction or necrosis of the

is no local hæmorrhage or marked swelling, as is seen with emetine. No toxic effects of any kind were observed when larger doses, viz. two grains, were injected intramuscularly. There is no doubt that the intramuscular route is the method of choice when treating acute cases of amœbic dysentery. The cause of failure in treatment both with emetine and the kurchi alkaloids is due to a secondary bacterial infection of these ulcers by streptococci, *B. dysenteriae* (Flexner), etc. These organisms form a large amount of acid from the carbohydrates, these diffuse into the tissues from the gut and also into the gut contents. These alkaloids are ten times more powerful when acting in a substrate at a pH of 8 than when acting in one at a pH of 6. There are three methods that are possible to overcome this acidity and so as to allow these alkaloids to work in an alkaline substrate. The first method, and one that seems the most obvious, i.e. to administer large doses of alkalies by the mouth, e.g., 5i to 5ii

of bismuth carbonate every 2 to 4 hours, sodium bicarbonate, citrate, etc., but these drugs have very little effect in reducing the acidity in the large gut. We have found this method useless clinically. The second method is to deal with the organisms that are responsible for the production of this acidity by isolating them, preparing a vaccine, and then immunising these patients against their own organisms. In this way we have been able to alter the pH of the stool from 6.8 to that of a pH 7.35 after three weeks of immunisation. The method is a sound one, as the results in Table II show, as one can assure a patient that even in spite of repeated failures with emetine he will be cured by the combined treatment of vaccines and emetine. Unfortunately, this method is not a very practical one and needs at least six weeks to effect a cure. The third method is to give the drug in large doses in order to attain a sufficiently high concentration for it to be able to be effective in an

acid substrate. Fortunately, the total alkaloids of kurchi bark are not in any way toxic, so that large doses can be given, and we can also form an insoluble bismuthous iodide compound, which will not begin to act until it reaches the acid substrate in the cæcum and large intestine. This actually does occur, as qualitatively we find the kurchi alkaloids in the urine of patients taking the bismuthous iodide compound. Now the *Entamoeba histolytica* may be living in the tissues or in the lumen of the gut. In the former case it will be in contact with the serum and body fluids at a pH of 7.2, whilst in the gut the contents may reach a high degree of acidity between a pH of 5 and 6.

Dobell and Laidlaw in 1926 found that emetine acted in a concentration of 1 : 50,000 when tested on cultures of *Entamoeba histolytica*; they did not give the pH of their cultures but merely stated that they were constant. Chopra and others (1927) found when using flakes of mucus from an infected kitten, that conessine killed these amœbæ in a dilution of 1 : 280,000 and emetine in a dilution of 1 : 200,000. In an acid substrate of a pH of 6 these figures would probably be reduced down to 1 : 28,000 and 1 : 20,000. When administering 10 grains of kurchi bismuthous iodide, we would really be only giving 3.3 grains of the total alkaloids that would come into the cæcum and ascending colon of a capacity of 4 litres where a concentration of 1 : 18,000 would be attained. Therefore a 10-grain dose will be more effective than a 4-grain dose when dealing with these amœbæ living in the lumen of the gut where the contents are acid. The amœbæ inside the bowel wall will not be affected unless the drug is absorbed and then excreted into the large gut. We are still in the experimental stage as regards dosage and this paper is only a preliminary note. Whether the combined treatment by injections with oral administration of these alkaloids is the best method still remains to be proved by us.

Our experience in the use of the total alkaloids of kurchi bark in the treatment of acute and chronic amœbic infections of the bowel justifies us in arriving at the following conclusions:—

CONCLUSIONS.

(1) In the laboratory, and to a greater extent clinically, the total alkaloids of kurchi bark are far superior to emetine.

(2) The kurchi alkaloids can be given in large doses, and so far no depressant, emetic, or irritative effects have been observed by us. They are much less toxic than emetine.

(3) Intramuscular injections of 2 grains of the total alkaloids cause transient hyperæmia and œdema; this is not visible to the eye unless the dose is injected subcutaneously, and the swelling passes off in 24 to 48 hours. Injections should be used for acute cases of amœbic dysentery.

(4) The kurchi bismuthous iodide can be given orally in 10-grain doses twice a day for 10 days without any deleterious effects.

(5) In chronic amœbic colitis, 4 grains of kurchi bismuthous iodide given orally twice a day for ten days cured 12 out of 18 cases, compared with one out of every two with emetine bismuthous iodide.

(6) Intramuscular and oral administration of the total alkaloids of kurchi bark cure non-suppurative hepatitis; their action on suppurative amœbic hepatitis has still to be investigated.

(7) The administration of the total alkaloids of kurchi bark, instead of conessine only, means a larger yield of the drug, and therefore cheapness in production.

(8) As *Holarrhena antidysenterica* grows in the submontane areas all over India from the Himalayas to Travancore, it is easily procurable in this country.

The total alkaloids for injection and the kurchi bismuthous iodide can be obtained from Messrs. Smith Stanistreet & Co., Ltd., Dalhousie Square, from the Bengal Chemical and Pharmaceutical Co. and also from The Union Drug Co., Calcutta.

THE ERYTHROCYTE SEDIMENTATION TEST IN LEPROSY.

By E. MUIR, M.B., Ch.B., M.D., F.R.C.S., Ed.,
*Leprosy Research Worker, Calcutta School of Tropical
Medicine and Hygiene.*

EXPERIENCE has shown that the rate of sedimentation of the red blood corpuscles varies in the different types, stages and phases of leprosy and that the use of the sedimentation test in leprosy provides a valuable guide in treatment, as well as giving information of diagnostic and prognostic value. The classification of leprosy used below is that adopted by the Leprosy Research Department of the Calcutta School of Tropical Medicine & Hygiene.*

The technique advised is an adaptation of that used by other workers and is chosen because it makes it possible to test a large number of bloods at once with fair accuracy and with the expenditure of a minimum of time. 0.3 c.c. of a 5 per cent. solution of sodium citrate in distilled water is drawn into an all-glass 2 c.c. syringe; 1.2 c.c. of blood is drawn from the patient's vein into the same syringe, and a small quantity of air having been taken into the syringe barrel, the blood and citrate solution are thoroughly mixed by reversing the syringe several times, and the mixture is evacuated into a clean test tube. If several patients are to be tested, their bloods are taken in a similar manner and placed in labelled test tubes in a rack. Sedimentation is carried out in 300 mm. pipettes graduated from above downwards from zero to 100, there being a space of 3 mm. between each mark. The content of the pipettes when filled up to zero is approximately 1 c.c., but a variation of 0.05 c.c. is allowed as such a variation makes no appreciable difference in the results. The pipettes are placed upright in a rack, with their points inserted in small holes bored in rubber corks (as in the illustration).

One of these pipettes is taken from the rack and its upper end is attached to a 10 c.c. syringe by means of a rubber tube. The point of the pipette is inserted in one of the test tubes and, suction being applied by pulling on the piston of the syringe, the blood-citrate mixture is drawn up into the pipette to the zero mark. The pipette is then replaced in the rack, the point again being inserted in the rubber cork which prevents the mixture escaping, and the rubber tube is then disconnected from the pipette. In this way the other pipettes are filled up to the zero mark from the other test tubes.

The top level of the erythrocytes is read off after $1\frac{1}{2}$ hours and again after $2\frac{1}{2}$ hours and the average of these two readings is taken as the sedimentation index (hereafter called "S. I."). Thus if the level of the top of the blood cells falls to 10 (30 mm.) after $1\frac{1}{2}$ hours and to 20 (60 mm.) after $2\frac{1}{2}$ hours, the S. I. will be the average of 10 and 20, i.e. 15. The maximum reading is about 80 (240 mm.). Generally speaking the S. I. in the different stages of leprosy increases in direct proportion to the number of bacilli in the body. In the early (A 1) stage, it is practically the same as in uninfected persons, i.e. between 10 and 20. In B 1 cases it may be slightly increased; in B 2 cases it is 30 to 40; and in B 3 cases 40 to 60.

The S. I. is also a criterion of the reaction phase in direct proportion to the degree and extent of the reaction. Thus the sedimentation index in a B 2 case may increase from 30 to 60 or 70 during a reaction, returning to the former level as the reaction passes off.

The S. I. is also a criterion of the reaction level. Thus a non-reacting patient, who shows for a considerable time more rapid sedimentation (high S. I.) than would be expected from the clinical stage of the disease, will react to a smaller dose of potassium iodide or any other reaction-producing drug than a patient with a comparatively low S. I. The more easily reaction is produced, the lower is the reaction level. This is important in the regulation of treatment, which can be pressed when there is a comparatively low S. I. (and therefore high reaction level), but must be proceeded with carefully when the S. I. is high, and the reaction level low; otherwise a severe reaction may be produced which will lower still further the resistance of the patient and cause an increase of the disease.

It must be remembered, however, that the sedimentation test is not in any sense specific in leprosy. A rise of the S. I. is caused by malaria, syphilis, septic processes, and in fact by everything which causes unusually rapid metabolism or breaking down of the tissues of the body and consequent absorption of waste materials. This must always be kept in mind in interpreting the S. I. These diseases and other causes also lower the

BLOOD
SEDIMENTATION TEST.

* *Leprosy, Diagnosis, Treatment and Prevention*, British Empire Leprosy Relief Association (Indian Council), Delhi.

patient's reaction level and lower his resistance to leprosy. In treating such cases special leprosy treatment must be delayed or given only in small doses, while predisposing and complicating diseases, etc., must be sought for and remedied. When this is accomplished the S. I. may be expected to fall, whereupon the special treatment may be pressed with safety.

The effect of a given dose of medicine (such as potassium iodide given orally, or injections of hydnocarpus preparations) upon the sedimentation rate, serves to indicate whether the next dose should be increased or diminished and after what interval it should be given. If the S. I. is low or only moderately high considering the type of case, and if there is no change produced in the rate of sedimentation by the given dose, there is a clear indication that the treatment may be pressed. If, on the other hand, there is a marked rise in the sedimentation index following the dose, the next dose should be delayed till the former level is reached and the dosage should not be increased but should possibly be lowered.

If the S. I. is high or shows further signs of rising, then special treatment (hydnocarpus, potassium iodide, etc.), must be stopped and drugs which have an anti-reaction effect should be used. One of the most valuable of these is potassium antimony tartrate given intravenously in 0.02 gramme doses every second day; alkalies given orally or intravenously are also useful for this purpose.

The gradual lowering of the S. I. which takes place under treatment is of considerable prognostic value as an indication that the disease is gradually being eliminated from the body.

An unusually low S. I. (3 to 8) which sometimes occurs even in B 2 cases, may generally be counted as a good sign. Such patients, as a rule, improve rapidly under treatment.

When a former B 2 or B 3 case has become bacteriologically negative, and if he can stand large doses of potassium iodide (up to 240 grains) without an increase in S. I., it is a good prognostic sign.

The sedimentation test is useful in testing the efficiency of any drug in the treatment of leprosy. If the remedy does not possess the power of raising the S. I., it is not likely to be effective in eliminating the leprosy infection from the body. There are however certain very useful reaction-reducing drugs, the effect of which is to lower the S. I., such as those mentioned above.

A NOTE ON CHOLERA IN INFANTS.

By J. DAS GUPTA, M.B., D.P.H.,

Demonstrator of Pathology, Carmichael Medical College, Calcutta, and Visiting Physician, the "Babies Home," Calcutta.

CHOLERA is seldom seen in infants, but during this past epidemic in Calcutta, I had

a number of cases in the fourth week of May and the first week of June while attending the infants at the "Babies Home." The first two cases ended fatally within a few hours of the attack and I could not diagnose the condition on account of the very peculiar symptoms which each of these babies presented and which I shall relate later. These cases were also seen by other physicians whom I called to my help. When the third case came, my suspicion arose about cholera, though the symptoms were abnormal, but there were a large number of cases in the immediate neighbourhood. It was only when I took a sample of stool from the third case, cultured it and performed the agglutination test with high titre cholera serum that I came to a definite diagnosis. Four other cases occurred after this in quick succession, and in each of these, excepting one, the stools were cultured and agglutination tests were performed and found to be positive. Fever was present in all these cases excepting one. The ages of these babies ranged from 3 months to 1½ years. As regards the source of infection, I tried to find it out, but there were so many difficulties in the way that I had to give up the idea; but when the nursing staff was entirely changed and the new staff and all the babies were inoculated with cholera vaccine and the utmost hygienic precautions were taken, the epidemic stopped without any further fresh cases. That the first two cases passed undiagnosed but to me appeared as cases of cholera will be evident from the following reports:—

Case No. 1.—Baby Sushila, aged 4 months. Passed the first stool in the morning on 29th May, 1929, white, curdy, in character; reaction acid when I saw the stool; no urination after the first stool. The child had another similar characteristic stool at 4 p.m. and after this it began to sink very rapidly; tympanites set in; the pulse became very weak; at about 9-30 a.m. the child began to show a peculiar continuous twitching of the face and legs, the knee jerks were exaggerated. The baby had received no injury. On 30th May, 1929, the baby had no stool, but the condition remained the same. Bromides and chloral completely failed to check the convulsions. The pulse was almost imperceptible. In the evening the temperature rose to 108°F., but it came down to 97°F. in two hours after cold sponging. The baby died the same evening. A provisional diagnosis of gastric tetany was given in the death certificate.

Case No. 2.—A Belgachia baby one year old; it was a healthy baby the previous night, i.e., on 30th May, 1929, and so no special notice was taken of it. On the morning of 31st May, 1929, the baby presented a quite changed appearance, eyes sunken, pulse very bad, toxæmic, with excessive tympanites; according to the nurse the baby had had two stools in the previous night and these were curdy white in appearance. Twitching of the face and legs set in the early hours of the morning; urination was absent after the first night stool until death. Rectal saline, atropine, adrenalin and a rectal wash were given, but the baby became uræmic so rapidly and collapsed that I had no time to give subcutaneous saline. The baby died the same morning.

These two cases aroused my suspicion that either they might be cases of food (milk) poisoning or cholera. I stopped the existing supply of milk and the utmost precaution was taken in feeding the babies. Still a third case developed.

Case No. 3.—Bibha, an older baby, 1½ years old. This baby showed the first symptoms in the early hours of the morning of 30th May, 1929, when it passed the

CASE No. 1.

Name, *Sushila*. Age, *4 mths.* Dis. *Tetanus.*

vomited several times and a condition of collapse set in with rigidity of the extremities very rapidly. I took one of the stools for examination and sent the baby to the Carmichael Medical College Hospital, where it was clinically diagnosed as cholera and my bacteriological examination confirmed the diagnosis. The baby survived after the usual saline treatment.

Case No. 4.—Charu, aged 4 months, lived with her mother; on 5th June, 1929, she had one loose yellow stool at 5-30 in the evening. Within an hour the pulse became almost imperceptible, the eyes sunken, and this was followed rapidly by tympanites and anuria. The usual saline treatment with atropine and adrenalin was given, but so rapidly did uræmia set in that the child died the next morning. It had no further stool and no stool was examined in this case. The baby had fever during the attack. Its mother was attacked with a clinical type of cholera the very next day after the death of the baby. She was sent to the Carmichael Medical College Hospital, where the case was diagnosed as cholera clinically and bacteriologically, and she died of it.

Evidently the mother got the infection somehow and transmitted the same to her baby, who succumbed earlier than her mother.

Case No. 5.—Baby H., aged about 3 months; this baby was attacked on 5th June, 1929, at about 4 p.m. The first stool was like that of the first two cases, white and curdy in character. The second stool followed after two hours and was more liquid. Anuria followed but there was no vomiting. Twitching of the extremities set in. Encouraged by the previous results, I took a sample of the stool and at once went to the laboratory for bacteriological examination and culture. which was found to be positive for cholera. Subcutaneous salines, rectal washes, atropine, adrenalin were given and the baby survived. This baby had fever during the attack.

Case No. 6.—Bella, 1½ years old, was attacked on the night of 30th May, 1929. The first stool was watery with white specks in it and the number of stools was rather frequent. Anuria was present. After the second stool the child collapsed very rapidly and so subcutaneous saline, atropine and adrenalin were given. In the morning the stool was taken by me for examination

CASE No. 4.

Disease... *Cholera.*

first stool which was white, watery, and slightly mucoid, attended with vomiting. It passed several stools, and

and the cholera vibrio was found on culture. The baby survived.

So it is evident that the characteristic rice water stool and vomiting are usually absent in cholera in infants. The number of stools

for giving me the earliest possible information about these cases and for keeping complete records of them.

CASE No. 5.

CASE No. 6.

is generally restricted to two or three, and in some cases to one only. Anuria, the rapid onset of uræmic symptoms, and collapse and white curdy stools are the most characteristic features noted by me in infants in this epidemic.

I am much indebted to Miss M. Kotval, Lady Superintendent of the "Babies Home,"

THE EFFECT OF TETRONAL ON THE PRODUCTION OF HÆMATOPORPHYRIN IN THE URINE.

By FREDERICK G. GERMUTH,

Division of Research, Bureau of Standards,
Baltimore, Maryland, U. S. A.

THE author has endeavoured to show in a previous research(1) concerning the

employment of the sulphones (sulphonol and trional) in the treatment of certain mental diseases, that following an increase in ethyl groups present in the molecule of the compounds constituting this series of hypnotics, there is also a corresponding increase in the amount of hæmatoporphyrin ($C_{31}H_{38}N_2O_8$) contained in the urine of patients to whom the drug is administered. It has been shown(1) that the portion of the porphyrin produced in the trional urines was greater than that present in the samples of urine obtained from those patients who had been treated with sulphonol in the relative proportions: 1.0 sulphonol: 1.34 trional. In the discussion following the presentation of this work, the author observed "it would be of interest to learn in this connection whether the continued use of tetronal is capable of producing an amount of hæmatoporphyrin in theoretical excess of that engendered by the administration of trional. In view of the facts herewith presented, it would appear feasible in the absence of experimental data to anticipate this condition."

The paper here presented furnishes results obtained in experimental clinical studies, employing the soporific tetronal:

Experimentation developed the fact that the method advocated by Salkowski(2) furnished a better means of ascertaining the quantity of the sought-for substance in the samples of urine than that of Garrod(3), the latter method finding wider employment in the determination of traces or minute portions of the porphyrin. For the benefit of those who may not be familiar with the technique involved in the procedure utilized, it is herewith presented:

Method Employed.

A mixture consisting of equal portions (by volume) of saturated barium hydroxide solution and ten per cent. barium chloride solution is added to the sample of urine under examination; precipitation of the solids resulting. The precipitate, which is washed at least three times with warm ($37^\circ C.$) water, contains the hæmatoporphyrin. This is permitted to stand one hour at room temperature in ethyl alcohol acidified with hydrochloric acid (1 c.c. of HCl , sp. gr. 1.20, in 25 c.c. of 95 per cent. C_2H_5OH), and then filtered. The alcoholic filtrate is thoroughly mixed with a like volume of chloroform, and two volumes of distilled water added. This is carefully shaken, and a lower layer of chloroform is obtained which contains a very pure hæmatoporphyrin, while the upper layer of alcohol and water contains other pigments in addition to a small amount of the compound.

Results.

The patients from whom the samples of urine were obtained had been treated with tetronal for at least three weeks prior to examination, the dosages employed being fairly constant. Meticulous attention was accorded to ten samples, representing the twenty-four hour output of patients to whom the medicine had been given. The observation was made

that the general relation existing between the three compounds, sulphonol, trional and tetronal as regards their ability to accelerate the formation of hæmatoporphyrin in urine is in the proportion: 1.00 sulphonol: 1.34 trional: 1.56 tetronal.

The fact that an increase in ethyl groups in the molecules of these compounds imparts a greater degree of therapeutic activity is generally afforded recognition. Apparently, the production of hæmatoporphyrin in the urine is considerably influenced by the molecular alkyl structure of the sulphone ingested.

GOITRE IN MULTAN DISTRICT.

By J. R. CHAUDHRI, M.R.C.S., L.R.C.P., D.P.H. (Camb.),
District Medical Officer, Multan.

IN the course of medical inspection the school children of Mulepur, a village, Kabirwala tahsil, it was noticed that a Sub-markably large number of children suffered from simple goitre. Out of a total of 70 boys examined, 32 were found suffering from goitre—a very high percentage. Further investigation showed that goitre exists not only amongst the students of the 1st and 2nd classes that were examined medically, but also in all classes. The following statement gives the extent of incidence of the disease in each class:—

Class.	Number of boys examined.	Number of goitrous boys.	Percentage.
I	57	20	35.1 per cent.
II	22	19	86.4 per cent.
III	13	8	61.5 per cent.
IV	8	7	87.5 per cent.
V	16	12	75.0 per cent.
VI	9	7	77.8 per cent.

This state of affairs naturally led me to look for goitre amongst the grown-up people of the village. I found a large number suffering from this disease. In a small village of 400 souls there are about 15 persons with very big necks (Derbyshire necks). These are the persons whom everybody in the village knows by reason of their prominent necks. But there exists a considerably larger number of persons who have goitres of too small a size to be noticed by laymen. As a matter of fact,

I believe that about 60 per cent. of the population of this village suffers from goitre.

I was told that the disease prevails much more amongst the females than amongst the males. I could not personally verify this fact because one is unable to see a large number of women. They told me, however, that there are more women than men who have got big goitrous necks.

There are in this village 3 persons who have subnormal brains, one of them is feeble-minded and has goitre, the other two are cretins, and one of them definitely suffered from goitre. It is possible that there is some correlation between goitre and cretinism.

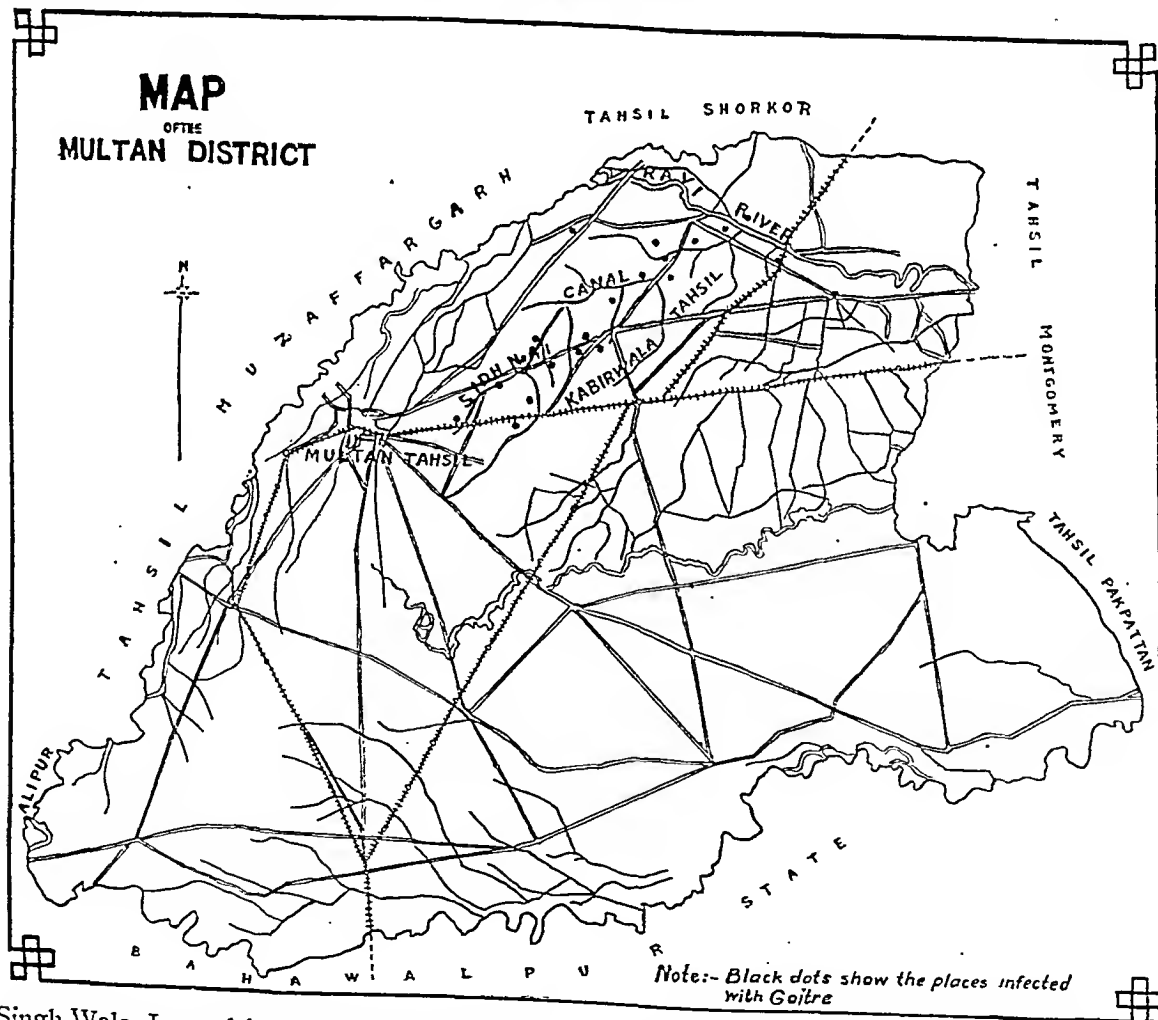

Age Incidence:—

The disease seems to attack all ages except the infants. I examined many infants but none of them showed any appreciable enlargement of the thyroid glands.

I also visited three villages situated in the neighbourhood of Mulepur, namely Bute

Class.	Number of boys examined.			Number of goitrous boys.		
	1	2	3	1	2	3
I	8	47	22	4	6	13
II	6	31	8	2	7	5
III	12	16	5	7	4	5
IV	13	12	7	5	2	6
V	..	14	3	..
VI	..	13	5	..

It is clear from the above that goitre is endemic in these villages also. Moreover, medical examination of school children at Sardarpur and Sarai Sidhu also revealed the existence of goitre in the villages of Aulak Sidhu, Bagar and Sardarpur. I have also seen cases of goitre in Jaso Kanwan, another village of Kabirwala *tahsil*. The following statement gives the incidence of simple goitre in each village, the situation of these villages is shown in the attached map of this

Singh Wala, Jawandsingh Wala and Kohiwala. The following statement gives the incidence of the disease amongst the school children in these 3 villages.

district. It would appear that the disease is highly endemic in the whole of Kabirwala *tahsil*, especially so in the villages situated along and quite close to the Ravi river. I have

also seen cases of goitre in some villages of Multan *tahsil*. In Multan city itself the disease is widely prevalent. I also noticed goitrous cases in Taraf Muabarak, a suburb of Multan city. Similarly, I noticed cases of goitre in Tulamba, Khanewal *tahsil*.

more than one factor at work in the causation of the disease, that some are more disposed to this disease than others.

Pathology:—

The size of the goitre varies greatly. All

Hajipur ..	VI	6	1	..	1	..	100.0 "
Luthar ..	VI	6	1	..	1	..	100.0 "

It appears therefore that the disease is essentially endemic in the whole of Kabirwala *tahsil*.

The extent of incidence in families in Kohirwala.

I enquired from five different families, taking them as random samples. I found the following:—

1. Of 7 members of a Hindu family 5 have got goitre of big size.
2. Of 3 members of a Hindu family 1 has got goitre.
3. Of 9 members of a Hindu family 3 have got goitre.
4. Of 6 members of a Mohammadan family 2 have got goitre (brother and sister).
5. Of 7 members of a Mohammadan family 2 have got goitre.

Symptoms and Ill Effects:—

The following four patients with big goitres were examined for symptoms:—

- (1) Satu.—A female, aged 35, big goitre, pulse rate 80, dyspnoea on exertion, no exophthalmos, no tremor.
- (2) Para.—A male, aged 60, big goitre, has tremor of the head, has dyspnoea, palpitation and giddiness, no exophthalmos, pulse rate 82.
- (3) Nand Lal.—A male, aged 10, shows tendency towards exophthalmos, has big goitre but no other symptom, pulse rate 80.
- (4) Chanan Das.—Pulse rate 88, has got big goitre, shows tendency towards exophthalmos.

The last two are brothers.

The fact that several members of a family escape from this disease shows that there is

varieties from slight but appreciable enlargement of the thyroid gland to very big hard colloidal goitres of the size of a foetal head can be seen. Amongst the school children it is simply a parenchymatous enlargement of the gland. In some of the grown-up people the goitre seems to be of the fibro-adenomatous type.

In most cases the whole of thyroid gland is involved, but I have seen cases of unilateral enlargement of the thyroid gland as well as cases in which the central lobe of the thyroid gland was enlarged.

It is now an established fact that goitre is due to iodine deficiency in water, food and soil, and that the thyroid gland undergoes compensatory hypertrophy in order that it may provide the system with the necessary quantity of iodine. Samples of water, food and soil taken from four different villages were sent for chemical analysis to detect iodine deficiency. The analyst reports that iodine is absent in the samples sent to him. Presuming that the analyst employed sufficiently delicate technique in detecting iodine in the specimens of food, water and soil, there is thus sufficient ground to believe that the theory of iodine deficiency is correct.

The condition of sanitation and the purity of the water supply are said to play an important part in the incidence of this disease. There is no doubt that the sanitation of the villages in which I have noticed cases of goitre is exceedingly poor, but other villages in

which goitre is not endemic are no whit better in the matter of sanitation. The purity of the water supplies in these villages is likewise highly questionable even as it is in other villages of the district. I cannot, therefore, establish any definite relationship between bad sanitation with impure water supply and the incidence of goitre.

Prevention of Goitre:—

As for the prevention of goitre, the following quotation from Rosenau solves the problem of prevention admirably:—

"The essentials of goitre prophylaxis are low cost, palatability, ease of administration, minute dosage, harmlessness and efficiency of the iodine preparation used. The method most favoured at the present time is the use of a chocolate tablet containing 10 milligrammes of iodine in the form of an organic acid. This form of iodine has the advantage of being tasteless, non-hygroscopic and very stable. It is so much more pleasant and practical than sodium iodide that Kimball recommends it. One or two of these tablets, according to the age and requirements, should be given each week during the school year to boys and girls, especially between the ages of eleven and sixteen."

It is proposed to try the administration of iodine both as preventive and curative amongst the school children in Kabirwala talhsil to begin with. Later on, I have no doubt the remedy will become very popular, as goitre is so prevalent, and we may well expect the people themselves to resort to this remedy. It may be interesting perhaps to note that most of the goitrous persons showed a considerable anxiety to get cured of this disease not on account of any particular disabling symptom, but because of the serious disfigurement the disease causes.

A LIST OF THE SPECIES OF MOSQUITOES COLLECTED IN THE FRENCH SETTLEMENTS IN INDIA.

By THE LATE DR. E. BOREL, M.D.,
Chief of the Malaria Research Laboratory,
Pasteur Institute of Saigon (Indo-China)*
and

MAJOR V. G. F. LABERNADIE, M.D.,
Chief of the Bacteriological Laboratory of
Pondicherry (French India).

We give below a list of the species of mosquitoes collected in the five French settlements in India.

If not otherwise specified the specimens were taken in private houses.

*We very much regret the recent death of Dr. Borel. His contributions to the study of malaria in French Indo-China were numerous and of great value from the epidemiological point of view.—EDITOR, I. M. G.

RECORDS OF ANOPHELINES FROM THE BENGAL DOOARS.

By BHUPENDRA MOHAN KHAN,

Sub-Assistant Surgeon, Bengal Public Health Department, Writers' Building, Calcutta.

THE anophelines of the Bengal Dooars were first studied by Stephens and Christophers in the year 1902, when they found only three species, viz., *A. minimus*, *A. maculatus* and *A. rossi*. Subsequently, Christophers and Bentley in 1903 reported the following nine species:—

- | | |
|------------------------------|------------------------------|
| (1) <i>A. minimus</i> . | (5) <i>A. fuliginosus</i> . |
| (2) <i>A. maculatus</i> . | (6) <i>A. leucosphyrus</i> . |
| (3) <i>A. rossi</i> . | (7) <i>A. sinensis</i> . |
| (4) <i>A. barbirostris</i> . | (8) <i>A. culicifacies</i> . |
| (9) <i>A. aitkeni</i> . | |

Sur and Iyengar, in 1926, recorded in their report of malaria survey of Jalpaiguri Dooars the above-mentioned species in addition to (10) *A. jamesii* and (11) *A. karwari*.

Strickland and Chaudhuri collected all the species previously recorded by Sur and Iyengar and, in addition, found (12) *A. maculipalpis*, (13) *A. kochi*, and (14) *A. vagus*. (*Report on a mosquito malaria survey of the Dooars Tea-gardens*.)

Thus previous records show that the detected species of Anophelines in the Dooars were 14 in number.

The writer, who has been stationed for the last nine years at the Meenglas Tea Estate, as officer-in-charge of the Experimental Anti-Malaria Scheme of the Bengal Public Health Department, has found all the above-mentioned fourteen species on the Meenglas Tea Estate as well as on the adjacent tea estates of Dalingkote, Nedeem and Rungamuttee. In November 1926, he collected four specimens of *A. kochi* from Meenglas, one of which was sent to the Central Malaria Bureau, Kasauli, and another to the Bengal Malaria Research Laboratory. The writer subsequently collected one specimen of *A. jeyporiensis* from Dalingkote Tea Estate in the same year and this is the only record of this species from the Dooars. This specimen was sent to the Malaria Research Laboratory for confirmation. In 1928 he collected some more specimens of the same species from the Baintbarie division of the Nedeem Tea Co.

Thus one more species should be included in the list of Anophelines of Jalpaiguri Dooars, the total number being 15 as far as our present knowledge goes. They are as follows:—

- | | |
|-------------------------------|-------------------------------|
| (1) <i>A. minimus</i> . | (8) <i>A. culicifacies</i> . |
| (2) <i>A. maculatus</i> . | (9) <i>A. aitkeni</i> . |
| (3) <i>A. rossi</i> . | (10) <i>A. jamesii</i> . |
| (4) <i>A. barbirostris</i> . | (11) <i>A. karwari</i> . |
| (5) <i>A. fuliginosus</i> . | (12) <i>A. maculipalpis</i> . |
| (6) <i>A. leucosphyrus</i> . | (13) <i>A. kochi</i> . |
| (7) <i>A. sinensis</i> . | (14) <i>A. vagus</i> . |
| (15) <i>A. jeyporiensis</i> . | |

The writer is grateful to the Director of Public Health, Bengal, for his kind encouragement to publish this note.

A COMPARATIVE STUDY OF THE EFFECT OF CLIMATE AND OF THE SEASONS ON BODY WEIGHT IN PULMONARY TUBERCULOSIS IN DIFFERENT COUNTRIES.*

By DR. M. KESAVA PAI, M.D., C.M. (Mad.),
Director, Tuberculosis Institute, Temple Gardens,
Royapettah, Madras.

In a paper(1) contributed to the Congress of the Far Eastern Association of Tropical Medicine in December 1927, at Calcutta and later in another(2) read before the South Indian Branch of the British Medical Association, it was shown by an analysis of the weight of over 550 cases of pulmonary tuberculosis treated during the five years 1923 to 1927 in the Madras Tuberculosis Hospital, that there was a definite relationship between body weight and the seasons of the year. It was shown that in Madras City there was a steady decrease in the gain of weight during the hot months March to September, and an increase in the gain of weight during the cooler months October to February.

A word of explanation is necessary in connection with the accompanying charts. The fall in the curve during the hot months does not mean there was a fall of actual weight during those months, but merely a fall in the rate of increase of weight. In the normal adult there is a physiological rate of increase of weight consequent on body growth, and pulmonary tuberculosis being a disease of adolescence, i.e., of the age period 15 to 35, it is important to distinguish the variation in weight in the normal individual from that observed in the progress of cases of pulmonary tuberculosis. Consequent on the wasting of the body resulting from tuberculous toxæmia, the increase in weight as a result of treatment under favourable conditions is often phenomenal, increases of 30 per cent. to 50 per cent. in the course of a few months being not seldom observed. What

* Being a paper read at the Medical and Veterinary Section of the Indian Science Congress held at Madras in January, 1929.

we are concerned with in this paper is the rate of increase at different seasons of the year.

It is important in drawing general conclusions that the analysis should be made from a large number of cases and that all possible errors due to accidental causes should be excluded. Thus highly toxic cases rapidly going downhill will interfere with the normal curves, and intercurrent infections like epidemics of influenza, diarrhoea, dysentery, etc., should be taken into due consideration in the calculations. In this paper the increase of weight has been calculated in percentages, and wherever there is a fall in the curve it merely means that the rate of increase has fallen and not the actual weight, unless the curve goes below the 100 line, when it means that the patient has actually lost weight. Thus in Chart I the patient has increased in weight from the beginning to the end, but the curve shows a rise and a fall all the same.

CHART I.

Weight curve of a case where artificial pneumothorax treatment was adopted.

According to Lunde(3) gain in weight in tuberculosis is due to deposition of fat resulting from good feeding and rest and better assimilation of food, and greater retention of water in the system in the cooler and more humid parts of the year. Fall of weight, he considers, can be explained by increased evaporation during the hot months and poorer assimilation and metabolism during the coldest part of the winter and hottest part of the summer. In winter there is also greater combustion and loss of fat to make up for the loss of heat from the body by radiation and increased urination. Lunde has shown that in Norway patients show a slight rise in the weight curve in spring and a higher rise

in late summer and autumn when the temperature and humidity are at their optimum with regard to comfort, assimilation and general metabolism. Conversely there is a fall in the curve in midsummer and in winter.

CHART II.

Weight curves of patients in the Sanatoria of Denmark and at Arogyavaram in South India.

Strandgaard's(4) work in Denmark gives similarly consistent results. Strandgaard lays some stress on dietary which he believes has considerable influence on the weight fluctuations, and adds the culinary to the seasonal factors in explaining the variations in weight of patients treated in different sanatoria. He proves by statistics that there is a loss of weight in the majority of Danish sanatoria in July, a gain in September, and a fall again in December. Sunlight, temperature and humidity, according to Strandgaard, combine in influencing body weight.

Frimodt-Møller(5) working at the Arogyavaram Sanatorium in South India produced very interesting figures and curves for the body weight of patients in his sanatorium. In the dry and hot months March to May, he observed patients gained less weight than in the cooler and more humid months June to September, and in the coolest months October to February the gain in weight was greater. These results completely agree with those of Lunde and Strandgaard in Europe, considering that there are no winter conditions in South India and consequently there is no winter dip in the weight curve.

Weight curves and figures for other countries are unfortunately not available in the literature, but it would be very interesting to know what the weight fluctuations are in the humid regions of Western India, in the sanatoria situated on the Himalayan slopes where seasonal conditions are not unlike those of Europe, and in the hospitals and sanatoria of other countries in the world.

Strandgaard, by comparative study of weight figures, pointed out that autumn was the season for maximum increase of weight in all temperate climates, the month of August in Norway, September in Denmark and other countries in Northern Europe, and October in the United States being the optimum months in this respect. Under the tropical conditions of Southern India, the months November to February, corresponding to the autumnal climate of the temperate zone, are the optimum for increase of weight.

CHART III.

Curves showing temperature, humidity, body weight and rainfall—Tuberculosis Hospital, Madras City. Average of the years 1921 to 1927.

Madras with its typically tropical climate has practically a twelve months' summer, of which the four months November to February are comparatively cool and pleasant. Consequently there are only two variations in the weight curve of Madras, the dip of the hotter months March to October, and the rise of the cooler months November to February. The temperature curve runs in an exactly opposite direction to the weight curve. The mean daily temperatures of Madras vary from 74°F. to 80°F. during the cooler months and 80°F. to 90°F. during the hotter months, the former being practically the summer temperature of Europe. The fluctuations in the weight curves of different countries thus represent fairly accurately the fluctuations of temperature and atmospheric conditions like humidity, sunlight, etc. Sunlight is a favourable factor in colder countries, just as it is the reverse in the tropics. The reason is obvious. The climates of the different countries of the world have therefore a direct bearing on metabolism and body weight, especially in tuberculosis. Whilst Madras has only two fluctuations, a

hill climate in South India like Arogyavaram has three, and colder countries like Norway and Denmark four, representing the seasons of the respective countries, viz., the hot and the cool seasons of Madras, the summer, autumn and cooler months of Arogyavaram, and the four classical seasons of Europe.

THE TREATMENT OF SEASICKNESS.

By A. SAHA, L.M.F.

Ship's Surgeon, British India Steam Navigation Co.,
Messrs. Mackinnon, Mackenzie & Co., Calcutta.

DURING my ten years' experience as a ship's surgeon I have had many opportunities of treating seasickness, and a brief account of methods which have been tried may be of interest.

The disease or condition is experienced only in rough seas (although it may occur in perfectly calm weather in extremely susceptible subjects), and it is usually considered to be primarily an affection of the central nervous system. With the rolling and pitching of the ship in a rough sea there is disturbance of the endolymph in the semicircular canals of the labyrinth, and the disturbance passes through the vestibular portion of the auditory nerve to the cerebellum. As the centre of origin of the eighth nerve is very close to the centres of vomiting, vertigo, etc., in the floor of the fourth ventricle, the loss of balance brings with it headache, vertigo, and vomiting.

The chief symptoms of seasickness are headache, extreme wretchedness, giddiness, vomiting and, in some very severe cases, an almost choleraic type of diarrhoea. This last group of patients will tolerate nothing by the mouth, not even fresh limes or ice to suck. It is in this group that cardiac failure may loom threateningly.

Many people however soon adapt themselves to the movement of a ship in a rough sea, and only some 25 per cent. of passengers are seasick in a rough sea on their first voyage. Even these however for the most part gradually overcome the complaint after a

few days, or in subsequent voyages. There is a residue of some one per cent., however, who never become adapted, and who are invariably seasick on every voyage. The choleraic cases are even fewer in numbers, but they are serious. In general, it may be said that women are "poor sailors" as compared with men. Infants in arms under six months of age appear to be quite immune, and such is also the case with many deaf-mutes.

Exciting factors appear to be constipation and starvation before sailing. The intending voyager would do well to have his bowels well opened and his stomach filled with suitable and nourishing food before embarking.

Some time ago certain European-American liners employed experts to investigate the biochemistry of seasickness, and their reports showed that associated with the condition was a change from the normal alkalinity of about $\text{pH} = 7.6$ of the blood towards an acidosis. From this it would appear that a useful precaution would be to swallow a solution of gr. 4 of sodium bicarbonate to 4 pints of water *ad lib.* before sailing, and I have found this measure very useful by way of prophylaxis. The auditory meati may also be cleared of wax and firmly plugged with cotton-wool; this measure may very considerably alleviate the distress or even prevent the onset of the sickness.

With regard to drugs and medicaments, the less bulky, the better. Bromides or triple bromides may be of value, if used from the commencement of the voyage. One-drop doses of pure chloroform in iced water are of more value. Chloretone, cocaine, and adrenalin together are of value, and may be combined in such a prescription as the following:—

R		
Chloretone	gr.	xx.
Cocaine hydrochloridi	gr.	xx.
Sol. adrenalin hydrochloridi	m.	xx.
Syrupi simplicis	dr.	i.
Aquam ad	oz.	i.

Two or three minims of the mixture in a teaspoonful of iced water every half hour; repeated five or six times, as necessary.

Camphor and belladonna are also useful. They may be prescribed as follows:—

R		
Camphor monobromata	gr.	xxv.
Tinct. belladonnæ	m.	xx.
Tinct. gelsemii	dr.	$\frac{1}{2}$.
Syrupi simplicis	dr.	i.
Aquam ad.	oz.	i.

Dose; one drachm every half hour, repeated five or six times as necessary.

Belladonna may also be combined with adrenalin, as in the following prescription:—

R		
Tinct. belladonnæ	m.	xx.
Sol adrenalin chloridi	m.	xx.
Aqua laurocerasi	dr.	ii.
Aquam destillata ad	oz.	i.

One-drachm dose every half hour, repeated five or six times if necessary.

For very obstinate cases, where other remedies fail, morphia may be combined with atropine and dilute hydrocyanic acid as follows:—

R		
Acidi hydrocyanici dil.	m.	v.
Liq. atropini sulph.	m.	v.
Liq. morphinæ sulph.	dr.	i.
Syrupi	dr.	ii.
Aquam destillata ad	oz.	i.

A little less than a teaspoonful every half hour, repeated six to eight times as necessary.

On long voyages these or similar prescriptions may be followed in turn, allowing an interval of some four or six hours in between.

Hypodermic injections of morphia and atropine have given good results, but morphia may make the patient worse instead of better. B. W. & Co.'s Tabloid morphine sulphate gr. $\frac{1}{4}$ with atropine sulphate gr. $\frac{1}{150}$ given hypodermically has given excellent results in my hands, even in severe and obstinate cases. In pregnant women it should be used in half doses and repeated when necessary.

"Vasano," introduced by Schering & Co., seems to be efficacious in a certain number of cases; and the same is the case with "Medinal"—a hypnotic—and chloretone as a sedative.

In severe cases with choleraic symptoms and severe diarrhoea, tinct. chloroform et morphinæ co. in 5-minim doses, repeated every hour for four or five doses yields excellent results. Intravenous saline transfusions may have to be resorted to, and give good results. These cases should be segregated, for they may be border-line ones, or even cases of true cholera, and therefore important from the point of view of port quarantine. I have seen such cases treated on board ship and recover; others sent ashore to hospitals on land; others die. On three occasions I have been able to send specimens of stools from such cases for bacteriological examination, but in all three no cholera vibrios were found. On the other hand the possibility of such cases being ones of true cholera should never be ignored.

The ætiology and treatment of aeroplane sickness are presumably identical with those of seasickness. This is one of the newer problems awaiting investigation by the medical profession.

OBSERVATIONS ON THE EXCRETION OF ALCOHOL IN THE CEREBRO- SPINAL FLUID AND URINE AFTER ORAL ADMINISTRATION.

By B. G. VAD, M.D.,

and

N. W. KULKARNI, M.B., B.S.,

Sir J. J. Hospital, Bombay.

A PATIENT was picked up by the police and brought to the J. J. Hospital, Bombay, in an unconscious condition. No history was available and except for the smell of alcohol in his breath, a complete clinical and laboratory investigation revealed nothing to account for the coma. The diagnosis of alcoholic coma suggested itself, and on examination of the cerebro-spinal fluid alcohol was detected in it. But it was ascertained later that about half an hour before examination and lumbar puncture, the patient had been given an ounce of rum; and the question arose whether that ounce of rum could account for the presence of alcohol in the cerebro-spinal fluid within half an hour. According to Purves Stewart, with the possible exception of a positive reaction for alcohol in the cerebro-spinal fluid, there was no single clinical sign which is pathognomonic of alcohol poisoning of the central nervous system, etc. (*British Medical Journal*, January 17th, 1925, p. 113) and hence one would not have expected to find alcohol in the cerebro-spinal fluid within half an hour after taking only one ounce of rum.

In order to find out whether alcohol can be detected in the cerebro-spinal fluid, with or without any signs of drunkenness, within half an hour or less after taking only an ounce or less of rum, the following experiments were carried out. We selected our volunteers from the medical students and patients of this hospital. Amongst them were total abstainers, moderate and heavy drinkers. As shown in Table I, these persons were given various quantities of rum and the cerebro-spinal fluid taken at varying intervals from the different subjects by lumbar puncture, and examined for the presence of alcohol. Before taking the cerebro-spinal fluid, all the usual tests for drunkenness, such as making the patient walk on a straight line, making him write to dictation, and do arithmetical calculations, etc., were carried out and in none of them could they be elicited. A rise in blood pressure and an increase in pulse rate were detected in all cases.

In all these cases the urine was also examined for the presence of alcohol at different intervals (Table I).

Having found that after the administration of even a drachm of rum by the mouth on the empty stomach, alcohol could always be detected in the cerebro-spinal fluid and urine within half an hour in total abstainers, we decided to find out whether alcohol can be detected in the cerebro-spinal fluid and urine after oral

administration of the B. P. tinctures. In these cases the following stock mixture was given in varying quantities, *Mistura Sodæ et Calumbæ*:-

R

Sodii Bicarbonas	..	grs. xx.
Spiritus Ammonizæ Aromaticus	..	m. xv.
Tinctura Nucis Vomizæ	..	m. v.
Tinctura Calumbæ	..	5ss.
Aqua Chloroformi	..	5i.
M. Ft. Mist.

Varying quantities of this mixture were given to the persons and the results obtained are shown in Table II.

The simple and easy test for the detection of alcohol in cerebro-spinal fluid and urine is the potassium bichromate test, which can be carried out anywhere. The only substance present in the normal cerebro-spinal fluid which may give a positive bichromate test is glucose, but in a number of cerebro-spinal fluids examined by us from various types of cases, including some of diabetes mellitus, the bichromate test was found to be negative in all cases, though the glucose percentage detected in some cases was up to 0.08 per cent. We therefore carried out a series of observations and found that glucose in the cerebro-spinal fluid will not give a positive bichromate test, unless it amounts to more than 0.16 per cent., a concentration which may sometimes be present in an extreme case of diabetic coma, which however, could never be mistaken for alcoholic coma or anything else.

Conclusions.

Alcohol can always be detected in the cerebro-spinal fluid and urine within half an hour of the administration of even a drachm of rum by the mouth on an empty stomach and in a total abstainer.

Alcohol takes a longer time for its appearance in the cerebro-spinal fluid if administered after food.

Alcohol can be detected in the cerebro-spinal fluid and urine earlier in total abstainers and when taken on an empty stomach; the habitual drinker requires a longer period and a larger quantity for excretion and detection of alcohol in the cerebro-spinal fluid and urine.

Alcohol can be found in the cerebro-spinal fluid of a person before he shows any signs of drunkenness and loss of mental control.

Glucose in the cerebro-spinal fluid is never present in a concentration sufficient to give a positive bichromate test for all practical purposes.

In view of these findings we entirely agree that as regards the tests for drunkenness and their applications, we find ourselves in the position of "as you were."

We are obliged to Colonel Vazifdar, Superintendent and Senior Physician, Sir J. J. Hospital, for giving us all the facilities for this investigation.

LOCAL ANÆSTHESIA BY APOTHESINE IN GENERAL SURGERY.

By A. B. BANERJEE, M.B.,

Anæsthetist, Carmichael Medical College Hospitals, Calcutta.

THE extensive adoption of local anæsthesia in minor or major surgical operations speaks for itself. The help afforded by this is such that it is difficult to recall the position before this came into vogue, especially in chloroform, in patients at a high degree of risk.

The immense popularity of local anæsthesia can certainly be gauged from the great number of drugs which have lately cropped up for use.

In the following series of cases apothesine was the drug used.

The local effect of apothesine can very well be prolonged and augmented by the addition of suprarenal gland extract to the solution. The constriction of the local vessels produces a better, fairly prolonged and intensified analgesia (evidently by apothesine acting on the local nerves in concentration). This also obviates the necessity for a large amount of the anæsthetic.

For the success of any local analgesic, it is essential to keep in mind the osmotic tension of the solution. Any solution approximating to the normal physiological strength will produce painless swellings (whereas solutions of higher concentrations are apt to produce irritation or even local death). The non-isotonic fluid is not only likely to cause local irritation but has at times been known to have considerably delayed the process of healing. The solution in our series was made in normal saline.

Apothesine—a synthetic product, is the hydrochloride of gamma-diethyl-amino-propyl-cinnamate (P. D. & Co.). This substance occurs in small white crystals and is very soluble in water. It will keep for a reasonably long time if there is no contamination. The solution is quite easily made and can be sterilised by boiling.

Solutions of a strength varying between $\frac{1}{2}$ to 1 per cent. have been used, but we found that one of 1 per cent. gives invariably admirable results. Two minims of adrenalin solution (1 in 1000) is added per ounce of the cooled sterile solution.

Encouraged by the work of Braun, adrenalin was made use of with fair impunity. With regard to the sterilisation of adrenalin solution there is one fact worthy of note. Adrenalin solution loses its efficacy if boiled in contact with an alkali, but it maintains its strength in association with a trace of hydrochloric acid.

There are some controversial points with regard to the use of adrenalin in the solution. Firstly a fairly large amount of adrenalin might produce a severe local constriction and thereby cause terrible after-pains and reactionary hæmorrhage. The second and the important remote effect is due to the toxicity of a large quantity of adrenalin being in the systemic circulation. This can be got over by using a small quantity only. Such a solution however will call for most careful technique in infiltration.

In all our operations either the infiltration or the regional method, or a judicious combination of both, was made use of.

MATERIAL AND TECHNIQUE.

The solution used must be prepared by the anæsthetist himself and it should be sterile, and as far as possible isotonic. The most convenient method is to dissolve the tablets (the synthetic suprarenin contained in these do not deteriorate in quality on boiling) in a glass beaker or a porcelain pot from which it can be drawn directly into the syringe. By boiling the tablet in a small amount of saline and then adding more till the proper amount is reached, the cooling takes very little time. The "Record" syringe has proved perfectly satisfactory for our purposes. Lately we have taken to using a local anæsthetic syringe with a bayonet catch for the needle.

The needle and syringes are to be boiled before use in plain water. For raising the small anæsthetic wheals in the skin a fine, short needle is used, whereas for deeper injections a longer and stouter needle with short bevel is best (2 to 4 inches in length). Non-breakable needles are very satisfactory. Needles must fit their syringes absolutely without leak.

A preliminary hypodermic injection of narcotics (morphine sulphate $\frac{1}{4}$ gr. with atropine sulphate 1/100 gr.) aids materially in the success of the anæsthesia by lessening the psychical stimuli in a fully conscious patient—a form of anoci-association. The visual stimuli are prevented by covering up the eyes.

It is a notable fact that in cases of perfect anæsthesia, the patient enquires at the end of the operation how much longer the operation is going to last.

Patients are prepared for operation in the usual way.

The following comprises the total number of operations done with 1 per cent. solution of apothesine with 2 minims of adrenalin solution per ounce:—

(a) Hydrocele	34
(i) With skin excision	12
(ii) Without excision	22
(b) Scrotal tumour	2
(c) Inguinal hernia	14
Strangulated hernia	13
(d) Abdominal operations	9
(i) T. B. mesenteric glands	3
(ii) Appendicular abscess	3
(iii) Internal strangulation by Meckel's diverticulum	1
(iv) Kink of small intestine	1
(v) Gastrotomy	3
(vi) Colostomy	2
(e) Cysts	66
(i) Sebaceous	29
(ii) Thyroid	3
(iii) Dermoid	30
(iv) Ovarian	1
(v) Dentigerous	3
(f) Other tumours	
Epithelioma of back	2
(g) Tracheotomy	21
(h) Rib resection	2

It is not possible to give a detailed description of the technique for different operations in a short paper. A few typical examples are given, indicating thereby the underlying principles. The technique varies according to the local anatomy, particularly the nerve distribution, without a thorough knowledge of which local anaesthesia cannot be successfully practised.

Although the preliminary administration of the narcotic makes the patient less receptive to external stimuli, yet it does not exempt the surgeon from being less vigilant in his task. Unless the surgeon is a person of cool temperament, calm judgment, and has a gentle but careful touch he is certain to fail in doing operations by this method, because tissues under local anaesthesia will stand cutting but will resent bruising or tearing. There should be perfect silence in the theatre, clanking of instruments should be carefully avoided.

Scrotal hydrocele.—The operation is performed thus. If the skin is not to be excised, a point is selected along the proposed line of incision and the needle is pushed in to the subcutaneous strata. Either the infiltration is then done, as the needle is gradually pushed in, or the same process is performed while drawing out the needle along the track through which it was inserted. The same process is repeated with the subfascial layer as well. The amount of solution necessary to do both these is about 2 c.c. (of the 1 per cent. apothesine-adrenalin solution).

When in the course of the operation the external tunic of the sac is reached, a few minims of the anaesthetic solution sprinkled on it acts admirably for further incision and eversion of the sac. Of the 34 cases operated on, 4 complained of a sense of tightness and oppression in the chest, preceded by lancinating pains up to the loins from the testes. The sensation complained of was sometimes so acute that stimulants were needed to rally them.

When the skin is to be excised, circum-injection is performed round the base of the scrotum; through the infiltrated area a vertical thrust is made into the cord; the veins are avoided by pulling up the piston before the solution is injected. The scrotal nerves are similarly infiltrated. The anaesthesia is completed by infiltration of the attachment of the gubernaculum.

A few of these cases showed oedema of the penis due to some extravasated fluid (within 24 hours), but they all showed absorption in 4 to 5 days time.

Only one case vomited at the close of the operation. *Superficial tumours* in any part of the body are treated in a similar way. The tumour itself is never touched by the needle. The lines of infiltration are made to appear like a rhombus within which the tumour lies; though the base of the tumour is infiltrated.

For *tracheotomy* the subcutaneous infiltration is easily carried out with a single puncture.

Amputations of toes, fingers or digits can be done by infiltration (subcutaneous) at the base of the terminal phalanx of the toe concerned. Two points are selected, one on either fold of the finger or the toe, and the solution is injected on either subcutaneous surface of the limb through these points.

Inguinal hernia are best operated on in the following way, especially if they are not very large or very complicated by firm adhesions. The blocking of the ilio-inguinal, ilio-hypogastric and the external spermatic nerves is the keystone to success. It is necessary to make two skin punctures; the first is made about $1\frac{1}{2}$ inches internal to the anterior superior iliac spine of the ilium. The needle is pushed in at right angles to the surface, piercing the aponeurosis of the external oblique muscle and muscle fibres of the internal oblique and transversalis, the solution being injected on the way in and on the way out. The needle is then re-inserted more obliquely towards the ilium and pushed on till it strikes the bone, injections being made continuously again while it enters and leaves. A third injection is made from the same puncture downwards towards the symphysis. This injection should reach below the aponeurosis of the external oblique. The external puncture is made at the external inguinal ring. From this point an injection is made along the inguinal canal. From both the punctures subcutaneous infiltrations are made at each side of the line of incision. When the hernia is irreducible, subcutaneous infiltration of the scrotum is also needed.

For *resecting a rib* four points of injection are employed, two over the intercostal space above and two over that below the rib. The points are so chosen that when injection is made through them, the portion of rib to be resected lies entirely within the area rendered insensitive.

After incising the skin wheals, the needle is pushed in vertically to the skin and injection is made between and into the intercostal muscle. When this is done the needle is withdrawn, but not completely, and is then directed so as to inject the soft tissues overlying the rib itself and the rib above and below it. About 14 c.c. are needed for resecting one rib.

For such an operation as that of *gastrostomy*, anaesthesia of the abdominal wall can be secured by local injection. Two punctures are made in the epigastrium, the higher one being close to the apex of the costal arch on the left side, and the lower at the lowest point of the line of incision to be made. The needle is pushed in vertically till it almost reaches the peritoneum. It is slightly withdrawn and is pushed more or less obliquely downwards several times, the injections being continued throughout the whole process. The same procedure is repeated several times from the lower puncture, the needle being obliquely directed upwards.

Since in this series there has been no occasion to perform splanchnic analgesia, any remarks regarding it are withheld.

The field or operations under local analgesia has been steadily and gradually increasing. The general practitioner of average class can perform the simpler operations with perfect safety, even in a very remote *moftusil* place.

I beg to record my indebtedness to the surgeons of the Carmichael Medical College Hospitals where these operations were performed, for their kind encouragement in my work and permission to publish the results.

SOME CASES OF *BACILLUS COLI* BACILLURIA.

By C. H. REINHOLD, F.R.C.S. (Edin.),

LIEUTENANT-COLONEL, I.M.S.,

Civil Surgeon, Delhi,

and

L. A. N. GREENWAY, M.R.C.S., L.R.C.P.,

House Surgeon, Hindu Rao Hospital, Delhi.

DURING the past year we have had seven cases of *Bacillus coli* bacilluria (which have been proved to be such by laboratory tests) pass through our hands, varying in degree from an ambulatory type to the most serious illness, which in one case terminated fatally.

The patients were all females and the age varied from infancy (18 months) through childhood (12 years) to mature middle age. One of the adults was unmarried and two were childless wives. They occurred at all seasons of the year.

Taking them in order of severity, the lightest cases first:—

Case No. 1.—Mrs. D., aged 35, no children, complaining of feeling run down with frequency of micturition and pain over the bladder. The urine was strongly acid and showed a pure culture of *B. coli*, and a course of alkalies and autogenous vaccine produced a complete cure, without confinement to bed, in six weeks.

Case No. 2.—Mrs. F. M., aged 24, never pregnant, had had bouts of fever elsewhere and troublesome frequency of micturition for over a year. When she came into our hands, she had a urine of high acidity and a pure culture of *B. coli* was isolated; a course of alkalies and autogenous *B. coli* vaccine rapidly relieved the symptoms and her general health, and a troublesome rash on the face was quickly relieved; though *B. coli* was still isolated from the urine long after her health was quite restored. In this case too there was no occasion to put the patient to bed.

Case No. 3.—Miss C., aged 30, was admitted on 7th January, 1929, on the 7th day of a fever, which had proved not to be malaria and sterile in bile salt culture for the typhoid group. On the 9th day *B. coli* was isolated from a catheter specimen of the urine and rapid defervescence followed alkalization of the urine and a morning draught of grs. xxx urotropine; she left hospital in a week as she was sailing shortly for England.

Case No. 4.—Margaret B., aged 18 months, was admitted on 28th March, 1929, after 5 days' illness and fever. Blood culture and the Widal test were negative, but *B. coli* was isolated from a catheter specimen of urine on the 30th. She remained very ill for 12 days and was much exhausted from lack of sleep; the fever

began to intermit on the 9th day and finally stopped by crisis on the 13th. Alkalization of a very acid urine by potassium salts apparently was responsible for the

CASE 3.
Name... Phyllis C.
Age... 30 years.
Date of Admission. 7.1.29.

cure in this case, though a vaccine was started later and continued for 5 doses at 5 days' interval.

Case No. 5.—Mrs. P., aged 40 (4 children, youngest 6 years) was admitted to the Hindu Rao Hospital on 29th September, 1928, on the 8th day of fever. The blood culture was sterile and no malarial parasites were found. She had definite swelling and tenderness of the right kidney and the urine which was highly acid was loaded with pus. *B. coli* was isolated and an autogenous vaccine made. There was a polymorphonuclear leucocytosis which rose as high as 22,500, but alkalization and urotropine brought relief and defervescence at the end of fortnight from the beginning of the illness, and this was consolidated by a course of her own vaccine. She left hospital on 22nd October, 1928, and has remained well since. This was, in our opinion, a case of *B. coli* pyelonephritis, but probably due to an ascending infection from the bladder.

Case No. 6.—Mary P., aged 12, was admitted to the Hindu Rao Hospital on 15th June, 1928, after a week's fever at school in Dehra Dun. She caught a chill after getting soaked in the rain. She looked very ill, had abdominal pain and distension and a coated tongue. The early physical signs suggested pneumonia but these rapidly cleared up in two or three days, but the abdominal distension still continued with high fever and a rapid pulse. No malarial parasites were found and the Widal reaction was negative on the 25th, i.e., *B. typhosus* 1 : 40 +, 1 : 80 ±, Para A neg., Para B neg. Albumin was found in the urine which was scanty and highly acid and showed *B. coli*. This was grown in pure culture from a catheter specimen on the 27th. Urotropine was given and the temperature gradually fell when the urine was alkalinized with potassium salts; the child being discharged cured on 15th July, 1928, and has since remained well.

Case No. 7.—Mrs. W., aged 30 (one child, 18 months), was admitted on the 9th day of a fever on 29th April, 1929. The Widal reaction was negative and the blood

the urine on 2nd May, 1929, and a stock vaccine was started in anticipation of an autogenous one. Difficulty of micturition was a marked feature and enormous quantities of urine were drawn off with the catheter. Alkalinization of the urine was difficult to accomplish as

is that it starts as a *B. coli* cystitis, and may ascend the ureter causing a pyelonephritis as in Case No. 5, or cause a general systemic infection.

Case 6. Name... Mary Age... 12 years. Date of Admission. 15.6.28.

Case 7. Name... Mrs. E. RAW. Age... 30 years. Adm. 29.4.29.

vomiting was very troublesome and it was urgently necessary to support the heart with stimulants. She never showed any signs of reacting to treatment, and passing into a typhoid state with Cheyne-Stokes' respiration, died on 9th May, 1929.

In all the five cases admitted to the Hindu Rao Hospital, the typhoid group of fevers was suggested as the diagnosis at the start, but the high pulse-temperature ratio led us early to look elsewhere for a cause; the tongue too never had the typical features of clean tip and edges. A gratifying improvement in symptoms accompanied alkalinization of the urine in all cases except the fatal one; we are not satisfied that urinary anti-septics were contributory to the cure, but believe that the *B. coli* vaccine helped to consolidate it. The limitation of the cases to females which has been remarked by all observers, has obviously an anatomical explanation. The two cases in mothers were not connected with recent pregnancies.

Our view of the pathology of the condition

A Mirror of Hospital Practice.

RETENTION OF URINE IN BLACK-WATER FEVER.

By S. C. NAG,

In-Charge, Barbheel Tea Estate Hospital,
P. O. Bargang, Assam.

SUPPRESSION of urine has been seen in black-water fever by many of those who have observed a large number of blackwater fever cases, but retention of urine, as far as I know, has not been mentioned in text-books, nor has it been recorded by any observer; the subject will, therefore, be of interest to many, I believe. From my little experience I have found that retention of urine does at times occur in cases of blackwater fever that are treated with plenty of fluids, and I believe that if a case of

blackwater fever, in spite of ingestion of proper fluids, will not pass urine, a soft catheter should be passed. I have met with five cases in my experience of about 36 cases of blackwater fever in which there was retention of urine.

Case No. 1.—Wife of an Indian doctor, aged 30 years, with a history of periodical attacks of malarial fever. On December 23rd, 1914, she had fever with severe rigor and vomiting and passed some black-coloured urine. She was slightly anæmic and her spleen was enlarged, she became intensely jaundiced and had persistent uncontrollable vomiting. The urine was of syrupy consistence. From the 2nd day of illness the patient had occasional convulsions and was occasionally semi-conscious. From the 4th day the patient complained of pain in the loins and in the bladder. On the 4th day she fell into a state of coma and on the 6th day she became delirious. She passed no urine on the 5th and the 6th day in spite of saline given subcutaneously and per rectum. A soft catheter was passed *per urethram* twice daily for 2 days and each time a large quantity of brown urine was let out. The hæmoglobinuria persisted 5 days and the post-hæmoglobinuric fever lasted till the 12th day. The patient was cured.

Case No. 2.—A labourer of a tea estate, male, aged about 35 years, with a history of several antecedent attacks of malarial fever. On August 6th, 1915, he exhibited fever preceded by rigor, was very sick, looked slightly jaundiced, his spleen was enlarged and tender, he was therefore admitted into hospital for observation. Next day, at about 3 p.m., he passed about 3 ounces of dark brown urine and after a couple of hours he again passed the same quantity of dark coloured urine which was rather thicker than normal. The following day the urine was very dark and so was the stool—as if mixed with blood. Vomiting continued and there was hicough and retching. The next day jaundice became intense, the patient complained of giddiness and thirst and in the afternoon, delirium and semi-consciousness had set in with retention of urine which continued next day. As the patient did not pass urine, notwithstanding plenty of saline fluid given subcutaneously and *per rectum*, and other fluids orally during consciousness, there was no shadow of doubt that the urine was retained. A rubber catheter was therefore passed and a large quantity of high coloured urine was let out twice in 24 hours. The patient was discharged cured after a stay of 29 days in hospital, during the first 8 days of which period the patient's temperature rose and fell every day.

Case No. 3.—Boy of 5 years of age, the writer's 3rd son, extremely susceptible to quinine, having a history of several attacks of malaria and four preceding attacks of blackwater fever during the past 7 months. In December 1922, the boy was getting fever, his spleen became enlarged and malaria parasites were found in the blood. A dose of $1\frac{1}{2}$ gr. quinine hydrochloride was given and within the next few hours, with slight rise of temperature, the colour of the urine became almost black. The following morning the temperature fell but the boy became intensely jaundiced and looked distinctly anæmic. The urine was lighter in colour but not without a trace of hæmoglobin. Pain in the loins and epigastrium was complained of and there was vomiting. In the evening of the 2nd day fever rose again and, in spite of the usual fluid treatment, there was no urine for about 11 hours for which a small rubber catheter was passed and 2 ounces of hæmoglobinous urine was evacuated. From the 4th day there was no fever and the urine became clear leaving the boy in a state of extreme anæmia. (Five months after this the boy was again attacked with blackwater fever for the 6th time. Retention of urine occurred only during the 5th attack.)

Case No. 4.—A labourer of a tea estate, male, about 34 years old, was brought to hospital on January 9th, 1928, in a bad condition after over 24 hours suffering from blackwater fever. One hour after admission the patient passed a few ounces of chocolate coloured urine and about one hour after this he again passed a similar

quantity. He vomited bile shortly after admission and there was intense jaundice. Sodii bicarb. was given with plenty of fluid by the mouth; saline was given *per rectum* and subcutaneously and caffeine sodii benzoate hypodermically. The next day the patient passed no urine from morning to evening in spite of repetition of the above treatment and the patient's effort to micturate. A rubber catheter was passed and about a pint of dark coloured urine was evacuated. Eight hours after this the bladder again seemed full, but no urine was passed in spite of the patient's straining effort. A catheter was again passed and a large quantity of dark brown urine was let out. A few hours after this the catheter was again passed, as the urine was not passed naturally, and this time too urine came out, but the patient died from syncope the next day.

Case No. 5.—A man, about 38 years old, labourer on a tea estate. History of several antecedent attacks of malignant malaria. Admitted to hospital with blackwater fever on 18th January, 1928. Passed urine three times in eight hours—scanty and inky urine. The usual saline was given rectally and into the cellular tissue, caffeine sodii benzoate hypodermically and sodii bicarb. orally. The next day the patient became drowsy and passed no urine naturally. Brown urine was let out by catheterisation twice in 24 hours. The patient was discharged cured after a stay of 11 days in hospital.

Regarding the cause of retention of urine, the writer is in opinion that the condition is due either to the debris of the residual urine blocking the posterior end of the urethra, or to the atony of the bladder caused by the exhausting disease.

Conclusion.—While suppression of urine is likely to occur in a case of blackwater fever when sufficient fluid is not given, retention of urine is not uncommon when, during the course of the disease, a large amount of fluid is given and the patient is exhausted.

A CASE OF ACCIDENTAL POISONING WITH BARIUM SULPHIDE.

By BHUPAL SINGH, B.A., M.B.,
Meerut.

B. L., Hindu male, aged 55 years, took about $1\frac{1}{2}$ drachms of a depilatory powder (containing 1 part barium sulphide and 8 parts washing earth, or *bolni mitti*) mistaking it for a laxative powder which he used to take as a home remedy, at 4 a.m. on April 14th, 1929. Vomiting commenced soon after and was persistent; he had 3 motions in the course of the next 4 hours. At 10 a.m. he noticed difficulty in lifting the arms and extending the legs and could not close the fist tightly.

I saw him at 5 p.m. on the same day: his condition was as follows:—

Tongue coated and dry.

Pulse slow, full and intermittent.

Heart sounds, booming—second aortic sound markedly accentuated—intermittent—missing a beat after every 5 or 6 beats.

Blood pressure, systolic—210;
diastolic—120.

Paralysis of arms and legs—grip very weak, the forearm could be flexed with much difficulty but could not be extended at all. If the arm was lifted up it would fall down with the elbow flexed. The legs could be drawn up with some difficulty, but could not be extended.

Deep reflexes absent.

No sensory disturbance.

Brain absolutely clear.

He was given magnesium sulphate 3i in solution every 2 hours and he took altogether 6 doses. He had 5 thin watery motions in the night.

About 6 a.m. next day he felt as if the power of his limbs had suddenly returned. Just to try it he got up and walked about and moved his arms fully in all directions and his grip became normal. Since then he has been perfectly normal.

The chief point of interest in the case is the transitory nature of the paresis induced and sudden complete recovery of power after about 20 hours.

CEREBRAL SYMPTOMS CAUSED BY *PLASMODIUM VIVAX*.

By C. R. DAS GUPTA, M.B.,

Ancillary Kala-azar Inquiry, Indian Research Fund Association, School of Tropical Medicine, Calcutta.

WHILE attending the village treatment centre at Kaurapukur on Wednesday, the 29th May, I was asked to see a patient, a relative of one of the workers at the dispensary, at his residence, a little way off. I was told that the patient had been suffering from fever since the previous Monday—the fever having started with ague. I was also told that the patient had been very restless and apathetic since morning.

The patient was a thinly built boy of 12 or 13 years.

Temperature, about 104°F. Pulse, 130 p.m. Respiration, 30 p.m.

Lungs, clear. Heart sounds, normal.

Tongue, coated but moist. Bowels, constipated.

Urine, said to be clear and sufficient in quantity.

The patient complained of an indefinite pain in the region of the head.

Treatment advised—

Saturated solution of magnesium

sulphate 5p, statim.

Mist. cinchona febrifuge . . . 5p, b.d.

Sponging and ice to the head.

There being no slides with me, blood could not be taken at that time. The relative of the patient came to me at 7 p.m. and informed me that the patient had been in a comatose state since 12 o'clock. No medicine was given to him and consequently his bowels had not moved at that time.

Examination at 8 p.m. The patient was unconscious and restless.

Temperature, about 100°F. Pulse, 110 p.m.

Respiration, 25 p.m. Reflexes, normal.

Blood taken for malarial parasites.

Treatment given—

Glycerine enema with good reaction.

5 grs. quinine bi-hydrobromide in 10 c.c. of normal saline, intravenously.

Icebag to the head was continued.

Next morning I was informed that the patient had regained consciousness in about half an hour from the time of injection and had been quite well since then. The place being a long way off, I could not go to see the patient on the next morning and I advised

him to continue the mist. quinine sulph. 5p, b.d., after a dose of magnesium sulphate. Since then the patient has been taking the quinine mixture regularly and has had no recurrence of the fever, or any other symptom.

While examining the blood smear I was astonished to find benign tertian parasites only—a fair number of growing trophozoites and scanty rings and gametocytes—in two thin films searched very thoroughly. I at once brought this to the notice of my chief, Dr. L. E. Napier, who was also satisfied that there were benign tertian parasites only. I gave slides to Dr. B. M. Das Gupta, Assistant Professor of Protozoology at the School to be examined; he reported as follows: "the slide shows a fair number of benign tertian growing trophozoites, scanty gametocytes and a few distorted rings—probably benign tertian."

After this I enquired into the periodicity of the fever and I was told that the patient had an attack of fever on the Monday with ague which rose very high. The fever subsided late at night and he was free from fever the whole of the next day. He got a second attack in the early hours of the Wednesday morning with vomiting. It was at this time that the blood was taken.

The magical effect of quinine clearly shows that the cerebral symptoms were due to malaria, while the periodicity of the temperature together with the findings of the blood examination would go to show that the whole illness was the result of an infection by benign tertian parasites—though such a case has not been reported previously.

Knowing as I do that without examining a very large number of slides or taking a culture it is not at all safe to give a verdict on the nature of the malaria parasite present, still I consider the periodicity of the temperature is very suggestive of the symptoms being caused by benign tertian parasites only. The only other explanation, as suggested by Lt.-Col. R. Knowles, is that it was a case of mixed infection, the cerebral symptoms being caused by malignant tertian parasites which were confined mainly to the internal organs, but there being so few parasites present in the peripheral blood, it was not possible to find them by examining two slides only.

My thanks are due to my chief, Dr. L. E. Napier, for permitting me to publish this short note.

TEMPORARY INSANITY FOLLOWING AN ATTACK OF MALARIA.

By S. C. SEN GUPTA, L.M.F.,

Resident Medical Officer, Lakhipara Tea Estate, Banarhat P. O., Jalpaiguri.

A TEA garden coolie, Hindu male, aged about 38 years, was attacked with fever accompanied by rigors during the evening of 2nd

April 1928, while I was away in the line on duty on the morning of 3rd April. I saw the patient in the following condition:—

Fever, 100°F.; respiration, normal; pulse, 94 per minute; tongue, moist and coated; spleen, enlarged 2 fingers below costal margin; liver, not palpable; heart and lungs, normal; bowels, constipated for 2 days.

Previous history.—The man had suffered from occasional attacks of malaria for the last two years; no history of syphilis was available.

Personal habits.—The man was addicted to drinking and tobacco.

Family history.—His wife and children also suffer from malaria now and then.

The man is moderately healthy, not anæmic; he can work hard in the garden.

As his blood could not be examined, I made a clinical diagnosis of malaria.

I gave him a good dose of castor oil and then quinine mixture, t.d.s. (quinine sulph.—gr. v per dose). The man was relieved from fever and apparently well on 4th April. On 5th April he was well all day long. During the night he woke up suddenly at about 11-30 p.m., became boisterous and chased his sons and wife with a knife. Gradually he became more and more noisy. Nobody could either check him or approach him.

In the morning when I was called, I saw the patient tied to a post in a naked condition. His eyes were congested. He was very noisy, using abusive language to whomsoever approached him. It seemed to me that he had gone mad absolutely. On examining him I found the following condition:—

Fever, nil; pulse, comparatively rapid; respirations, a little hurried, spitting now and then; tongue, slightly coated and moist; pupils, dilated to some extent; spleen, as before enlarged.

No other abnormality could be detected. However, I tried to give a big dose of bromide mixture with tincture of hyocyamus, but the man was determined not to take it until I administered it by the help of a mouth gag and tongue forceps; there was no effect till 7th April.

On 8th April at about 9 a.m., when I saw the patient again I thought that the previous attack of malaria might be the cause of his trouble. I then gave 1½ ounces of magnesium sulphate and twenty grains of quinine sulphate in mixture form once only by the help of stomach tube.

During the evening of the same day he had 16 loose motions and became weak and quiet too.

Next morning (9th April) when I went to see him, to my utter surprise, I saw the patient perfectly calm and quiet, but he neither spoke nor replied to anybody.

Again I gave quinine mixture (quinine sulphate gr. xv) once only.

From 10th April he became all right, speaking well. When asked how he felt all these past days he told me that he could not remember anything, but felt very weak. He thought that some evil spirit might have attacked him during his sleep. Since then he is all right and working well.

A CASE OF STAPHYLOCOCCAL SEPTICÆMIA.

By HARENDRA NATH BAGCHI, M.B. (Cal.),

Assistant Surgeon, Calcutta Police Hospital.

R. S., Hindu male, aged 21, a male nurse of the Calcutta Police Hospital was admitted into hospital on 3rd September, 1928 for:—

Continued fever, headache and generalised pain all over the body; duration 2 or 3 days.

He gave a history of chill. The patient took to bed from the date of admission into hospital, being prostrated by fever, there was a perceptible spleen, but his liver was normal. His heart and lungs were also normal. He had faint rose spots, especially noticeable over the lower abdomen, which faded the next day. His tongue was clean and there were no sordes on the teeth. His gums were healthy and bowels constipated.

No malarial parasites were found and his white blood count was 7,000 per c.mm. From the 4th day onwards there was noticed a moderate degree of tympanites, though there used to be two loose motions a day. There was no delirium and the patient used to sleep well at night.

On the 4th day after admission into hospital the blood was sent for culture for bacteria and for leishmania, and the report was a pure growth of *Staphylococcus albus*. The patient was passing scanty, high-coloured urine which on examination showed specific gravity 1,030, acid, albumen present (marked trace), no sugar, bile present, a few granular casts. From the beginning of the second week of his illness the patient developed slight bronchial catarrh which lasted the whole of that week.

As the spleen remained palpable I did the antimony test for kala-azar which was negative.

On 20th September, 1928, I sent blood for culture again as well as for Widal reaction against T. A. B. and sent his stool for culture. The report again showed a growth of *Staphylococcus albus*, the Widal reaction was negative for T. A. B. and his stool culture result was a growth of *B. coli* and *B. lactis aerogenes capsulatus*.

The patient made an uneventful recovery.

Differential diagnosis.—Typhus fever, in favour in which are the following points: fairly abrupt onset, with a continued fever lasting about 2 weeks, followed by a rapid lysis of temperature, eruption of rose spots on 4th or 5th day about the abdomen and bronchial catarrh.

Against this diagnosis.—No lice were found on the patient, there was no moderate leucocytosis and blood culture showed a growth of *Staphylococcus albus*.

My thanks are due to Major B. G. Mallya, F.R.C.S. (Edin.), I.M.S., Police Surgeon, Calcutta, for kindly giving me necessary permission to publish this case in the journal.

A CASE FOR DIAGNOSIS.

By PRAFULLA KUMAR BACHASPATI, L.M.F.,

Joari Charitable Dispensary, Joari P. O., District Rajshahi, Bengal.

THE patient was a Mahomedan boy, aged about 5 years. He was of a dark complexion. His chief complaint was fever and a peculiar sound simulating the chirping of tiny birds inside the head, which could be heard and felt by the patient himself and his guardians.

The patient located the sound to be on both the temporal regions, occiput, and angle of the jaw, right side. Duration of his complaint was 2 months.

Past history.—No history of hereditary syphilis or rheumatism. The patient gives a history of occasional epistaxis.

Lungs—normal.

Heart—First sound at the apex seemed to be a little prolonged. Second sound at the pulmonary region was unduly accentuated. Aortic second sound was normal.

Pulse—rapid and of moderate tension.

Abdomen—Spleen 3 inches below the costal arch and of soft consistency. Liver 2 inches below the costal arch. No tenderness over the spleen or liver. No abnormal pulsation felt by hand or through auscultation over the abdomen.

Digestive system—Appetite good. Digestion good. Tongue—quite clean. Bowels—regular. He was anæmic to a great extent. Sense of hearing was good.

I put my ears over the angle of the jaw, right side, and over the entire head. I was astonished to hear the peculiar sound over the spots already noted above. These sounds disappeared on firm pressure over the angle of the jaw, right side. The sound was accentuated by the pressure of the stethoscope. I took the blood for the aldehyde test; it was positive for kala-azar. The patient would not submit to a course of intravenous treatment. Intramuscular injections of antimony with albolene and creo-campor were given. Intravenous injections were not possible, as the very sight of the needle made the patient jump.

(*Note.*—We have not been able to arrive at any conclusions with regard to the cause of the noises in the head. Perhaps some reader of the *Gazette* might be able to make some suggestions.—EDITOR, I. M. G.)

NOTES ON A CASE OF HUMAN HERMAPHRODITE.

By M. C. ALBUQUERQUE, L.R.C.P. (Lond.), M.R.C.S. (Eng.), L.M. (Rotunda),

Lady Medical Officer, Maternity Hospital, Bangalore, and

T. SESHACHALAM, L.R.C.P. (Lond.), M.R.C.S. (Eng.), Assistant Surgeon, Victoria Hospital, Bangalore.

A WOMAN, aged 27, presented herself at the Maternity Hospital, Bangalore, with the following history:—

When she was a child of five years two swellings, each of the size of a small cherry, were noticed in the groin by her parents. The swellings increased in size very gradually. She was married when about fifteen years of age. There is no history of menstruation. She lived with her husband for seven years, and during this period was having sexual intercourse and responded spontaneously. As she had no children the husband married again. Both the wives are now living with the husband. Within the last six years the swellings have very rapidly increased in size, and as they caused pain she sought medical advice.

The woman was well built. The feminine secondary sexual characteristics were very well developed, but curiously enough she had no shyness in speaking of sexual matters.

On examination two cystic swellings, one in each groin, of about the size of a lemon were found (Fig. 2). On palpation both the swellings were tender, irreducible, cystic in character and had no impulse on coughing. On vaginal examination it was found that the vaginal canal was about 4 inches long, and that neither the cervix nor the body of the uterus could be felt. Two roundish swellings each of the size of a small marble were felt, one on either side of the middle line in the pelvis. The clitoris was of normal size.

Operation.—With the provisional diagnosis of bilateral hydrocoele of the canals of Nuck an operation was performed. On making a longitudinal incision and separating the cysts from the surrounding structures,

Fig. 1.

it was found that there was a solid lump with a large cyst attached to its anterior aspect. Tracing these

Fig. 2.

further upwards there was a pedicle in the inguinal canal. The pedicles were ligatured, the cysts were removed and the incision sutured. The patient made an uninterrupted recovery.

The swellings measured 9 cms. in length and 19 cms. in circumference. The entire structure was fluctuating to the touch and there was a relatively soft solid structure behind. On sectioning one of the cysts in the sagittal plane, it was noticed that it was bilocular and that the two compartments were communicating at one place by a small aperture in the septum. The fluid contained in the cyst was clear. The wall of the cyst was highly vascular. The entire cyst could be easily peeled off from the solid portion (Fig. 3).

Fig. 3.

Microscopic Examination.—The material was fixed in 10 per cent. formalin and paraffin, sections of 10 μ thickness were cut and stained with Delafield's hæmatoxylin and eosin. The solid portion consisted of spermatid tubules, but spermatozoa were not present in the lumen. Degenerative changes of the tubule were evident. There was a relative increase in the connective tissue matrix.

The occurrence of true hermaphroditism in man is rare. The presence of well-marked mammae and the vagina are indicative of the feminine type, but the histological evidence revealed by the microscopic examination point to the masculine type. The case reported here is in all probability an instance of the combination of male and female characters, i.e., a true hermaphrodite. Unfortunately the patient did not consent to an abdominal section to find out whether the two rounded swellings inside the pelvis were ovarian in character. The presumption that they are ovarian in nature is justified by the well-marked secondary sexual characteristics and the periodic strong desire to mate.

We are very greatly indebted to Dr. A. Subba Rau, Professor of Physiology, Medical College, Bangalore, for the help given to us in the preparation of this paper.

A CASE OF ABSCESS OF THE IRIS.

By JADAVJI HANSRAJ, D.O.M.S. (Eng.), L.M. & S. (Bombay).

Consulting Ophthalmic Surgeon, Fateh Majzil, New Queens Road, Bombay.

An abscess of the iris is a very rare condition, so much so that one cannot find any description

of the condition in a text-book like Fuch's. It is the rarity of the condition which has induced me to publish the notes of a case which came to me in the out-door department of Ramwadi Free Eye Hospital.

A patient, aged 35 years, labourer by occupation, presented himself at the R. F. E. Hospital with pain and redness in the left eye. The only history he gave was of rubbing the eye with a coarse cloth six days before.

On examination there was marked ciliary injection, photophobia, and lacrimation in the affected eye; the ciliary injection was much more marked on the temporal side, i.e., on the side on which abscess was situated. The cornea was absolutely clear. The temporal half of the anterior chamber was occupied by an oval substance, yellowish white in colour, absolutely immovable either with the position of the patient or by pressure on the eyeball itself. The pupil, jet-black and elongated vertically, could only be seen on the nasal half, the temporal half and the portion of the iris peripheral to it being completely covered by the mass in the anterior chamber. The visible portion of the iris was slightly muddy, the crypts on its anterior surface being obliterated and the pattern of the iris lost. The tension of the eye was definitely above normal. The vision in this was finger-counting at one foot only; the other eye, of course, had full vision.

A diagnosis of dislocated lens in the anterior chamber was made. The points in favour of such a diagnosis were:—(1) the colour and appearance of the mass, (2) the shape and size of the mass, and (3) increased intra-ocular tension with signs and symptoms of secondary glaucoma.

Treatment.—An immediate operation was decided upon and the patient was prepared for operation. An incision was made in the outer half of the cornea so as to facilitate the delivery of the supposed dislocated lens. As soon as the anterior chamber was opened, along with a little aqueous humour muddy coloured pus began to ooze out and the protuberant mass in the anterior chamber, described above, began to disappear. On irrigating the anterior chamber, it was observed that pus was coming from an opening in the iris on the outer half. The outer layers of the iris were changed in colour so as to present quite a muddy colour and formed a thin capsule of the small sac which contained the pus. The eye was washed and bandaged.

After-treatment.—On the day of the operation 100 c.c. 1 per cent. solution of mercurochrome was injected intravenously. In the evening the patient had a rigor and the temperature went up a little, most probably due to reaction to mercurochrome. The eye was dressed as usual with atropine drops, and bandaged. Two more injections of mercurochrome were given on alternate days. The iris cleared entirely, but posterior synechia resulted. The patient regained vision up to finger counting at 4 feet and is improving gradually. Of course the pain and injection are gone. The patient is still under treatment.

Ætiology.—In this case there was no ectogenous infection as far as one could find. Endogenous infection was the only explanation one could put forward. It is quite probable that the focus of infection was in the root of some tooth or teeth, as the patient was suffering from a very bad type of pyorrhœa alveolaris.

The patient while rubbing the eye inflicted a certain amount of trauma to his iris and, the infection being there already in the blood vessels of the iris, an abscess started. Looking to the vascular nature of the iris one would have expected a mild form of iritis instead of a localized abscess, but very often the ways of nature are beyond our logic.

A CASE OF DIVERTICULUM OF THE ŒSOPHAGUS.

By C. D. TORPY, I.M.D.,

Military Assistant Surgeon, In-charge Radiological Department, British Military Hospital, Trimulgherry.

Boy M., aged 2 years, suffering from sore throat and dysphagia. Enlarged tonsils were found on

was then taken to Bombay where a diagnosis of "foreign body in the Œsophagus, possibly a fish bone" was made by radiological examination.

Symptoms continued to persist, and the child was then brought back to Secunderabad.

A skiagram was first recorded of the neck and upper chest, but there was no x-ray evidence of a foreign body. The patient was then given barium emulsion to swallow, and its passage through the Œsophagus was noted under the x-ray screen. An Œsophageal pouch,

Skiagram before barium meal.

examination. These were removed by the guillotine. The child } the size of a rupee, at the level of the upper Œsophagus
 Dysphagia still persisted even after operation. The child } was seen to fill and gradually to spill over from the

upper limit of the sac. The smooth roundness of its lower pole, and its symmetry proved it to be an oesophageal diverticulum. Another skiagram of the pouch was recorded.

tonsils as well, this naturally did not facilitate a correct diagnosis in the first instance.

(3) The diverticulum was not and could not have been diagnosed except with the aid of an opaque meal.

Skiagram after barium meal.

The points of interest are:—

- (1) Dysphagia was not noticed so long as the child was on liquid or semi-solid food. Symptoms were first noticed when the child was put on solid food.
- (2) The child was suffering from hypertrophied

My thanks are due to the Officer Commanding, the British Military Hospital, Trimulgherry, for his kind permission to publish these notes.

Indian Medical Gazette.

SEPTEMBER.

PREVENTABLE BLINDNESS IN INDIA.

INDIA is a land of blindness, much of which is preventable. The 1927 census for England and Wales shows that there were 119 blind persons per 100,000, the corresponding figure for India in 1921 being approximately 152—a marked increase on the figures for 1911, when recording was perhaps less accurate. The 1921 census for Madras Presidency shows a general figure of 153 blind per 100,000.

The proportion of blind among the general population in India compares with that in Great Britain as 152 : 119, but it is obvious that the relative, as well as the absolute, number of blind persons in India is greatly in excess of that in Great Britain.

A fact which emerges from the census returns is that blindness is essentially a disease of old age. The graph depicted in the 1921 census shows that the proportion of blind in

the population rises with succeeding age periods. This graph is here reproduced. At thirty years of age the proportion of blind is only about 117 per 100,000; at fifty years of age it has risen to a proportion of about 380 per 100,000; in old age it rises to a figure of some 900 per 100,000. Women suffer more than men, there being 1,047 blind women for every 1,000 blind men. Mr. J. T. Marten, I.C.S., talks of the dry, hot climate; small, dark, and ill-ventilated huts; dust—always an important element in the Indian atmosphere—

the long hours of Indian children at school without meals, the strain of child education in ill-lighted and ill-ventilated schools. The higher Indian castes are relatively free from blindness, but blacksmiths and durzies and those whose work compels them to work in close or smoky atmospheres are stated to have much more blindness than agricultural castes or jungle tribes. Further, cataract is the special foe of the old in India, whilst religious mendicants and professional beggars naturally show a very high proportion of blind. Dr. E. Jackson points out the cumulative action of all causes of blindness and the fact that minor ailments, insufficient to rank as blindness, starting early in life, come into operation later. He says, "blindness is the summing up of strain, injury and disease that has gone before." It is, however, that blindness which occurs in the first five years of life which forms the main nucleus of the total blind, and much of this is preventable. In western countries the most important cause operating in this period is ophthalmia neonatorum which is estimated to be responsible for 8 per cent. of the total blind. We do not suppose that gonorrhœa is less prevalent in India than in those countries, and, with India's customs of "dirty midwifery," ophthalmia neonatorum must play an important part in the causation of preventable blindness in this country.

The British figures show that of 46,822 blind persons in a population of 39,290,000, 258 were under five years of age, the Madras statistics that out of 37,162 blind persons in the presidency 768 were under five years of age. These comparative figures would appear to show that ophthalmia neonatorum is an even more important cause of preventable blindness in India than it is in Great Britain, but, as we shall see later, it does not necessarily rank first.

How much of the blindness in India is preventable? Until we have more information it is impossible to state, but the *Annual Report of the Government Ophthalmic Hospital for Madras* for the year 1928 by Lieut.-Col. R. E. Wright, I.M.S., the Superintendent, which has recently come to hand, and is reviewed on page 534 of this issue, contains some most interesting information with regard to the Madras Presidency and the hospital which he and his predecessors have raised to such a high pitch of efficiency and eminence.

Colonel Wright considers that the first step to take is to enquire into the cause of blindness during the first five years of life. And here keratomalacia stands out pre-eminent in the Madras Presidency, and is apparently more important than ophthalmia neonatorum. Large portions of the poorer people in the Madras Presidency are in what may be termed the "twilight zone" as far as their nutrition

Assurance Medical Directors and Actuarial Society of America.

Theoretical normal standards for vital capacity have been worked out on the basis of the standing height, body weight, body surface area, sitting or stem height, and chest circumference. It is now generally admitted that the standards according to body surface area and standing height are most constant, and therefore most reliable. In my observations, however, I compared the actual figures for vital capacity obtained in each individual with the normal theoretical standards, as given by Myers, according to *all* the different factors mentioned above, namely, standing height, body weight, body surface area, sitting height and chest circumference. In this way, one tried to find out what percentage of the normal theoretical vital capacity the actual figures obtained in each case represent.

The results showed that there is a close similarity between the percentages obtained from the standing height and surface area standards. This is as was to be expected. The other three standards, namely, sitting height, body weight and chest circumference showed marked variations. But no matter what standard is taken into consideration, one fact is perfectly obvious, namely, that the vital capacity of the lungs of this group of 100 Indians is much smaller than the normal standards given for Western people. A great majority of them have vital capacities between 70 and 90 per cent. of the normal, and the proportion of those with figures above 100 per cent. is very small, amounting to only 2 or 3 per cent., if reckoned according to the surface area or the standing height standards respectively.

Taking into consideration all the observations on these 100 normal subjects, it would appear that the average vital capacity of Indians is lower than that of Europeans, both in the total volume and in proportion to the body surface area. While the average vital capacity of Europeans is 3,500 cubic centimetres or over* and 2,500 cubic centimetres per square metre of body surface area, for Indians the figures are about 3,091 c.c. and 1,960 c.c., respectively.

The actual body weight of a large majority of these men was much below the theoretical normal standards as laid down for the Western people by the Association of Life Insurance Medical Directors and Actuarial Society of America.

The figures for vital capacity obtained by me correspond to a certain extent with those obtained by Foster and Hsieh for the Chinese.

A comparison of these figures for Americans, Chinese and Indians is given in the following table:—

	Vital capacity, per square metre body surface.	Vital capacity, height per centimetre.
Americans—Men	2.5 litres.	25.0 c.c.
Chinese—Men ..	2.0 litres.	19.0 c.c.
Indians—Men ..	1.96 litres.	18.52 c.c.

This clearly shows that there is a racial factor which markedly influences the vital capacity, and that it is definitely lower in the Indian and Chinese than in the Western people. There is a great need for further investigation. Normal standards for Indians should be

* Halliburton gives the vital capacity for the European as 3,500 to 4,000 cubic centimetres. If the figure be taken as 3,750 c.c. and the capacity per square metre as 2,500 c.c. (Major Bhatia's figure), then the average body surface area would be 1.5 square metres. But according to Major Bhatia's figures the average body surface area of Indians is 1.577 square metres, or greater than that of the European. This is, however, not a fact.—Ed., I. M. G.

worked out carefully, for the existing European and American standards are not applicable to us. Apart from its physiological importance, the subject is of great clinical significance.

Some of the applications of the vital capacity test in clinical medicine and surgery may be mentioned.

The vital capacity is reduced in the following conditions:—

(1) In a majority of persons suffering from old pleural adhesions resulting from pleurisy, pneumonia and empyema.

(2) In certain old standing deformities of the thorax and ossification of the costal cartilages and costo-vertebral joints.

(3) In disturbed functions of the intercostal muscles. In paralysis of the diaphragm, or interference in its action owing to great abdominal distension, especially of acute onset.

(4) In cardiac disease. This aspect of the question has been extensively studied in recent years. According to Levison, the vital capacity of cardiac patients runs roughly parallel to their dyspnoea. The reduction of vital capacity in cardiac disease is an important clue to prognosis, for it is said that the greater the reduction, the worse the prognosis. During failure of compensation in heart disease, the vital capacity is much diminished, but it increases as compensation is established. The test is also a valuable guide to treatment. It is an index of cardiac tolerance and has a close relationship with exercise tolerance in any given case.

(5) In hyperthyroidism. Here it corresponds with the tendency to dyspnoea. Robinowitch reports some cases showing that decreased vital capacity has a close relationship with increased basal metabolism in hyperthyroidism. It is believed that this reduction in vital capacity is due to cardiac involvement, and the greater the reduction the poorer the prognosis.

(6) In bronchial asthma, emphysema, bronchitis and pleurisy. Also in pneumothorax, both spontaneous and artificial, and hydrothorax.

(7) In pulmonary abscess, bronchiectasis and new growths in the thorax.

(8) In pneumonia *par excellence*. According to Myers there is no acute disease of the lungs which so reduces the vital capacity from the commencement of the illness as pneumonia. The reduction is maximum about the time of the crisis. Then with convalescence it steadily rises. If however any complications occur, e.g., abscess or empyema, this increase does not take place. Thus the test affords valuable evidence of the progress in this disease.

(9) In pulmonary tuberculosis. Hutchinson originally introduced the test as an aid in the diagnosis of pulmonary tuberculosis. From the very commencement of the illness there is a steady reduction in vital capacity. As the condition improves, vital capacity also increases. It is a valuable guide to treatment and prognosis. This test is largely employed in this disease and its value is well established. The work of Burrell and Dreyer in this connection is of special interest.

(10) Extensive thoracoplastic operations produce a marked reduction in the vital capacity. Hence it is necessary that before such an operation is attempted, the vital capacity should be measured. If it be already very low, only minimal surgery should be resorted to. Such a precaution is necessary before an open drainage is established for empyema, or a thoracoplastic operation performed for pulmonary tuberculosis. In carrying out artificial pneumothorax also for pulmonary tuberculosis, it is advisable to know the vital capacity beforehand, for if low, only a small quantity of air should be introduced into the pleural cavity.

These are some of the pathological conditions in which this test is serviceable. When taken together with history, clinical findings, x-rays and other aids to diagnosis, there is no doubt that it affords valuable help in judging the severity of the condition as well as the course and ultimate outlook of the case. As a test of physiological fitness in healthy people, it is useful chiefly in so far as the condition of heart and lungs is concerned.

The test should be employed oftener than it is at present. But it is obvious that it can be helpful only if there are reliable normal standards to go by. The existing standards for Europeans and Americans will not do for Indians. It is necessary that we should work out the normal standards for the inhabitants of this country. The study of 100 normal subjects described here is an attempt in that direction.

Current Topics.

Some Modern Aspects of Nephritis.

By W. LANGDON BROWN, M.A., M.D., F.R.C.P.

(Abstracted from *The Brit. Med. Journ.*, May 4th, 1929, p. 797.)

I SHALL adopt the following classification of nephritis, slightly modified from Aschoff:—

- (1) Degenerative Group.
 - (a) Acute. *Toxæmic Kidney*—such as that produced by drugs (for example, corrosive sublimate and carbolic acid) or by the toxæmias of pregnancy.
 - (b) Chronic. *Amyloid Kidney*.
- (2) Inflammatory Group.
 - (a) *Glomerulo-tubular*.
 - (i) Acute—ordinary acute nephritis.
 - (ii) Subacute—chronic parenchymatous nephritis; large white kidney.
 - (iii) Chronic—chronic mixed nephritis or contracting kidney.

It must be recognized that these may either follow one another in this order, or (ii) and (iii) may apparently arise independently of (i).

(b) *Focal Embolic Nephritis*—as seen in infective endocarditis, when the nephritis is set up by multiple emboli from the heart valves.

(c) *Chronic Interstitial Nephritis*—the small red or granular kidney.

(3) Vascular Group.

(a) *Hyperplastic*.

(b) *Senile or Athermatous*.

To my mind the position has only been made more difficult and obscured by Volhard's introduction of the term "nephrosis," which has by some writers been so extended as to include chronic parenchymatous nephritis. I consider this term should be limited to toxæmic kidney in which there are merely degenerative changes in the tubules without any inflammatory reaction. There is marked œdema, excess of cholesterol in the blood, and massive albuminuria, but there are no cardio-vascular changes or casts. The urea of the blood remains normal, as does the globulin, but its albumin content falls as the disease progresses. Nephrosis is part of a general toxæmia, and some observers claim that when it is experimentally produced the first protein to appear in the urine may be hepatic in origin. At the necropsy a large amount of cholesterol may be found in the kidney tubules, the so-called "myelin" kidneys. Death or complete recovery is the rule, but occasionally a toxæmic kidney may lead to chronic nephritis.

Of late the tendency has been towards a secretory rather than an anatomical classification. This is really an advantage since the anatomical basis can only be established after death when the opportunity for treatment is past.

Broadly speaking, the kidney may excrete two classes of substances: (1) those which can be of use to the body—water, salt, sugar, bile, hemoglobin; (2) those which are purely waste products—urea and allied nitrogenous substances. Against the excretion of the first group the kidney presents a threshold; it does not attempt to excrete them until their concentration in the blood reaches a certain height, for it would not do for such

substances to be drained out of the body. For the second group no such barrier is needed. The secretory classification is as follows:—

(1) *Hydræmic Nephritis* (which broadly corresponds to chronic parenchymatous nephritis).—Here the excretion of Class 1 is involved, particularly of water and salt. The output of urea may be normal, and there will not be any retention of it in the blood. Not so with chlorides, the content of which in the blood will be raised. Œdema may be very marked, but there will be little evidence of cardio-vascular change.

(2) *Azotæmic Nephritis*.—Here there is gross failure of the concentrating power of the kidney, and since the great work of the kidney in concentration is in relation to nitrogenous waste products, and as urea is the most abundant of these, we find not only a fall of urea in the urine, but a rise of it in the blood. There is a rise from the normal 20 to 40 mg. per cent. to 80, 100, or much more in severe cases. The cardio-vascular changes tend to be very marked.

(3) *Mixed Types*.—As interstitial changes, which are chiefly associated with azotæmia, proceed more slowly than the parenchymatous, which are chiefly associated with hydræmia, the former gradually alter the picture. A chronic parenchymatous nephritis either dies of intercurrent infections or passes into the contracted stage with interstitial changes; the œdema subsides, the blood pressure goes up, and the heart hypertrophies. Both sodium chloride and urea are retained in the blood. If there is both nitrogenous retention and renal œdema, the case must be a mixed one.

I shall next consider some clinical features and the treatment of three leading types of nephritis—the acute, the hydræmic, and the azotæmic.

ACUTE NEPHRITIS.

It is important to treat the cause of acute nephritis as soon as possible. The principal causes are:—

(1) *Acute Specific Fevers, such as Scarlet Fever*.—Recent observations show the great value of the administration of alkalis in scarlet fever as a prophylactic measure against the complication of acute nephritis.

(2) *Diseases of the Respiratory Tract*.—This applies particularly to the upper respiratory tract, especially the tonsils. I recently had a case of acute hæmorrhagic nephritis associated with an infected antrum, drainage of which was followed by rapid improvement. But Sir Thomas Horder has also called attention to the importance of extended sepsis as well as of focal sepsis. Thus a widespread infection of the bronchial tubes can lead to troubles similar to those due to a small collection of pent-up pus. This is particularly well seen in hyperpæsis and nephritis.

(3) *Diseases of the Skin*.—Since the skin is a part of the excretory apparatus, the association between diseases of the skin and of the kidney is not surprising. Extensive burns are well known to cause acute nephritis, though here extended sepsis is probably the chief factor. I have recently had two cases of scabies causing a staphylococcal infection of the skin, which were followed by acute nephritis. Here ultra-violet rays helped to clear up the skin very quickly, and the nephritis rapidly improved when this was achieved.

(4) *Purpura*.—Here presumably the purpura and the acute nephritis are both consequences of a common cause, but it is not infrequent for the nephritis to occur later than the purpura.

(5) *Epidemic Type*.—This is the type encountered during the war, of which I have written elsewhere. It is sufficient here to point out that dyspnoea was an early symptom, and that Shaw Dunn found multiple thromboses in the lungs. So perhaps this is really a special instance of (2), though presumably due to some unknown specific infection. According to Aschoff the renal lesion is a pure glomerulitis.

In the treatment of acute nephritis, I am strongly of opinion that the conventional milk diet is a mistake in the earliest stages. Far better results accrue from von Noorden's plan of giving nothing but fruit, fruit juice, sugar, and water. If there is much hunger, I generally allow toffee as well. The question of diuretics

will be dealt with under hydræmic nephritis. Later on, milk can be given and the conventional treatment followed. Sufficient alkalis to render the urine alkaline seems a wise measure, and it is well to keep the patient in bed until the centrifugalized urine shows no red blood corpuscles on microscopic examination.

HYDRÆMIC NEPHRITIS.

There has been much controversy as to the cause of the dropsy which is the outstanding feature of this type. Vidal attributed it to the retention of sodium chloride, but the results of a salt-free diet have been disappointing. Moreover, as Izod Bennett points out, "the same kidneys which at first secreted a urine poor in chlorides will, a week later, when œdema is subsiding, secrete a urine containing abundant chlorides." In other words, if water is retained, salt must also be retained. But I do not agree with Bennett when he says that an increase in the blood chlorides has never been demonstrated in this condition. Thus, in a recent case of mine, the blood chlorides were 580 mg. per cent., as against the normal 360 mg., and the urinary chlorides 150 mg. per cent., instead of 500 mg. I think that while retention of chlorides has been over-stressed in the past, it may be a factor in renal œdema.

Epstein's explanation of renal œdema involves two main factors: (a) there is a serious drainage of blood proteins into the urine, which may mean that as much as 10 per cent. of these proteins are lost daily. In this way there is a fall in the osmotic pressure of the blood, with consequent retention of water in the tissues. Subsequent investigations on the osmotic pressure of proteins have supported this conclusion. (b) In hydræmic nephritis the lipoids, especially cholesterol, accumulate in the blood and tissue fluids, which he believes increases the tendency to œdema.

A recent case of mine showed a cholesterol content of 390 mg., falling to 250 mg. as the œdema subsided, whereas the normal lies between 100 and 190 mg. Bright himself called attention to the milkiness of the plasma and body fluids in nephritis with dropsy, and J. Maxwell has recently devoted attention to the subject. He showed that the cholesterol of the plasma is almost invariably increased in every type of renal œdema, and though not necessarily proportional to the amount of œdema its presence in increased amounts is prognostic of a chronic course. He did not think, however, that the cholesterolæmia and the œdema were related as cause and effect, but rather that both are the results of some toxic action on the tissues.

Epstein advised a high protein diet and very little fat in such cases. It is true that a high protein diet may sometimes greatly reduce œdema in hydræmic nephritis, but in part this is due to urea, the natural diuretic, which must be formed in large amounts from the amino-acids into which that protein excess disintegrates during digestion and before it is absorbed.

In passing, why forbid eggs in albuminuria, as is so often done? Now that we know how completely protein is disintegrated before it is absorbed, how can it "run through" from the bowel to the kidney?

Again, raw eggs may cause a slight toxic albuminuria in those sensitive to them, but this does not occur after cooked eggs. I have deliberately added eggs to the diet of patients with hydræmic nephritis, and have found no increase in the albuminuria produced thereby.

It naturally follows that the high protein diet is only applicable when it is certain that there is no urea retention. Mere estimation of the percentage of urea in the urine seems to be of little value, since so much of the urea is exogenous, coming directly from the disintegration of food proteins. Many patients with nephritis are already on a low nitrogenous diet, which will necessarily lower the percentage of urea in the urine. MacLean's urea concentration test is, however, of considerable value, since it shows whether, given a definite amount of urea to deal with, the kidney is capable of doing adequate work. I have often found that though the blood urea is normal, the urea concentration test gives too low a figure. This presumably means that the kidney can only just get along on its low protein diet,

and that urea retention is just beginning. Such cases are not suitable for Epstein's treatment. There seems little justification for his embargo on fats, since it is only cholesterol that is concerned, and that probably not in causal relationship. Moreover, Epstein is not consistent in this, since he allows eggs, which contain cholesterol in fair amount.

It would appear, then, that Epstein's method is only of limited application to cases of hydræmic nephritis proved to be free from nitrogen retention. Then a high protein diet may help to make good the excessive protein loss, while diuresis may be assisted by giving urea as such in doses of 40 to 60 grains three times a day. It is entirely non-toxic. Some thirty years ago it was given in large doses in tuberculosis. I doubt if it ever did any good for that disease, but it certainly did no harm, so that one need feel no scruples about using it in the type of case here described.

This brings me to the subject of diuretics in nephritis. They may act—

(1) *By producing vaso-dilatation in the kidney.*—The caffeine group act in this way. They probably act as direct stimulants to the renal epithelium, the vascular change being secondary.

(2) *By increasing the cardiac efficiency.*—The digitalis group apparently act as diuretics in this way.

(3) *By increasing the quantity of circulating fluid:* (a) by absorption of water from the intestines, as by giving the patient large quantities of water to drink; (b) by increasing the osmotic pressure of the blood. The saline diuretics and urea itself act in this way, attracting water from the tissues into the blood stream.

How far are these methods applicable to hydræmic nephritis? The first breaks the physiological law of resting damaged structures; I believe all the stimulating diuretics are capable of doing harm in this disease. The second is presumably only helpful when there is cardiac insufficiency as well. The third can do no harm, and may do good.

A study of the ætiology of renal œdema leaves us with the impression that it is "at once suggestive of pathological changes in tissues other than the kidney" (Bennett). This is the idea underlying the use of novasurol and euphylin as diuretics in nephritis, since they are believed to act on the tissues, enabling them to give up the water they are retaining. It is necessary to raise the hydrogen-ion concentration of the blood first by giving 1 to 2 drachms of ammonium chloride on each of two days, and then on the third day injecting $\frac{1}{2}$ to 1 c.cm. of novasurol intramuscularly. Both parts of this treatment are usually repeated after a few days' interval. Some give larger doses of ammonium chloride and over a longer period. This plan may be adopted in obstinate cases, but it often fails. In acute nephritis I believe that 3 (b) is the only method that should be tried unless there is cardiac insufficiency as well, in which case digitalis may also be given.

Elimination by the skin as an alternative route of excretion has long been a common practice in nephritis. It is open to the following objections.

(a) Only 3 grams of nitrogen can be got rid of through the skin in the day, compared with 8 grams which can be more easily eliminated by the bowel.

(b) Physiological rest for the kidney is not secured by giving it a highly concentrated urine to deal with.

(c) Diaphoresis is an exhausting process, and may depress the heart.

(d) The withdrawal of so much fluid without a corresponding removal of organic solids must increase the concentration of the toxins in the circulation.

It has been argued in support of this method of treatment that after a hot-air bath the patient may be actually covered with small crystals. These are, however, chiefly crystals of sodium chloride, though there may be some urea as well. Herein we have a clue to the type of case in which diaphoresis will be of service, namely, the one when there is salt retention as a factor in the œdema, as explained above. The elimination of salt may then be of indirect service by breaking a vicious circle. In cases of this sort I have actually seen diaphoresis followed by diuresis, which can only be explained in this

way. I conclude that the hot-air bath is only suitable when dropsy is actually present. Another indication that the treatment is having a good effect is the occurrence of sweating at a lower temperature than the one originally required to evoke it.

Decapsulation was revived a few years ago as a method of treatment in chronic parenchymatous nephritis by Sir Thomas Horder. It had previously been advocated chiefly for chronic interstitial nephritis, and finally abandoned for this condition. In cases of parenchymatous nephritis, the following have been considered to be indications for this procedure:—

- (1) Persistence of the oedema for three months in spite of careful medical treatment.
- (2) Absence of urea retention.
- (3) Absence of cardio-vascular changes.

But even when all these indications are fulfilled the results are often unsatisfactory, and I cannot recommend this operation.

AZOTÆMIC NEPHRITIS.

When there is reason to believe that nitrogen retention is occurring the interpolation of two days of von Noorden's fruit juice and sugar diet, as mentioned under acute nephritis, may be of great benefit. I look upon this plan as comparable in value with the vegetable and egg diet in the treatment of diabetes in the pre-insulin days. After this a diet containing a restricted amount of protein should be given, and one which contains as little extractives as possible, since these give work to the kidney without providing a corresponding amount of nourishment. It is possible for an adult to maintain nitrogenous equilibrium on 1 gram per kilogram of body weight, and for a time less than this will suffice if there is nitrogen retention. This means that a man of 10 st. requires 66 grams of protein. During the epidemic of war nephritis I drew up the following two diets, the low nitrogen diet being given for the first week and the moderate nitrogen diet for the second and subsequent weeks as required.

1. Low Nitrogen Diet.

Breakfast.—Milk 4 oz., porridge 8 oz., bread 2 oz., butter $\frac{1}{2}$ oz. Fluids: Coffee 10 oz., milk 2½ oz.

Lunch.—Bread 3 oz., butter $\frac{1}{2}$ oz., lettuce or tomato 1½ oz. Fluids: Milk 5 oz., barley water 10 oz.

Dinner.—Potato 4 oz., greens 5 oz., butter $\frac{1}{2}$ oz., stewed fruit 4 oz., boiled rice 4 oz. Fluids: Lemonade, imperial drink, or barley water 12 oz.

Tea.—Bread 3 oz., butter $\frac{1}{2}$ oz., lettuce or tomato 1½ oz. Fluids: Weak tea 10 oz., milk 2½ oz.

Supper.—Potato 4 oz., butter $\frac{1}{2}$ oz., greens 5 oz., stewed fruit 4 oz. Fluids: Lemonade or barley water 12 oz.

This diet contains: Protein 49 grams; carbohydrate 358 grams; fat 35 grams. Caloric value 1,992.

2. Moderate Nitrogen Diet.

Breakfast.—Egg 1 oz., bread 2 oz., butter $\frac{1}{2}$ oz. Fluids as in No. 1 diet.

Lunch.—Bread 4 oz., butter $\frac{1}{2}$ oz., tomato or lettuce 1 oz. Fluids as in No. 1 diet.

Dinner.—Mutton or fish 3 oz., bread (alternate days) 2 oz., butter $\frac{1}{2}$ oz., stewed fruit 4 oz. Fluids as in No. 1 diet.

Tea.—Bread 4 oz., butter $\frac{1}{2}$ oz., tomato or lettuce 1 oz. Fluids as in No. 1 diet.

Supper.—Greens 2 oz., potato 3 oz., bread 4 oz., butter $\frac{1}{2}$ oz., stewed fruit 4 oz. Fluid: Milk 5 oz.

This diet contains (on average): Protein 63 grams; carbohydrate 407 grams; fat 91 grams. Caloric value 2,772.

These diets have proved suitable in the experience of other observers also. Alcohol is certainly undesirable in azotæmic nephritis.

It is generally recognized now that there are decided dangers in lowering the raised blood pressure in azotæmic nephritis by means of vaso-dilators. The rise of blood pressure is compensatory and should only be treated by such methods as help in eliminating the toxins whose action is forcing the pressure up. For this purpose I find the internal administration of tincture of iodine

as useful as anything. Sometimes a small dose, say $\frac{1}{2}$ grain, of thyroid extract twice a day will help this. Gentle exercise in the open air will also assist in the physiological lowering of blood pressure.

The necessity for a raised blood pressure in this type is illustrated by the case of a man admitted under my care with chronic interstitial nephritis and much dyspnoea. His blood pressure was 160 mm. systolic and 100 diastolic. On 15 minims of tincture of digitalis three times a day his blood pressure rose to 200 mm. systolic and 125 mm. diastolic, while his blood urea fell from 100 to 40 mg., and his general condition greatly improved. Evidently his blood pressure on admission was too low for due elimination of nitrogen by his defective kidney, and it had fallen through cardiac insufficiency. When the condition of the heart was improved by digitalis, it was able to cope more successfully with the necessities of the situation. In such a case to lower blood pressure is to court disaster.

A case of azotæmic nephritis may terminate through failure of the pump, the tubing, or the filter; in other words, through heart failure, rupture of a vessel as in cerebral hæmorrhage, or uræmia.

Uræmia.

What signs and symptoms can rightfully be included under this heading? Personally, I should exclude the diarrhoea and vomiting which may be regarded as alternative methods of excretion. I have already pointed out that 8 grams of nitrogen can be eliminated by the bowel in this way; and Graham has shown that considerable quantities of ammonium salts are present in the vomit of a uræmic patient. The skin rashes I should also look upon as an attempt to excrete toxins. This leaves us with three groups of symptoms which can be fairly classed as uræmic, but I would urge that these groups are due to different toxic substances and are of different significance.

1. *Convulsions and Amaurosis.*—Though very dramatic symptoms, these are really of less serious significance than the others. Patients may recover not only from the attack, but actually from the nephritis. They may occur also in eclampsia and toxæmic kidney, both conditions from which recovery may be complete. In my series of 160 cases of war nephritis convulsions occurred in 8. They all recovered and escaped without permanent damage to the kidney. It has been suggested that these symptoms are due to some toxin acting on the liver rather than to the kidney lesion. On this view I am in favour of treating such patients with insulin and dextrose, since a hepatic toxæmia is best helped by providing an ample store of glycogen in the liver. But there is no doubt that the best and most rapid relief can be given by prompt venesection. Bennett ingeniously compares the convulsions to tetany, pointing out that there is a reduction of blood calcium in both conditions.

2. *Uræmic Asthma.*—The sufferer from this has been graphically described by Rose Bradford as "a drowsy patient, with hissing respirations and bleeding gums." I believe that the cause of this distressing syndrome is acidæmia from failure of the kidney to excrete acid sodium phosphate. The hydrogen-ion concentration of the blood is consequently raised and the dyspnoea is an attempt at compensation for this by washing out carbon dioxide from the lungs. A compensated alkaline defect may exist without dyspnoea, but an uncompensated alkaline defect will cause dyspnoea and calls for free administration of alkalis. De Wesselow finds that a rise of blood phosphates and a fall in calcium content go together.

3. *Headaches; drowsiness; twitchings; hemiplegia; monoplegia; neuralgias; formication; pruritus.*—All this group of symptoms appear to be associated with nitrogen retention. The actual cause of the symptoms seems to be exudate of lymph and even of actual blood through the capillary wall, especially into the cerebral and the subcutaneous tissues. Small punctiform hæmorrhages are commonly seen in necropsies on uræmic patients, and large or small purpuric areas in the skin are not infrequent. Canti considers that a blood urea of 300 mg. is a sure portent of a fatal issue; and I should agree, though I have had one case with a blood

urea of 500 mg. reduced to 70 mg. under treatment, and sufficient clinical improvement for the patient to leave hospital. He died, however, about six weeks later. In this case, as there was no dyspnoea, the plan of giving hydrochloric acid was adopted, and the improvement certainly appeared to follow this. It has been suggested that in this way toxic amino-acids are converted into ammonium chloride, but I am not convinced that this is chemically sound. But, as already pointed out, dyspnoea implies an acidæmia calling for free administration of alkalis, under which I have also seen some slight fall in blood urea.

In connection with nitrogen retention, I should like to call attention to the different results given by the hypobromite and urease tests for non-protein in the blood. The former method gives the amino-acids as well as the urea, the latter the urea only. Now in health 92 per cent. of the nitrogen given by the hypobromite test comes from the urea, but it must not be assumed that a similar proportion exists in disease. I have, indeed, found the hypobromite test yield twice as much nitrogen as the urease test in uræmia. In other words, in uræmia there is a large increase in the relative and absolute amount of non-protein nitrogen other than urea, and it is presumably this "unknown" amino-acid fraction which is toxic, since urea is a harmless substance. If only one method is going to be used, it is better to employ the hypobromite test. But using both gives most useful information as to the amount of toxic material.

This is well illustrated by the great rise of blood urea, sometimes accompanied by tetany, in cases of pyloric obstruction and in toxic conditions severe enough to produce anuria; here the hypobromite and urease methods may give identical figures showing that a rise of blood urea is merely secondary to failure of excretion; there is not, at any rate at first, any excess of amino-acids produced by altered metabolism. Pyloric obstruction presumably acts by preventing ingestion of fluids into the blood stream, so that there is not sufficient for the kidney to function properly. The combined use of the hypobromite and urease methods is a useful way of recognizing such conditions and of proving that they are not primarily renal in origin.

It will be seen that I do not subscribe to the doctrine sometimes advanced that the symptoms of uræmia are due to one specific toxin, albeit of unknown nature. On the contrary, it seems to me that the three different groups of symptoms above detailed are much more likely to be due to different chemical poisons.

Conclusion.

In conclusion, I am conscious that these more recent investigations appear to have had a destructive rather than a constructive effect on treatment. This must be admitted, but new aids to treatment will surely spring from a sounder pathology. In the meantime, our patients will do all the better and be more comfortable if we realize that many of the methods formerly recommended in the treatment of these diseases are impotent where not actually harmful.

The Treatment of Pulmonary Tuberculosis.

By F. G. CHANDLER, M.A., M.D., F.R.C.P.

(*The Practitioner*, May, 1929, Vol. CXXII, p. 273.)

THE treatment of pulmonary tuberculosis will depend in some measure on the type and extent of the disease. If when the patient first comes for advice, there is widespread involvement of one lung with evidence of activity, either with or without cavity formation, then some special treatment will probably be indicated. This is true also in such cases as uncontrollable hæmorrhage and a rapidly spreading tuberculous broncho-pneumonia. The special treatment I refer to is chiefly artificial pneumothorax, the marvellous efficacy of which never ceases to astonish me. This will be discussed later.

If the disease is early and proved by the discovery of tubercle bacilli in the sputum or in the fæces, strict treatment on sanatorium lines should at once be instituted

and the patient must be warned at the outset that treatment, though not necessarily at a sanatorium all the time, will be necessary for at least a year. Many will not submit to this, but, nevertheless, it is our duty to advise it. Failures are often due to the shortening of this time period. We are tempted again and again to yield to the appeals of the patient because of financial and domestic difficulties, but nothing is gained by it, for it only means more loss of time from work later and a recrudescence of the disease and a worse prognosis. If the patient's work is not suitable, it is better to consider changing it from the outset. This, however, is a counsel of perfection which frequently cannot or will not be followed.

If the symptoms are so suggestive that a diagnosis of tuberculosis cannot be dismissed yet tubercle bacilli are not found in the sputum or fæces, the x-ray picture is negative, and there is not that complete conjunction of cardinal symptoms that is almost proof positive of tuberculosis, even without finding tubercle bacilli, then, in my opinion, the advice to take a long holiday with rest, fresh air and good food is probably sufficient.

When according to the criteria already mentioned, we recommend sanatorium treatment, we may expect one of several reactions on the part of the patient. If he is endowed with that rare possession, common sense, he will probably accept the view held by all experts, that the greatest of all remedies are rest and fresh air, and that the knowledge how to use these to the best advantage can only be obtained under expert supervision. Unfortunately, however, a great many medical men do not appreciate the paramount importance of rest nor what actually is meant by it. Others will say that nothing on earth will induce them to go to a sanatorium—they would be so affected by the sight of sick people, they would be afraid of catching the disease worse. We have to explain that they will meet there many who are far fitter than themselves, that any danger of a sort of super-infection is a myth, and that at a well-appointed, well-disciplined sanatorium the danger of a spread of infection is probably less than elsewhere.

Another reaction may be that the patient will be incredulous and careless and cannot be bothered by irksome restrictions, and, unfortunately for the rest of mankind, sometimes he is lucky and Nature heals the lesion with no co-operation, and during the healing period he is a danger to others. Another is that at the word "tuberculosis" he flies into a panic, and, finding that the doctors will not guarantee a cure and do not boast a certain specific which will cure him surely, permanently and speedily, he flies off to some quack who readily gives such a guarantee, and, again unfortunately for the rest of mankind and for the cause of truth, Nature will sometimes assert herself and cure the disease, and the quack or charlatan gets the credit.

Another reaction is a kind of reflex. At the word "tuberculosis," the word "Switzerland" flies to the mind. One has to explain that patients will do better lying in an East End hospital than walking about among the most beautiful mountains of Europe. Switzerland is beautiful, sunshine may be enjoyed when there is but little in this country, the so-called diaphaneity of the air is greater and the beauty of the scenery may prove a great mental stimulus, but I am convinced that there is no special magic about Switzerland and that patients can be completely and permanently cured by proper treatment in England.

(1) *Rest*.—Of all treatment, rest is the most important. If there is fever, rest in bed should be prescribed until the temperature has been practically normal for three weeks. If there is much fever, patients must rest absolutely, neither feeding nor washing themselves. As the temperature falls, first feeding and then washing are allowed and then the use of the lavatory. When the temperature has become perfectly normal, it must be impressed on the patient that it is rest and not exercise that is needed. Very gradually increasing exercise on the level, carefully controlling it by the temperature chart, is allowed; no violent exertion is advisable for two or three years.

(2) *Sunshine*.—Sunshine, though used so successfully in the cure of bone and joint tuberculosis, has been

looked at a little askance in pulmonary tuberculosis. For all that, I believe that it is of great value; but it must be employed with great caution and the technique advocated by Rollier at Leysin must be followed. The first part to be irradiated should be the feet and legs. The affected part must very gradually be approached and cautiously exposed. The head must be protected and the sunbath must end as it began—by exposure to the feet. The exposures must be carefully controlled by the temperature chart and the pulse rate.

(3) *Climatic Treatment.*—The criteria of a suitable climate should be freedom from damp and bleak winds, a dry subsoil, freedom from dust and crowds of people, the maximum of sunshine, hill rather than valley. But I would emphasize again that it is the life lived rather than the place in which it is lived that is the more important. The advantages of high altitudes in the mountains are the long weeks and months of unbroken, unfiltered sunshine, the clear, pure, bracing air and the inspiring scenery. That all these are good is, of course, obvious, but I would again stress this—that if the right kind of life be not lived then there is little advantage.

(4) *Institutional Treatment.*—In my opinion, the sanatorium is or should be the ideal place for the treatment of the tuberculous patient. It must be fully equipped, however, and the discipline must be good. All advantages are lost if patients with evening temperatures are dancing and drinking cocktails, and instead of taking their prescribed amount of exercise are strolling to the nearest bar and drinking, coming back and faking their temperature, and if the mental atmosphere of the place is one of seething discontent, introspective valetudinarian conversation, and malicious gossip. I am not suggesting that these practices are invariable or that they are confined to the sanatoria of any particular country; but that they do occur I know, and the ignorance and folly of the patients who act in this manner pass all comprehension. Many sanatoria will not take patients while they are febrile. This is for two reasons. The first that by so doing they protect themselves from the very advanced case which is, as a rule, quite unsuitable for sanatorium régime (though it is only too painfully evident that institutions for such cases are urgently needed). The second is a domestic reason. Febrile patients need more nursing and more attention. With the introduction of recent methods of treatment, however, it is obvious that a fully-equipped sanatorium will welcome many febrile cases and will be willing to admit, temporarily, advanced cases in the hope that they may prove unilateral and amenable to special treatment. This is one of the great advantages of a sanatorium. The patient can be watched for long periods under ideal conditions. The progress can be observed and the need for special treatment decided upon and advised at the right moment. Another advantage is that patients are taught how to use fresh air, how to rest and how to exercise. If a sanatorium cannot do all these things and does not teach all these things, it is failing in its duty and is a bad sanatorium.

(5) *Medicinal Treatment.*—So far as we know, there is no medicine given by mouth or spray or inhalation or injection into the wind-pipe that has any specific action against the tubercle bacillus. Of the supposedly specific remedies I will speak later. Nevertheless, there are many substances which have a reputation for doing good, and it is of immense psychological importance to have at our command many remedies in a long protracted illness.

One of the oldest that is still used, having survived the vicissitudes of many centuries, is tar. Dioscorides, surgeon to Nero, strongly recommended its use in phthisis, and creosote is prescribed daily at the present time. It is given in enormous doses at Victoria Park and I have never seen it do any harm. Its psychological effect is great; whether it has any other value I do not know. I am inclined to doubt it. The allied substances, guaiacol and ichthyol, can be used. Arsenic, I think, is of value, and also tonics such as iron, quinine, hypophosphates, glycerophosphates. Iodine and intensive iodine treatment have been employed, but there is no evidence that it is of any special merit.

The efficacy of cod-liver oil is well known. It is valuable for its nutritive properties and vitamin content. An attempt has been made to isolate a specific substance, but it has not so far been successful. Malt is both a food and a digestive ferment and contains, of course, vitamin B. Calcium has some reputation in the treatment of tuberculosis, and many wild claims have been made for it. Successive generations of my house physicians, fired by enthusiasm after reading these reports, ask permission to use it, so that I have had plenty of opportunity of watching its effects, but I have not been very favourably impressed. It is, however, well worth trying, especially in acute cases, in one or other of the various preparations available. Yeo's inhaler—with carbolic, creosote, chloroform, iodine and ether—is also worth trying.

For the relief of cough much ingenuity may be needed. Open air will frequently stop all coughing. The patient must learn to relax and to let the cough be useful and not paroxysmal. It is surprising how greatly the cough can be lessened as the patient is taught control. Such simple remedies as glycerine and lemon, and black currant sweets may help, or pastilles of slippery elm or menthol and cocaine may be used. Other preparations which help greatly are hydrocyanic acid, numerous opium preparations, tinct. camph. co., linctures containing some form of opium or heroin, the delectable syrupus cocillana co.; cocaine and cannabis indica. An excellent list of remedies for cough will be found in the Therapeutic Index of Martindale and Westcott's Extra Pharmacopœia.

AFTER-CARE.

Points to be observed after the definite treatment period comprise the following:—

- (a) The general condition of the patient.
- (b) The weight.
- (c) The evening temperature—6-30 p.m., two or three years.
- (d) Sputum examination.
- (e) Physical signs in the chest.
- (f) Periodic x-ray examination.

It is exceedingly difficult to persuade patients to submit to these precautions. It depresses them. They like to think themselves cured and to take no further thought for the body. I deeply sympathize with this attitude, but alas! it is foolish policy and one which over again leads to disaster. We must explain that taking these precautions should not lead to worry and introspection, but do, in fact, remove the cause for worry. Slight exacerbations may occur from time to time, causing a rise of temperature. If the patient will rest at these times, he will prevent a lighting up of a small focus and gain more immunity. Herein lies the value and importance of such an institution as the Papworth Colony, where patients can work under suitable conditions and under observation.

SPECIFIC TREATMENT.

If under the régime mentioned above the disease continues to advance and it is bilateral, can we make any attempt at specific treatment? There are four possible ways known to us of treating infective disease specifically:—

- (a) Killing bacteria direct.
- (b) Neutralizing toxins.
- (c) Stimulating antagonistic mechanisms, whether in blood or tissues.
- (d) Making an unfavourable soil or medium for the growth of the organism.

In tuberculosis there are three remedies for which specific claims have been made:—

- (1) Sera.
- (2) Tuberculins.
- (3) Gold (Sanocrysin or Crysabine).

(1) *Sera.*—From time to time antitoxic sera have been introduced. Starting with the usual flourish of trumpets and the usual record of marvellous results, they have enjoyed a brief season of favour and then have been found wanting. Such were Maragliano's and Marmorek's serum. In another category was Mr. Spahlinger's serum, which I have had opportunities

of testing and which now rests obscured beneath a well-deserved cloud. Of Unlenhuth's serum, a horse serum prepared by injecting horses with virulent tubercle bacilli, I have had no experience nor have I heard of any recent results. An antiserum was at first used in the early days of the administration of Sanocrysin, made by injecting horses with Dreyer's diaplyte tuberculin, but was soon given up as useless.

(2) *Tuberculin*.—So plausible are the claims made from time to time on behalf of different tuberculins that I am almost compelled to review and re-review my opinion and to try and try again. But I am afraid it is the old story once more—a new tuberculin, an evanescent popularity, then swift decline. I have not had a large personal experience of the older tuberculins; but when Dreyer's diaplyte tuberculin was first introduced, through the Medical Research Council and the energies of Dr. S. Roodhouse Glyne, I was able, with my colleague, the late Dr. Clive Riviere, to make a fairly exhaustive test of this, but found it useless. It was possible, in acute cases, to work up to enormous doses, to desensitize patients completely to tuberculin, yet with no beneficial effect whatsoever on the clinical course of the disease. To test it further, I tried giving enormous initial doses in cases of tuberculous meningitis and got no reaction at all of any kind, which would appear to show that it has no influence at all on closed tubercles. Nevertheless, as a non-specific protein shock reaction it may do good in certain cases, if carefully controlled, and it seems that it is on the lines of tissue stimulation rather than on bactericidal action that we have the greatest hope of curing the disease.

(3) *Gold Salts*.—For a long time gold has had a reputation in the cure of tuberculosis. Many other substances have also been tried—antimony, arsenic, calcium, cobalt, copper, mercury, nickel, silver, sulphur—yet none has proved of real value, though some have obtained temporary popularity. An exception ought perhaps to be made in favour of arsenic, which, given as Fowler's solution, does appear to have some sort of tonic effect.

I remember in 1913 seeing several cases treated by potassium auro-cyanide. More recently Professor Mollgard has introduced the well-known double thio-sulphate of gold and sodium; Crystalline is a similar preparation. Knud Secher, in his book on Sanocrysin, published in 1926, claims that if used at the right stage it is possible to obtain with Sanocrysin a *sterilisatio magna*. Needless to say, it is a greatly exaggerated claim which subsequent experience has by no means confirmed. During the last three years I have treated between forty and fifty cases with gold, and I am still in a state of uncertainty with regard to its value. I have chosen two types of cases—the one, patients with advanced disease, who are obviously going rapidly downhill with what is called the exudative rather than the fibrotic type of tuberculosis; and the other, patients who, while not afflicted with a large area of disease, are unable to put up any effective resistance, and who, in spite of prolonged sanatorium treatment, remain constantly febrile with tubercle bacilli constantly present and who are slowly losing ground. Of the cases I have treated, ten have responded in what appeared to be a very striking manner, losing their fever and their tubercle bacilli, with the picture changing from one of steady progress of the disease to an arrest of it. For the remainder, and by far the greater number, no beneficial effect was obtained. Of course, the difficulty in these successful cases is to know what would have happened if Sanocrysin had not been used, and time alone will show whether Sanocrysin is really effective. In the second type of case I have mentioned, I think it is well worth trying if the patient does not experience any unpleasant or serious reactions. At the beginning, we used much larger doses, but now the general consensus of opinion is in favour of small doses beginning with 0.05 of a gram, giving injections at six-day intervals, and working up to 0.1, 0.25 to 0.5 of a gram and continuing at this dose until the patient has received 5 grams. The course is then repeated a few months later. Sometimes when there is no reaction I

still occasionally give 0.75 of a gram at one dose, but I no longer give the full gram.

An aura of suspicion seems to rest over Sanocrysin because of stories of terrible reactions. Such reactions are possible, but if care be taken they are very unlikely to occur. It must be given intravenously with the same precautions as salvarsan, as it is extremely irritative to the tissues. Reactions that may occur are albuminuria, which, if slight, may be ignored; but if blood cells and casts appear in the urine, injections must be stopped until the urine is absolutely normal. Other reactions include ulceration in the mouth, nausea or vomiting after the injection, diarrhoea, a generalized scarlatinal erythema which soon passes off and does not seem to matter much, and lastly, dermatitis with loss of hair. At the slightest sign of dermatitis the injections must be stopped and, in my opinion, never repeated. If small doses are used and all reactions carefully observed, no serious complications should arise.

SURGICAL PROCEDURES.

If the case be unilateral and progressive, in spite of the most careful treatment, there can be not the least doubt that something more should be done.

(1) *Artificial Pneumothorax*.—With this method of treatment, when successfully induced, we can completely rest the lung and in many cases stop the progress of the disease. It is simple, painless, and, if not doing good, can easily be undone. It is one of the most ingenious methods of treatment ever devised and one of the most dramatically successful in its results. In spite of this I am altogether opposed to employing it in early cases of pulmonary tuberculosis. In all cases I would give Nature every chance to heal the patient. There are many reasons for this which have been put forward so many times that it is not necessary, even if there were time, to do so again now. Apart from severe recurrent hæmoptysis and a rapidly spreading tuberculous bronchopneumonia, the following is what I consider the indication for artificial pneumothorax—unilateral disease, which is spreading in spite of careful and prolonged treatment on strict sanatorium lines—it should not depend on the extent of the disease. It may be difficult to know exactly when to decide to step in and induce pneumothorax, but if the case is under observation it usually, sooner or later, becomes obvious when this should be done. If there is fever which will not subside, if there are repeated hæmorrhages, if tubercle bacilli are constantly present in large numbers, if there is a cavity which is increasing rather than diminishing, if the general condition of the patient is not good, if he is unable to get about without showing signs of toxic absorption, if signs and the x-ray picture show an increase of the affected area, then artificial pneumothorax should be considered. The length of time during which it must be kept up will vary greatly according to the case, and the termination of a pneumothorax is often a most difficult and anxious problem. If, however, the patient can be observed carefully during the process of expansion of the lung, then it is usually, but not always, possible to know whether any reactivation of the disease is taking place. In any case, it is better to warn the patient that the treatment will probably be necessary for at least two or three years—in advanced cases longer.

(2) *Oleothorax*.—A common complication during the course of artificial pneumothorax is a pleural effusion. This can frequently be ignored and it will disappear. Sometimes it can be allowed to remain for quite a long time with no apparent ill effects. Sometimes, however, the amount of fluid is so great that tapping is necessary and then, if a tendency to repeated reaccumulation of fluid occurs, there is a danger of the pleural space becoming smaller and a condition known as obliterative pleurisy may occur, which will undo all the good work that has been done and is one of the dreaded complications of the treatment. The same may occur after two or three attacks of pleurisy with a comparatively small amount of fluid. When obliterative pleurisy has once well started, no amount of air pressure will keep the pleural layers apart. Little by little, with invincible force, the tentacles of contracting fibrous tissue draw the

pleural layers together from below upwards. By drawing off the fluid and replacing it by olive oil containing 5 per cent. oil of gomenol, this process may be prevented. Even though the pleural layers come together at the base, the oil will be driven to the upper part of the chest and then the space can be contracted no farther and it is usually just this upper part that we want collapsed. In this way, a condition which might render the severe surgical procedure of thoracoplasty necessary may be prevented.

(3) *Phrenic Avulsion*.—If because of adhesions an artificial pneumothorax cannot be induced, what other method have we at our disposal? The simplest is phrenic avulsion. Under a local anæsthetic the phrenic nerve is exposed in the neck, held with forceps, cut above and then carefully dragged out by gentle pulling until the whole length and some of the diaphragmatic branches come out whole.

This is specially indicated in basal tuberculosis and may be sufficient to bring about an arrest of the disease. It is worth trying in any case, even though it be but a preliminary to more drastic procedures. The reaction is usually very slight. Patients can even walk about the day after the operation.

(4) *Apicolysis or Pneumolysis*.—If the disease be apical, the next least severe procedure is the so-called apicolysis. An incision is made between the second and third ribs or in the axilla; the ribs are retracted, the parietal pleura is stripped from the chest wall by the hand, and the whole of the upper lobe pressed down by the fingers or fist. Into the space so produced either fat or plastic paraffin is pressed and the incision sewn up firmly. It is an excellent operation involving little shock, but unfortunately both of the packing substances used are apt to be extruded little by little through a pin-hole sinus. Nevertheless, though this may happen, a large apical cavity may remain closed with its walls adherent.

By pneumolysis is meant a similar stripping of the parietal pleura and packing over some part of the lung other than the apex.

(5) *Thoracoplasty*.—If these methods fail or if the disease is too extensive for the lesser procedures, then thoracoplasty must be considered. Performed on the right type of case the results are marvellously good. I have seen most brilliant and lasting results from the operation, but there is no disguising the fact that it is a big operation and one would think more than once before recommending it. It demands the most perfect technique and the most complete comprehension of what is to be achieved. The following are the types of cases suitable for a thoracoplasty:—

(a) If a successful artificial pneumothorax has been allowed to terminate and there has been a recurrence of symptoms and recollapse is not possible.

(b) If an artificial pneumothorax be imperatively indicated in a case of progressive unilateral disease, yet by reason of adhesions it is not possible to induce one.

(c) If chronic unilateral disease is present causing distressing symptoms—excessive expectoration, recurrent hæmoptysis, fever, inability to work, etc.

(d) In cases of persistent tuberculous empyema causing toxic symptoms, which will not yield to air or oxygen replacement or replacement by gomenolized olive oil.

The Treatment of "Crescent Carriers" with Plasmoguin Compound.

By RICHARD GREEN, M.B., B.S.

(Abstracted from *Bulletins from The Institute for Medical Research, Federated Malay States*, No. 3, 1929, p. 1.)

SUMMARY.

(i) AMONG 741 cases infected with *P. falciparum*, examined prior to quinine treatment, the average percentage of gametocyte carriers was 42.3 over a period of seven months, the monthly variation being from 30 per cent. to 56.1 per cent.

(ii) In 250 cases infected with *P. falciparum* given an average of 7.1 days of quinine treatment and examined before and after treatment, it was found that the number of cases with gametocytes had increased and that among these the numbers provisionally regarded as capable of infecting mosquitoes had also increased.

(iii) Fifty-six cases of sub-tertian malaria showing the presence of gametocytes in the blood were treated from ten to fourteen days with plasmoguin compound, being given a daily dose of 0.04 grm. plasmoguin and 0.5 grm. quinine. Among these, crescents disappeared from the peripheral blood within an average period of 7.9 days, limits 4 to 13 days. Trophozoites were present or reappeared after the third day in 21.5 per cent. of the cases.

(iv) Ten similar cases were given quinine, grains xx daily, with an additional number of five crescent free cases, making a total of 15 controls. In the ten cases with crescents these did not disappear during the course of observation and treatment; that is, from 12 to 20 days, but in all cases, no trophozoites were to be found after the third day.

(v) Abdominal pains occurred among 5.4 per cent. of the cases receiving plasmoguin compound. No further toxic symptoms were observed.

(vi) With the dosage of plasmoguin compound employed, no evidence of renal damage or adverse effect on either the cardio-vascular system or hæmoglobin could be found.

(vii) Slow pulse rates between 40 and 50 per minute while the patients were reclining were observed with equal frequency among the patients treated with plasmoguin compound and those treated with quinine.

(viii) The average reduction in the size of the spleen over a period of ten days among cases in which measurements could be made, was 4.2 cm. in the cases treated with plasmoguin compound and 2.3 cm. in those treated with quinine.

CONCLUSIONS.

The results recorded appear to justify the following conclusions:—

(1) Quinine is not an effective drug when used over periods of less than 21 days with the object of destroying the gametocytes of *P. falciparum*.

(2) A dose of 0.04 grm. plasmoguin daily in adult sub-tertian cases is an efficient gametocide among Asiatic hospital cases as described. The dosage is sufficiently free from toxic effects to be given to these patients, but continuous medical supervision is necessary in view of the narrow margin between the effective dose and that which may cause toxic symptoms. This dosage is sufficiently active against gametocytes to be effective in sterilizing all but a very few "crescent carriers" during a period of approximately twelve days.

(3) In its present form plasmoguin compound is not a well-balanced drug and although the two drugs may be given separately and each be effective in its own sphere, a combination permitting the convenient daily administration of 0.04 grm. plasmoguin and gr. xx quinine would be an advantage in treating cases of sub-tertian malaria which are also "crescent carriers."

The Treatment of Quartan Malaria with Plasmoguin.

By RICHARD GREEN, M.B., B.S.

(Abstracted from *Bulletins from The Institute for Medical Research, Federated Malay States*, No. 3, 1929, p. 21.)

SUMMARY.

(i) Forty cases of quartan malaria were given 0.06 grm. plasmoguin daily. Ten control cases were given quinine hydrochloride gr. xx daily.

(ii) The average time of disappearance of quartan parasites, including gametocytes from the peripheral blood among the cases receiving plasmoguin treatment, was 6 days; limits 4 to 9 days.

(iii) Among the cases treated with quinine the average time of disappearance of all forms of the parasite

was 10 days; limits 4 to 14 days. In two cases gametocytes were still present on the eleventh and sixteenth days of treatment.

(iv) Ten per cent. of the cases receiving plasmoquine complained of abdominal pains. Five per cent. had cardiac irregularity which was regarded as being due to the drug. No further toxic symptoms were observed.

(v) Pulse rates below 45 per minute were met with in 6.6 per cent. of the plasmoquine cases and in 25 per cent. of the quinine cases.

(vi) The average diminution in the size of the spleen was 3.45 cm. in the plasmoquine cases and 4.9 cm. in the quinine cases.

(vii) In doses of 0.06 grm. daily, no evidence was found that plasmoquine caused albuminuria or that it influenced unduly the blood pressure or hæmoglobin content.

CONCLUSIONS.

(i) Plasmoquine appears to be somewhat more efficient than quinine in destroying both sexual and asexual forms of *P. malariae*.

(ii) A dose of 0.06 grm. daily given to 40 male Asiatic patients, whose average weight was 48.5 kg., did not give rise to severe toxic symptoms but as the gametocidal effect of plasmoquine appears to be somewhat greater than that of quinine, it would probably be of advantage to combine quinine with smaller doses of plasmoquine for the treatment of quartan cases. A dose of 0.04 grm. plasmoquine in combination should be sufficient for the type of patient described.

GENERAL CONCLUSIONS REGARDING PLASMOQUINE.

(i) Plasmoquine appears to be more efficient than quinine in destroying the gametocytes of both *P. falciparum* and *P. malariae*.

(ii) The addition of 0.04 grm. plasmoquine daily to quinine treatment of adult cases should be an advantage from the epidemiological view-point in cases of subtertian malaria which have crescents in the blood. For cases of quartan malaria a similar dosage for the purpose of more rapidly freeing patients from gametocytes might be considered.

(iii) No evidence has been found among 96 cases that plasmoquine causes bradycardia.

(iv) The contradictory results observed in the subtertian and quartan cases do not permit the conclusion that plasmoquine causes a more rapid reduction than quinine in the size of spleens which have become enlarged as the result of malarial infection, nor do they, on the whole, support the suggestion that abdominal pains observed among cases taking plasmoquine are due to rapid reduction in the size of the spleen.

Colles's Fracture: An Efficient and Economical Method of Splinting.

By W. MITCHELL SMITH, M.D., C.M.

(Brit. Med. Journ., April 27th, 1929, p. 765.)

THE cost of after-care (massage, physiotherapy, and electro-therapy) in the treatment of fractures has been mounting up in recent years to an alarming extent. The time has come for the surgeon who prescribes this treatment—often as a matter of routine—to consider whether this expense is justified, or whether equally good, or even better, results might not be obtained by well-considered splinting.

Efficient splinting should ensure complete immobilization of the fragments after reduction, and, in the case of the Colles's fracture, fixation of the hand in such a position that the patient is able to use it as soon as the damage to the soft tissues begins to subside. Jones's and Carr's splints are the two most commonly used. The former provides the more perfect fixation of the fragments; the latter the better position from which to start re-education. I find that the best features of both splints can be combined in a carefully applied plaster case.

The treatment of a Colles's fracture may be divided into three stages: (a) reduction of the fracture; (b) splinting; (c) after-care.

A. Reduction of the Fracture.

Reduction of the fracture under an anæsthetic can generally be easily obtained by steady traction on the hand and manipulation of the fragments into position by the thumb and forefinger. If more force is required the well-known manipulation of Sir Robert Jones provides all that is necessary; but as little force should be used as possible. Complete reduction is indicated by the restoration of the radial curve, as described by Sir Robert Jones, and of the correct relationship of the styloid processes.

B. Splinting.

A roll of stockinet is run up the arm, extending from the knuckles to the elbow. Over this a light plaster case is applied. With the thumb and forefinger of one hand the surgeon holds the fragments of the radius in the corrected position, and with the other hand holds the wrist in about 15 degrees of dorsiflexion and slight ulnar deviation while the plaster sets. It is essential that the plaster should be closely moulded to the dorsum of the wrist and that the angle of dorsiflexion should be exactly opposite the joint. To prevent rubbing the skin, the plaster should extend, glove fashion, half-way up the metacarpals, and should allow full palmar flexion of the metacarpo-phalangeal joints.

The occurrence of pain and swelling of the fingers may be avoided by cutting out from the back of the plaster, before it sets, and from the underlying stockinet, a strip about half an inch wide, leaving a bridge at the top and the bottom. A radiogram to confirm the correction should be taken through the plaster.

C. After-care.

As soon as he recovers from the anæsthetic, the patient is encouraged to use his fingers and gradually to develop the use of his hand. In a week or ten days he is able to do anything within the limits imposed by a cock-up splint. The plaster case is removed at the end of a month, by which time bony union has generally taken place, and as the patient has already been using his hand freely for two or three weeks no further treatment is required.

I have been treating Colles's fractures by this method for the past three or four years with uniformly good results and with considerable saving in the cost of treatment.

Reviews.

MENTAL DEFICIENCY (AMENTIA).—By A. F. Tredgold, M.D., F.R.C.P., F.R.S. (Ed.) Fifth Edition (largely rewritten), 1929. London: Baillière, Tindall and Cox. Pp. XVI plus 535, with 35 illustrations and 12 tables. Price, 25s. net.

SINCE its first appearance in 1908, Dr. Tredgold's book has been rightly acknowledged to be the standard work on mental deficiency, a subject which he has made peculiarly his own. The years between the publication of the fourth and fifth editions have witnessed two events of importance in this particular field in England and Wales, first, the passing of the Mental Deficiency Act of 1927, and, second, the investigations of Dr. E. O. Lewis on behalf of the joint Mental Deficiency Committee of the Board of Education and the Board of Control.

With regard to the causation of mental deficiency in general (and it may be remarked in passing that the number of mental defectives in Great Britain relative to the general population is showing a disquieting increase), the author strongly upholds the view that in approximately eighty per cent. of cases the condition is due to inheritance. Other predisposing causes such as alcoholism, tuberculosis, syphilis and consanguinity of the parents are regarded by Dr. Tredgold as of relatively much less importance in the ætiology of primary amentia.

Incidentally it might be of interest from the historical point of view to have the opinions of Professor Elliot Smith and other Egyptologists on the effect of the con-sanguineous (and, in the eyes of modern civilisations, incestuous) unions contracted by some of the earlier Pharaohs: fortunately the question in practical form does not now arise.

The general structure and composition of the book are excellent and such criticisms as can be offered are directed against minor points only. It is probably true that "the importance of abnormalities of labour as a cause of amentia has been much over-rated," but the statement that "the proper use of the forceps can play no practical part in the production of amentia" overlooks the fact that the application of this instrument is still, we fear, far from "proper" in many cases. If the misapplication of forceps can produce permanent injury to the brachial plexus in a small but appreciable proportion of cases, surely it is even more capable of damaging the delicate cortical neurons—even in the absence of a "neuropathic predisposition."

We should like to have seen some mention made of the part played by malaria in the causation of mental deficiency and retarded mental development. Bianchi states that intensely malarious districts (of Italy) where the majority of the inhabitants have enlarged spleens and a certain degree of anemia are veritable nurseries of imbecility. The same sequence was noted in France by Montfalcon over a hundred years ago and more recently by Conti in Sardinia. In this connection examination of the peripheral blood of the case described on p. 263 (mild amentia consequent on "meningitis" at fifteen months of age—in India) might have had interesting results. When Dr. Tredgold sets out to refute the popular misconception regarding the close relationship of mental abnormality to genius, he is doing sociology and psychology an undoubted service, but when he states (p. 507) that "the great majority of men and women of outstanding ability have been particularly sane and have come of sane and healthy stocks," he puts on himself the onus of defining a man (or woman) of outstanding ability. Cowper, Dean Swift and Coleridge were at least "unstable," while Byron was a high grade defective with a thoroughly bad family history. Charles Lamb, himself the gentlest and most loving of men, had a neuropathic heredity which weighed on him throughout life—witness his own incurable stammer and the sudden outbursts of homicidal mania to which his sister was so tragically subject.

Of actual errors there are few—and these trifling. "Recently" on p. 37 refers to a paper published as long ago as 1913 and the same word (on p. 213) to a paper dated 1912.

Dr. Tredgold is to be congratulated on his book having attained its majority, and the fifth edition will certainly enhance its reputation still further as the authoritative guide to those engaged in the study of mental deficiency whether it be from the clinical, pathological or sociological aspects. Printing and general format are excellent and the price is eminently reasonable.

J. M. H.

CONTRIBUTIONS TO PSYCHIATRY, NEUROLOGY AND SOCIOLOGY.—Dedicated to the late Sir Frederick Mott, K.B.E., Hon. LL.D., M.D., F.R.C.P., F.R.S. by his colleagues, friends and former pupils. Edited on behalf of the Mott Memorial Committee by J. R. Lord, C.B.E., M.D., F.R.C.P.E. London: H. K. Lewis and Co., Ltd. 1929. Pp. XII plus 401, with numerous illustrations. Price, in Great Britain 21s. net.

By the death of Sir Frederick Mott on 8th June, 1926. medical science in general lost an able leader and psychological medicine in particular one of its chief ornaments. The volume under review, comprising a series of thirty-one papers by former colleagues and students is a fitting tribute to him who inspired and taught them. Striking evidence of Mott's international reputation is afforded in the list of contributors—France, Germany and Holland, Italy and Switzerland, Norway and Denmark, Australia and Canada, Japan, America and England are all

represented, and the range of subjects dealt with is equally varied—from a somewhat whimsical note on common errors in neurological nomenclature (by Sir Edward Sharphy-Schafer) to a study of the blood-sugar in mental disorders.

The article entitled "The Prevention and Early Treatment of Mental Disorders" by Sir Hubert Bond (one of the Commissioners of the Board of Control in England) is in some ways the most interesting and important of the series. For it emphasises—and it appears that emphasis is needed—the total inadequacy of the present Lunacy Laws in England. At the moment, certification and judicial intervention are essential preliminaries to treatment and there is practically no provision for the "patient" suffering from early but as yet uncertifiable mental disorder. That legal cognisance of the so-called "borderland case" has not yet been taken must, we think, be attributed to an ill-defined but lingering suspicion in the minds of the lay public that any extension of the existing laws to include those not demonstrably diseased in mind except to the critical examination of the expert might allow of perfectly sane persons being in some mysterious manner "put away" by the machinations of their enemies. Incidentally the law in Scotland is different (though Sir Hubert Bond does not mention the fact). Section 6 of 25 and 26 Vict. Cap. 54 (1862) intitled "an Act to make further provision respecting Lunacy in Scotland" makes definite provision for allowing persons to enter asylums voluntarily.

The present vogue of malaria therapy in general paralysis of the insane is reflected by the presence of two articles dealing with this subject in the series under review. Evidence is gradually accumulating in support of the undoubted value of this mode of treatment; in this connection it is interesting to note that of sixteen cases so treated who afterwards came to autopsy at periods varying from three months to two and a half years from the cessation of treatment, in only one—a case of congenital general paralysis of the insane—were spirochetes found in the brain. This would appear to be significant, as these organisms can be found in the brains of about sixty per cent. of untreated cases. Another point of interest is the observation that cases showing a strongly positive Wassermann reaction in the cerebro-spinal fluid before treatment appear to have a better prognosis—other things being approximately equal—than those in whom this reaction is not so strongly marked. This raises the much bigger question as to whether the intensity of the Wassermann reaction in any given case is an index of the degree of infection or of the antibody response to infection in that particular case.

Mention must also be made of the charming appreciation of Mott from the pen of Professor W. D. Halliburton—a lifelong friend. Here we get an intimate sketch and one realises that to have had the privilege of Sir Frederick Mott's friendship was in itself a liberal education.

J. M. H.

ULTRA-VIOLET RADIATION & ACTINOTHERAPY

—By E. H. Russell, M.D., Dunelm, and W. K. Russell, M.D., B.S. Dunelm. Third Edition, Edinburgh: E. & E. Livingstone. 1928. Pp. 648, with 259 illustrations. Price, Rs. 15-12 net. Messrs. Butterworth and Co. (India), Ltd., Agents in India.

ULTRA-VIOLET ray therapy owed its origin to the astute observations of many physicians and surgeons in the past. Hippocrates was aware of the beneficial effects of sunlight in certain cases, and since his day many have testified as to the accuracy of his observation.

With modern methods it is possible to control scientifically the rays which one administers to the patient, but only if the operator is fully cognisant of the physical principles involved. Much harm can be done by indiscriminate ultra-violet therapy, and only in the hands of a doctor who is also a radiologist is this treatment safe. The reviewer has known of many cases where bad results have occurred through ignorance of technique, but he has also known cases to recover under

ray therapy, which was properly administered, which were almost hopeless. It is significant that ray therapy was prescribed for the King-Emperor with excellent results.

The lesson, then, to be drawn is that in ray therapy a powerful weapon is put into the hands of the physician, but the control of this power is essentially the domain of the specialist. Drs. E. H. and W. K. Russell, who present the same phenomenon as Monsieur and Madame Curie, of husband and wife working together for medical and scientific ends, are to be congratulated on their third edition of their "Ultra-Violet Radiation and Actinotherapy."

The work can be recommended both to specialists in the subject and to general practitioners, because the specialist will find the detail he requires in difficult and obscure cases in this book, while the general practitioner will be able to realise how many of his intractable cases can be benefitted, if not cured, by actinotherapy. He will also be able to realise the limitations of ray therapy, and know when not to expect too much.

There are a few statements in this book which require further amplification and proof, but in the main it is an excellent book, thoroughly to be recommended to all interested in ultra-violet therapy.

C. G. R. M

LIGHT AND HEAT IN THERAPY (WITH A CHAPTER ON FOAM TREATMENT).—London: The Actinic Press. 1929. Pp. 174. Illustrated. Price, 6s. 6d. net.

THIS little book constitutes the *Proceedings of the Second International Congress of Heat and Light in Medicine and Surgery* held in London in 1928. It contains papers showing many advances in the subject. The names of the contributors, e.g., Sir Henry Gauvain, Drs. Franz Nagelschmidt, H. S. Cermach and W. Flashamp are sufficient in themselves to make the papers authoritative. One of the most interesting papers is that by Dr. Nagelschmidt who with Dr. Arsonval must be ranked as one of the two earliest pioneers in the value of diathermy. He has devised a new diathermy machine, working at a higher potential than usual and with condenser electrodes. By means of these he can raise the body temperature to any degree compatible with the safety of the patient and can maintain states of hyperpyrexia for indefinite periods. It will be very interesting to see and contrast the results obtained by this means in cases of progressive paralysis, as compared with those obtained with malarial therapy.

G. G.

THE PHYSICS OF X-RAY THERAPY.—By W. V. Mayneford, M.Sc. London: J. A. Churchill. 1929. Pp. 177, with 106 illustrations. Price, 10s. 6d. net.

THIS little book, written for radiologists, deals with the physical aspects of x-rays especially as applied to therapy. The subject is treated in a concise but lucid manner. Mathematics, the *bête noire* of the average doctor, is conspicuous by its absence.

The chapter on x-ray measurements, giving details of the modern apparatus for the purpose, will be found especially useful.

G. G.

AN INTRODUCTION TO ANATOMY.—By N. S. Sahasrabudhe, M.S. With a Foreword by Dr. Y. G. Nadgir, M.S. Published by the Author. Sitabuldi. Nagpur, C. P. 1929. Pp. VI plus 236, with 13 illustrations. Price, Rs. 3 (Inland), 7s. net (foreign).

THE book has been written with the object of making the method of study of anatomy easy and interesting to students. It contains 16 lectures, the first of which is on "Terms and parts of the body." Where such terms as "anterior and posterior, superior and inferior" have been introduced, no mention has been made of the "anatomical or formal position" of the human body. The second and third lectures are devoted to "general anatomy" in which the various systems to be studied have been introduced and explain the necessity for the existence of each system. The fourth lecture deals with some points in practical anatomy, such as the method of

preservation of dead bodies and the subdivision of the entire body into parts for distribution to students for dissection. The distribution of the arm and axilla to one student and the remaining part of the superior extremity to another by dividing it below the middle of the arm is undesirable as it prevents the study of one part in continuity by the same student. The same disadvantage is met with in the proposed distribution of the inferior extremity by dividing it into two below the middle part of the thigh. The practical hints given for the use of the instruments for dissection will be extremely useful to beginners in dissection. The author impresses on his students the method of reconstruction and visualisation as the only means for carrying a mental picture of the dissected parts. Lectures 5 to 9 deal with the description of bones in a general way without going into details, and giving a rough idea of the position and parts of the bones. Lectures 10 and 11 deal with joints and muscles, laying stress on the method of study of these systems. Lectures 12 and 13 are devoted to the digestive, respiratory and urinary systems in a general way. The 14th lecture is on the circulatory system clearly explaining the pumping mechanism and the arrangement of the valves of the heart. The 15th lecture is on the nervous system and the last lecture covers the generative system, endocrinology, and the special senses in a general way. Though the author has generally followed the new terminology it has not been strictly adhered to. For the sake of simplicity anatomical accuracy has been ignored at many places, e.g., where the author calls the cavity of the mid-brain the 3rd ventricle and the dura mater the "water bag" outside the arachnoid. There are 13 illustrations and they are original and useful, though not in colour. The author is to be congratulated on introducing a method of study of anatomy on entirely new lines which may cultivate in students a strong power of visualisation, reasoning and self-help which are essential for the study of the important subject. The book should be useful to those studying anatomy for the diploma in nursing. The book however stands badly in need of revision and emendation.

A better get-up of the book and less typographical errors may be expected in the next edition.

N. P.

PUBLIC HEALTH AND HYGIENE: A STUDENTS' MANUAL.—By C. F. Bolduan, M.D. Philadelphia and London: W. B. Saunders Company. 1929. Pp. 312, illustrated. Price, 12s. 6d. net.

THIS is an attractively got-up book, worthy of the publishers' reputation. It differs from the usual run of elementary textbooks in that it gives an excellent historical survey of the growth of public health. Excellent pictures of all the well-known hygienists and medical discoverers are given, and the opening chapters give a very good resumé of the development of medical and sanitary knowledge and science. The preface states that the book is meant as a useful introduction to preventive medicine. This may account for the rather brief and rather superficial treatment of the subject matter. Rickets for instance is stated to be due to a diet deficient in vitamin A, while vitamin D is not mentioned in connection with rickets at all and no recent work on A and D is quoted. It is a pity there is not more uniformity in the nomenclature of the typhoid group. The paratyphoid bacillus B is stated here to be "frequently present in the intestines of normal animals, especially pigs, and can therefore often be found in meat products." This is not in accordance with English findings on paratyphoid B. The book is very readable and will be an excellent student's handbook, especially in the United States, though it will be interesting to all.

A. D. S.

ELEMENTS OF HYGIENE AND PUBLIC HEALTH.—By Rai Bahadur J. P. Modi, L.R.C.P. & S., L.F.P.S., with an Introduction by Lt.-Col. E. J. O'Meara, F.R.C.S., D.P.H., I.M.S. Third Edition. Revised and Enlarged. Calcutta: Butterworth and Co. (India), Ltd. 1928. Pp. XIV plus 645, with 74 illustrations. Price, Rs. 6 net.

THIS is a book on hygiene and public health of a type of which in India there are now several available for

medical students. That is it in its third edition testifies to its popularity and acceptance amongst the medical students for whom it is written. It has the defects of these qualities, in that it is written to a syllabus. The teaching of public health to the Indian under-graduate is not an easy matter. It is a point of view that one wishes to inculcate rather than a few facts about water supply, refuse disposal, and ventilation. This can be done only by the whole body of teachers, and not by Professors of Hygiene alone, by practical demonstration of the application of the principles of preventive medicine in the everyday life of the town and state. This latter is so deficient in India, and the general practitioner is called upon to play such a negligible part in preventive medicine, that it is not surprising that the syllabus of hygiene in our schools and colleges should be so restricted and defective, since they must of necessity reflect in some measure the state of the public health opinion of the country.

With these reservations, however, Dr. Modi's book is a good one. It contains all that the student will require to know for his examination. While there is much that is new, we think Dr. Modi might have missed out much that the non-discriminating student learns by rote and writes as knowledge—the A.B.C. process, the amines process, Jennings' inlet, Stevenson drawer, Hatton's hopper ventilator for instance only uselessly clog the memory of the student. We would have preferred the subject of ventilation to have been treated in a fresher and more up-to-date manner. The kata thermometer is described under meteorology and not mentioned under ventilation. The importance of the physical condition of the air, though mentioned, is not sufficiently insisted on. The illustrations of the ventilation of a large hall is one of the "cold feet and hot heads" systems which has been said to account for the poor quality or much legislation in the past. There is much new matter in every chapter and the author has evidently taken great pains to incorporate essential matter pertaining to Indian conditions and diseases published during the last few years. The chapters on plague, village sanitation, and the sanitary arrangements at fairs and *melas* are quite good, though it is rather startling to find that fleas can "fly."

The illustrations are smudgy and disappointing. The "*B. pestis* in the human blood" and "Anopheline eggs" might be anything; the pictures of an "Anopheline" and a "*Stegomyia*" seem to have got transposed and in any case are not good representations of the actuals. We often insist that textbooks for under-graduates should contain only definite facts and not loose statements which may be memorised and mistaken for fact. The author states that "the embryo and eggs of the following parasitic worms are often found in water and may be taken into the stomach of man.....*Filaria sanguinis hominis*....."

The book will doubtless find many readers amongst under-graduates and students preparing for their examination in hygiene.

A. D. S.

THE WORK OF MEDICAL WOMEN IN INDIA.—By M. I. Balfour, C.B.E., M.B., C.M., and R. Young, M.B.E., B.Sc., M.B., Ch.B. With a foreword by Dr. Mary Scharlieb, D.B.E., J.P., M.D., M.S. Humphrey Milford. Oxford University Press: Bombay, 1929. Pp. XIV plus 201, with 15 illustrations and 1 map. Price, Rs. 6 net.

"The work of Medical Women in India" by Dr. Margaret Balfour, and Dr. Ruth Young, recently published by the Oxford University press and with a foreword by Dame Mary Scharlieb, one of the pioneers of Women's Medical work, contains a most vivid and interesting account of the endeavours made by women to establish medical relief for the women of India, of the difficulties they met with and overcame, of the sympathy and support forthcoming from many sources in India, and of the great growth of and the scope for the work at the present time.

The apology contained in the preface: "Lastly we would ask our readers to remember that the book has been written in the intervals of our work, during weekends and on journeys, and finally completed during our

not very lengthy furlough" suggests more than any references to their own work in the book (for in it we find almost none), something of the debt which women's medical work owes to those two authors, whose efforts in organizing the women's medical service as it is to-day, have been so untiring and so constant. The opening chapter dealing with the field of work gives a very clear and concise account of some of the causes and customs so widely spread in India which led to the need for medical relief being commenced and carried on among the women of India in zenana hospitals. The difficulties of the young Indian medical women are also discussed; how often they have had to meet trouble with family or social objections; how sometimes they have to conquer their own caste prejudice and natural diffidence, and accustom themselves to appear publicly, how they have to carry on their medical study in another language than their own and one usually acquired after childhood is passed.

The work of the pioneers is also of exceptional interest and there is a very clear and connected account of the reasons which called for the start of their work, of their early recognition of the call for service, their overcoming and meeting the problems both of obtaining training for themselves and then of staffing and equipping hospitals and training schools for women.

The history of the Countess of Dufferin's Fund and the subsequent efforts of various Vicereines and of the practical support of the Indian Government and of private individuals is very well told, and shows how the value of the work of these medical women, and the need for it became more widely recognised, and how the organization became more widespread. The mistakes and shortcomings made in the early days are discussed with great candour and even emphasised, and also the efforts to improve the status of medical women.

The chapter on Women Medical Missionaries is full of sympathy with and insight into their work, past and present, and some interesting problems are put forward which are likely to affect them in the future, also of how they are devoting more attention to preventive medicine and Child Welfare work than in the past years.

The scope of the present day work is told of in the later chapters, general medical practice, the medical education of Indian women with the commencement of medical schools and colleges exclusively for their training, and of the great field of preventive medicine which is opening up branches of such particular interest to women workers, namely, maternity and child welfare work and medical inspection of school children.

Finally, there is a short account of research done by medical women in connection with childbirth and infancy and in it a note of regret is expressed that this research has been so limited considering the ideal conditions for it and the amount of material at the disposal of the workers, but with fairness pointing out the impossibility of both coping with the practical hospital work, with limited staffs and limited means preventing employing more, and also giving adequate time for research as well.

The whole book is not a long one, but its contents are so well thought out and the description of problems of the work so carefully considered, that besides being of much historical interest it is of great practical value to all those who have the health and welfare of the women of India and the future generation of the country at heart.

M. C.

MODERN PHARMACOLOGY AND THERAPEUTIC GUIDE.—By A. R. Majumdar, M.B., Bengal Medical Service, Teacher of *Materia Medica* and Physician, Campbell Medical School and Hospital, Calcutta. 1929. Pp. 540. Calcutta, The Book Co., Ltd., Price, Rs. 4-8.

It is becoming increasingly clear that the needs of the Indian medical student for cheap, yet accurate and reliable textbooks is being realised. We have previously reviewed the author's *Bedside Medicine* favourably, and may here say that we consider this companion volume to be equally good. In a foreword, Lieut.-Col. R. N. Chopra, I.M.S., Professor of Pharmacology, Calcutta

School of Tropical Medicine, writes that "the book is intended to be a stepping stone to the more detailed study of pharmacology. The author has certainly succeeded in his object and has put before the student in clear and concise terms the main actions of the important drugs and their therapeutic uses."

In brief, this volume is an Indian medical student's and practitioner's "Hale White." It is a summary of the author's lectures to students of the Campbell Medical School, Calcutta, studying for the L.M.S. qualification of the State Medical Faculty of Bengal. These students finish their medical curriculum in four years, of which the first two are devoted to pharmacology and materia medica among other subjects. They therefore require a textbook which shall be relatively simple, yet reliable, and suitable for everyday use.

The arrangement of the book follows upon the lines usual in such works. Successive sections deal with the inorganic pharmacopœia, vegetable products, animal products, a synopsis of pharmacology—outlining the general groups of drugs and remedies—; materia medica, pharmacy, incompatibility, a therapeutic and a general index. Throughout the book footnotes on almost every page give prescriptions and this lends a specially added value to the book, for they will prove very useful.

The publishers have carried out their work well, and the book is pleasingly free from misprints. It is of a convenient size and well printed—the use of leaded type serving to bring out the most salient points.

We are glad to welcome this book as one which is almost certain to appeal equally to the medical student and the general practitioner in India. It is well designed, well put together, and well published. It is an interesting example of progress in medical education in India.

R. K.

THE MEDICAL MUSEUM, BASED ON A NEW SYSTEM OF VISUAL TEACHING.—By S. H. Daukes, Director, The Wellcome Museum of Medical Science, Size 10" × 7", Pages 172. (The Wellcome Foundation Ltd., Endsleigh Court, 33, Gordon Street, London, W. C. 1.)

THIS book is not merely a theoretical contribution to the improvement of museums in general and medical museums in particular, but a description of practical achievement based upon theory and vision.

The author is precise, clear, and has obviously devoted much study, skill and care to a subject in which this book stamps him as an expert. Having in the first chapter discussed the functions of a medical museum and made a plea for reform and for a wider outlook, Dr. Daukes proceeds in subsequent chapters to describe and discuss the details of the new system of visual teaching on which the ideal medical museum is based.

This is followed by appendices dealing with the application and development of the system, with types of buildings, walls, screens, cases, labels, illustrations and technical details of preserving and mounting specimens. In conclusion there is a very valuable and complete bibliography of technical museum publications and 45 whole-page illustrations of screens, sections and specimens which are most helpful as providing practical evidence of the soundness and practicability of this new system of visual teaching.

The volume is most admirably printed, bound, illustrated, and got up.

The letterpress is in large, easily read type and the typography gives an air of distinction to the publication which is further enhanced by the technical perfection of the photographs of difficult subjects and the high quality of the half tone reproductions.

Everyone interested in museums, whether in regard to construction, development, control or use, should read and study this book. Having done so there will be a natural desire to see its methods developed in actual practice, which, fortunately, is possible for all those who can visit The Wellcome Museum of Medical Science, 33, Gordon Street, London, of which Dr. Daukes is Director.

Annual Reports.

REPORT ON THE ADMINISTRATION OF
BENGAL, 1927-28. CALCUTTA, BENGAL
SECRETARIAT BOOK DEPOT, 1929.
PRICE, RS. 6.

Climatic conditions and their effect on public health.—Even the slight departure of actual rainfall from the normal that occurred during the monsoon season of the year under review was not without its effect on the general public health of the province. The incidence of cholera and smallpox was practically double that of the previous year, while slight increases were noticed in dysentery, diarrhoea and respiratory diseases. Deaths from fever and all other causes, however, showed some improvement.

Vital statistics.—The very slight increase in the birth rate over that of the previous year and its attendant rise in the death rate points in the same direction. The net result of these two rates, as shown by the natural increase in the population, is very disappointing. It was 4.4 per mille in 1923, 3.6 in 1924, 4.7 in 1925, 2.7 in 1926 and 2.1 in 1927. Bengal has thus been standing last on the list for the last two years as compared with the other provinces. Its birth rate in 1926 was higher than Burma alone and the death rate lower than Bombay, Punjab and the Central Provinces. Again, all the other provinces except the Central Provinces and Burma had a lower rate of infantile mortality than Bengal. Although there was an increase of births over deaths in 20 of the districts of Bengal, this was more than counterbalanced by the prevalence of deaths over births in the remaining 6 districts—Hooghly, Howrah, 24-Parganas, Jessore, Khulna and Bakarganj, all contiguous to one another.

Epidemic diseases. *Cholera.*—Cholera and smallpox again reappeared this year in a more virulent form than in the previous one. The death rate from cholera increased by 92.3 per cent. compared with the previous year and the decennial mean; it practically rose to the same height as it did in 1919. The percentage of cholera deaths to total mortality was higher than it had ever been during the last 20 years. About 22 per cent. of the total number of villages in the province were affected. Starting on its upward trend in December 1926, it continued with fluctuating intensity till May, when it declined. It again became very virulent towards the latter part of the year. Practically all the districts were affected except Jalpaiguri and Darjeeling which escaped lightly, Malda being the worst sufferer. Had it not been for the timely vigorous measures adopted by the local bodies in co-operation with the Public Health Department, it would have undoubtedly fared worse with Bengal. The anticholera inoculation, which has already established its reputation in the previous years, proved, as usual, extremely efficacious in controlling local outbreaks. About two and a half million cubic centimetres of the vaccine were issued and nearly two million inoculations were performed. Again 39,356 wells and 33,550 tanks, in addition to a number of river ghats, were disinfected by the local sanitary staff, besides 3,592 wells, 1,235 tanks and 504 latrines done by the staff under the Public Health Department. The local sanitary authorities also undertook disinfection of the infected houses and of the patients' clothes wherever possible. The Public Health Department co-operated by making a free supply of disinfectants to the local bodies and placing at their disposal the services of 100 Sanitary Inspectors and 20 Sub-Assistant Surgeons sanctioned temporarily by the local Government in addition to those of their permanent medical staff. Special watch was maintained over pilgrims for Puri Rathjatra and Gangasagar festivals. The Publicity Department arranged for the distribution of posters, lectures and magic lantern demonstrations to enlighten and educate the public on the preventive measures essentially required to be adopted in this connection.

It was with the help of these measures that cholera epidemics were kept within proper control.

Smallpox.—The quinquennial outbreak of smallpox which started towards the end of 1924 entered upon the fourth year of its existence during the year under review, and it seems that by the end of the year it had not spent its force. In fact, it appears more than probable that it will finally merge in the pandemic forecasted to appear about 1930-33. Its virulence is shown by the fact that the death rate in 1927 exceeded the previous year's rate by 80 per cent. and the decennial mean by 200 per cent. It was ten times higher than what it was in 1923, which was a normal year. The death rate was practically doubled in all the other towns and trebled in Calcutta. The urban rate exceeded the rural by about 70 per cent., thus proving that smallpox is more particularly a disease of the towns than that of the villages. A little over 10 per cent. of the total villages in the province were affected, indicating the widespread nature of the epidemic. The age distribution is very interesting. About a quarter of the total number of deaths appear to have occurred among infants and children below 10 years of age and the remaining three-fourths among age periods above 10, thus emphasising again the necessity of repeated revaccinations as soon as the effect of a previous vaccination has worn off, which it gradually does from 5 to 7 years. With the exception of Darjeeling, Jalpaiguri, Khulna, Bakarganj, Bankura, Rajshahi, Jessore and Nadia, which suffered comparatively lightly, all the other districts were more or less seriously affected, the main brunt being borne among others by Midnapore, Murshidabad, Calcutta, Pabna, Bogra, Rangpur and Malda. The Malda epidemic deserves more than a passing notice. The outbreak first made its appearance towards the middle of November 1927, and very soon became widespread, so much so that before the year was over it had affected about 12.7 per cent. of the villages in the district and claimed 1,537 victims. Its virulence can be judged from the following statement showing its weekly progress for 18 weeks from its commencement:—

Week ending—	Cases of smallpox.	Deaths.
January 7th, 1928 ..	157	21
" 14th, " ..	158	32
" 21st, " ..	249	45
" 28th, " ..	111	36

" 11th, " ..	367	52
" 18th, " ..	298	94
" 25th, " ..	314	66
March 3rd, " ..	479	89
" 10th, " ..	286	64
" 17th, " ..	378	80
" 24th, " ..	380	78
" 31st, " ..	390	64
April 7th, " ..	819	165
" 14th, " ..	831	189
" 21st, " ..	575	140
" 28th, " ..	398	115
May 5th, " ..	387	86

A campaign of mass revaccination was immediately started, with the active co-operation of the energetic District Magistrate, Mr. J. Peddie, I.C.S., and up to the present nearly half a million vaccinations have been performed. In addition to the district board expenditure, the local Government have contributed Rs. 6,800 towards meeting the cost of the campaign which is still going on. This campaign by its results has conclusively justified the belief that if timely measures are taken, it is reasonable to expect a complete control of smallpox outbreaks before they assume epidemic proportions. Warned by the Public Health Department from time to time and guided by their own previous experience, the District Health Officers have not been slow in starting mass revaccinations in many of the affected districts: in fact, the process has been continuously going on ever since the present quinquennial outbreak started.

From 2,057,724 vaccinations in 1923-24, the number has risen to 3,975,837 in 1927-28, and this reflects great credit on the activities of the local bodies. Going still further back, it is observed that the number of vaccinations during the last 20 years has increased by 109.5 per cent. and this increase has especially been marked since the transfer of the rural vaccination affairs from the Civil Surgeons to District Health Officers in 1921. Some of the districts, e.g., Pabna, Malda, Murshidabad, Dinajpur and Darjeeling, in fact have more than trebled the number of vaccinations during this period. But in spite of their best efforts, the District Health Officers feel that their work is extremely hampered by the absence of compulsory legislation to enforce revaccination and by the law's delays according to the present procedure of dealing with the offenders. The Government as usual contributed Rs. 50,000 during the year for promoting free vaccination; the expenditure of the district boards as a whole for this purpose was also considerably increased as compared with the previous years.

Malaria.—The death rate from malaria further decreased during the year, the trend still continuing on the decline. Even so, it accounted for 36.1 per cent. of the total mortality in the province. Judged from the total admissions from this cause to the various medical institutions, the number of cases began to increase gradually from July till it reached its maximum in November. Nadia and Burdwan with a mortality of over 50 per cent. were the worst sufferers, while Daeca, Tippera and Bakarganj escaped very lightly with a rate below 10 per cent. The death rate in rural areas was a little over 5 times of the urban rate. The diminished incidence of malaria was responsible for a reduced consumption of quinine by 1,227 lbs. as compared with the previous year. The other anti-malarial activities consisted in the experimental schemes at Banka Valler, Jangipur, Singaran, Toposi, Meenglas and Krishnagar, which were continued during the year. A number of anti-malarial co-operative societies, some recently established and organised, the kala-azar centres and the district board dispensaries, in addition to distributing quinine, treated these cases also, while the former in addition carried out minor anti-malarial operations.

Kala-azar.—Kala-azar mortality showed a decline throughout, the death rate being reduced by 19.4 per cent. for the province, 27.4 per cent. for the towns and 14.3 per cent. for the rural areas compared with the previous year. In Calcutta the decrease was 15.6 per cent. Thus, the improvement started in the previous year was maintained during the year under review. Rajshahi, Nadia, Jessore and the 24 Parganas returned the highest death rate, while Birbhum, Bankura and Midnapore were practically free. Kala-azar cases treated at the various dispensaries and special treatment centres, however, showed an increase in 19 districts over the preceding year and a reduction in the remaining 8. This increased attendance shows the anxiety of the people to get themselves cured of the disease, which their own experience has shown them to be amenable to the latest method of treatment. The Government contributed a sum of about Rs. 2 lakhs during the year for stamping out kala-azar, and with the help thus received the district boards were able to maintain 964 special treatment centres during the year. Of these, 69 are being run by voluntary public health agencies, e.g., the Central Anti-malarial Co-operative Society and Bengal Health Association.

Other epidemic diseases.—Filariasis is reported by the District Health Officer, Bankura, to be spreading in his district, where some of the villages in the Sadar subdivision are said to be full of lepers. About 50 per cent. of the people in the Sariakandi and Dhunat police-stations in Bogra district are stated to have enlarged thyroid. Cases of epidemic dropsy have been noted in Bakarganj and Faridpur districts.

General.—The amount of school hygiene work done by local bodies in the mufassal during the year surpassed all past records. The Vishva Bharati at

Santiniketan (Bolepur) in the district of Birbhum, the Karapara High English School in the Khulna district, the Shyamagram High English School in the Tippera district and the Burdwan Raj School at Kalna in the Burdwan district, initiated school hygiene work in their institutions through registered medical practitioners, and the District Board of Hooghly and the Municipalities of Chittagong, Krishnagar, Serampur, Nabadwip and Hooghly-Chinsura through their respective Health Officers. One hundred and ninety-six schools and 11,746 boys were examined by the officers of the Bengal Public Health Department. The Assistant Director of Public Health in charge examined 131 plans and reviewed 2 books on Hygiene.

Grants were made to the various local bodies for *dai*-training. Altogether 1,170 *dais* were thus trained in 104 classes started by 49 local bodies and one health society. It is expected that if this rate is maintained, the infant mortality will, in course of time, be greatly reduced.

The Publicity Bureau of the Public Health Department has come to be recognised as an institution of national importance, judging from the gradually increasing and pressing demands for its officers and materials by all classes of public bodies, irrespective of party denominations. Three hundred and forty lectures were delivered and 131 bioscopic shows given by the officers of the bureau during the course of the year. As a result of this educative campaign, 35 health exhibitions and 32 baby shows were organised during the year compared with 10 exhibitions and 20 baby shows held during the previous year. Mention may be made in this connection of the Eastern Bengal Railway demonstration train, organised as the result of a suggestion made by the Public Health Department. No less than 186,000 people visited the demonstration health car. A series of health lectures was delivered to the prisoners in the Central and Presidency Jails at Calcutta. Sixty-one sets of multi-coloured magic lantern slides were designed and prepared by the Publicity Branch during the year, in addition to two films on maternity and child welfare.

Rural public health organisation.—The summary would be incomplete without special mention being made of the rural public health organisation scheme. This scheme came into operation during the month of August 1927, when 138 rural health circles, each corresponding with a police thana unit, were started. Each circle was placed in charge of a staff consisting of a rural Sanitary Inspector, a Health Assistant and a carrier directly under the control and supervision of the District Health Officers. With the increase in the number of available Sanitary Inspectors, the number of health circles rose to 258 during the year. The total number of health circles admissible under the scheme for the whole province is nearly 600. The officers in charge of the health circles being responsible for the entire epidemic work including vaccination in their respective jurisdictions, the existing staff of Vaccination Inspectors and Sub-Inspectors are being gradually absorbed in the rural public health establishment, and as such will finally have no independent existence.

GOVERNMENT OPHTHALMIC HOSPITAL,
MADRAS. ADMINISTRATIVE REPORT,
STATISTICS AND PROFESSIONAL REPORT
FOR THE YEAR 1928. BY LIEUT.-COL. R. E.
WRIGHT, M.D., C.I.E., I.M.S. MADRAS:
SUPERINTENDENT, GOVERNMENT PRINT-
ING. PRICE, RS. 2.

COLONEL WRIGHT'S annual reports are very different from the usual type of annual report which we are alled upon to review, for they are full of interesting important matter. In fact we cannot conceive of e information for Rs. 2—the price of the report—where. The medical man who practises eye work s country should undoubtedly purchase it annually. write this not to push the sale of an official publi- but solely in the interest of our readers.)
ort for 1928, as usual, is divided into a long
ing professional report, tables of statistics,

and a short administrative report. Colonel Wright has much to say about the important question of preventable blindness in India, and this is dealt with in the editorial for this month, so that only the rest of the report remains for review.

No less than 25,282 out-patients and 3,936 in-patients were treated during the year; the average daily totals dealt with being 253.9 for out-patients and 247.7 for in-patients.

Cataract is the first subject dealt with. Here Colonel Wright is very emphatic. Operative work on cataract seems to be an obsession with a high percentage of ophthalmologists in India. They will neglect the emergencies of ophthalmology, the acute glaucomas, the hypopyon ulcers, and the causes of preventable blindness, such as keratomalacia, and endeavour to establish a reputation as cataract operators. They will rush into print with trivial and unimportant articles. Ophthalmic surgery in India appears to mean cataract operation and nothing else to far too many medical men in the country; the real science of ophthalmology is neglected and the opportunities for scientific investigation missed. Further, far too many men carry out cataract operations who are not competent to do so, and add their dozens or hundreds to the cases of preventable blindness in India.

The Madras practice in cataract operation is substantially that described in Colonel Kirkpatrick's small textbook, but naturally many changes in procedure have crept in during the past ten years. Nearly all the patients get novocaine blocking of some sort, 7th nerve, ciliary ganglion, circumorbital muscles, or local infiltration of the levators. Control of the lids after the operation by means of sutures is at present in vogue, but some simpler and better method remains to be devised. Anyhow the old days when the patient was seriously able to interfere with the operation by squeezing the lids together are gone.

The second big step forward in cataract operation is the necessity for some simple, quick and efficient method of maintaining the lips of the section together as the last step in operative technique. What amounts to twilight sleep may have to be administered to troublesome patients; blocking of the 7th nerve was employed in 508 cases and deep orbital or ciliary novocaine injections in all Barraquer cases, and in practically all cases where it was desirable to obviate pain. Bridge flaps are unsuitable owing to the special tendency to hæmorrhage in Indian patients. This method was tried out on an extensive scale during the year and every type of flap resorted to, the method being tested in 617 cases during the year. But the method increases the time taken over the operation, the lens matter does not come away as cleanly as it does without a flap, and blood clot under the flap is a bugbear. The irrigator is here of great help, and should be resorted to. But bleeding is a serious matter in Indian patients, not only at the time of operation but afterwards from the tendency for pigmented fibrous bands to form. Arteriosclerosis of old age is an element in the causation of this tendency to bleed, but is not the only factor. Hypo-adrenia may be a factor, but theorising does not help in the operating theatre. For the present Colonel Wright proposes to retain bridge flaps until he evolves something better.

The iridectomy adopted is nearly always a peripheral button-hole. Cases in which the pupil will not dilate with free instillations of cocaine, atropine and homatropine are often associated with central or peripheral posterior synechiae. These and others with frank old standing iridocyclitis are better dealt with by a complete iridectomy. For opening the capsule needling has always been the method adopted in Madras, but one wants something better, some method of removing the whole of the anterior capsule. During the year a method was adopted by which a flap of the anterior capsule is formed with its hinge below, this flap being torn off before or after delivery of the lens.

The question of intra-ocular pressure in the posterior segment during operation was investigated in a large number of cases. The majority of cases operated on in India are old patients with loss of elasticity in the

muscles and a diminution of fluids in the tissues of the orbit and globe—"withered eyes" in fact. Anchoring of the globe otherwise than by a tangential force raises the intra-ocular pressure and causes the lips of the section to gape. The various hooks and forks used in this connection are unsatisfactory; if the patient can be made to look steadily downwards (and with nerve block this is secured more readily than without it) the operation proceeds satisfactorily. "The comfort of operating on a patient who can bring no muscle power to bear, either circumorbital or orbital, and who cannot feel, would be appreciated by those who have to operate on patients such as we sometimes deal with." Intra-ocular hemorrhage is still a further factor in raising the intra-ocular tension.

The state of the vitreous, rather than muscular action, would appear to explain the tendency of the corneal section to gape in some patients. In 164 such eyes the tension was normal or subnormal in 158. In certain pathogenic states the vitreous appears to be increased in volume, whilst the state of turgescence of the choroid is also important. The reverse condition, where the eye is sunken, and on removal of the lens the iris drops backwards, is apparently due to an essential shrinkage of the vitreous. Of 1,187 eyes operated on in connection with which the posterior segment pressure was observed 214 were normal, 412 showed an increased intra-ocular pressure, and 561 diminished pressure.

The vitreous loss rate for all types of cataract and all operators in the hospital is low, 1.87 per cent.; for straightforward capsulotomy 0.75 per cent. This improvement on the previous records Colonel Wright attributes to the nerve-block methods of control which he now uses so extensively. The iris prolapse rate for all cases was 1.39 per cent.; for straightforward capsulotomy 1.16 per cent.; and of 1,314 straightforward capsulotomy cases operated on by Colonel Wright and Dr. Nayar Avargal, D.O.M.S., the vitreous loss rate was 0.61 per cent. and iris prolapse rate 0.97 per cent.

"Safety first" in brief is the motto of the Madras School with reference to cataract extraction (and we could wish that other operators in India would adopt it). Each case must be studied on its own merits, and mass operations are rather a mistake. A single morning may exemplify practically every well-known device for aiding the extraction of the cataractous lens.

Patients for the Barraquer operation have to be very carefully selected. It is more suitable for the sunken than for the bulging type of eye. In the former class of case, subsequent to the iridectomy, the chamber is filled with saline. In the latter, the trouble is that the vitreous tends to follow the lens and push the iris forward with it. The method is especially suitable for immature cataracts, where the patient from economic reasons desires early operation rather than to wait for ripening of the lens.

On p. 10 of the report a most interesting table is given of the methods of cataract extraction used during the year; of a total of 1,870 cases, 1,460 were dealt with by capsulotomy, 6 by the intracapsular operation, 243 by Barraquer's method of phacoerisis, 2 by linear operation.

Glaucoma forms the second subject dealt with in the report. During the year a clinical investigation was carried out into the different non-operative methods of treatment of primary glaucoma, each case being dealt with in accordance with a definite plan of examination. The total number of cases of which such a record was kept were 100. These cases fall into two main groups, congestive or non-congestive, i.e., posterior segment types, or anterior segment types. In the former the important factor is the increase in bulk of the vitreous which pushes the iris forward. In these, cupping of the disc may not take place until quite late in the history. In the anterior segment type of case there is chronic glaucoma with a normal chamber, an iris in the vertical plane, and deep cupping. Investigations were carried out with regard to biochemical examination of the blood of the patients, the presence or absence of syphilis, the general blood-pressure, intra-ocular tension, and other factors. "From a clinical point of view there was

nothing to distinguish our glaucoma cases from our non-glaucomatous cases except the local changes." A large number of empirically suggested drugs were tried; intravenous iodine, intravenous hypertonic saline, intravenous injections of sodium sulphate, drugs applied locally and others taken by the mouth. The results were poor; intravenous injection of hypertonic saline (30 per cent.) and sodium sulphate (30 per cent.) will bring the increased intra-ocular pressure down with a sudden drop, but it rises again within the next 6 to 8 hours. Eserine and local adrenalin pack may be helpful in bringing the patient into a far better condition for operation than he would be without them. In one case homatropine, used as a means of diagnosis, produced a rise which was uncontrollable by any means except intravenous hypertonic saline.

Sclero-corneal trephining remains the sheet anchor in the treatment of glaucoma, and was adopted in 92 cases as against 21 treated by other methods of decompression. Anterior segment cases are easier to handle than posterior segment types.

Refraction.—In the refraction rooms 2,392 cases were dealt with. "Bifocals" are extremely popular in Madras; even bifocals of plain glass! Although the ordinary patient usually goes to the bazaar to have his refraction tested, yet the pressure on this department is so heavy that the refraction room has been so increased in size as to allow six in place of three assistants to do routine examinations.

The professional part of the report contains, as usual, a number of selected and interesting case reports. For these we must refer our ophthalmological readers to the original report itself. Two cases of angiomatosis retinae were observed, and ten cases of brain tumour or allied conditions. A case of cystic tumour of the hypophyseal region is illustrated by a photograph and skiagrams. Another very interesting case was one of internal hydrocephalus in a male of 19, following syphilis, with extensive pressure markings on the floor of the anterior fossa.

The report then goes on to deal with the principal diseases seen in out-patients. Here catarrhal conjunctivitis (5,820 cases), Koch-Week's conjunctivitis (2,045), and angular conjunctivitis (856), head the list. Then follow superficial punctate keratitis (801), ulcers of the cornea (746), phlyctenular conjunctivitis (762), trachoma (642), and follicular conjunctivitis (284).

Trachoma is often misdiagnosed as such by the ordinary medical man. "Granular lids" is in reality no diagnosis at all; it may mean anything. The result, however, of such a universal diagnosis is the almost universal application of severely irritant treatment which may do untold harm to lids which, otherwise, might have recovered if left alone. An interesting case was one of possible trachoma where an intravenous injection of iodine was followed by acute iodism with a generalised rash; a month later the eye condition had completely cleared. Webster's operation is used in the treatment of entropion following trachoma. Enucleations and eviscerations are now done freely in the out-patient department under local anaesthesia, thus saving both time and beds.

The pathological department examined 74 eyeball specimens and 57 others. Blood specimens sent for the Wassermann test numbered 1,300, of which 328 were positive and 972 negative. Tumours and neoplasms constitute an interesting section of the work and several are here detailed; a melanotic sarcoma of the upper lid, a Meibomian carcinoma, a cavernous angioma of the orbit, a basal-celled epithelioma of unusual type, an epithelial tumour of the nose invading the orbit, an aneurysm of the orbit, and an angioma of the lid and anterior temporal region. A special study of lymphoblastoma of the orbit and allied conditions has been made by Colonel Wright, and an article dealing with this subject was published in the *Lancet* for the 19th January, 1929. Blood-pressure in the patients treated in the hospital is in general low, only some 50 per cent. having a systolic pressure of 120 and over. Glaucoma is not associated especially with an increased general

blood-pressure; and almost all of the really high pressures are associated with kidney disease and albuminuria.

The acquisition of a supply of radium by the local government enabled 11 cases to be treated up to the end of 1928. It proved of considerable value in a case of lymphoblastoma, but not as active in a case of glioma. Angiomata, rodent ulcer, orbital aneurysm, and localised carcinomata were treated by radium. Among interesting cases dealt with were a hypopyon ulcer due to a fungoid infection, and cataract in two sisters aged 3 and 8 years respectively. For leucoma tattooing with gold chloride was found inferior to Indian ink.

A special investigation carried out during the year was one into an epidemic of superficial punctate keratitis which commenced in May and lasted over into 1929. Over 800 cases were seen during this period. This appears to have been due to a filter-passing virus, and to be a condition similar to herpes febrilis. It is probably similar to the keratitis described by Herbert in Bombay in 1901, and that described by Kirkpatrick in Madras in 1920. Inclusion bodies appear in the corneal epithelium which very much resemble those characteristic of infections with the filtrable viruses.

Both under-graduate and post-graduate training in ophthalmology at Madras is considerably in advance of that at most English-speaking medical colleges. From sub-assistant surgeons to I. M. S. men are continually coming for training. New ophthalmic teaching centres have been opened up of recent years by the Madras Government at Vizagapatam, Calicut, Tanjore, Madura, and elsewhere, largely staffed by men trained at the Madras hospital. A licentiatehip in ophthalmology has been established and is much sought after. The report includes a most interesting map showing the distribution of government ophthalmological departments connected with schools or colleges, ophthalmological departments connected with missions, and the distribution of men with more and less than six months' training respectively at the Madras School, throughout the Madras presidency. No other province in India so far can show a similar map.

* * * *

The second section of the report is given over to statistical tables; a table of cases treated by radium; one of 500 blood-pressure readings arranged by ages and diseases; and then comes the administration report as the final section of the annual report. During the year 128 medical students and 72 post-graduate students received training at the hospital. The expenditure during the year on establishment, medicines and stores, diets, buildings, etc., came to Rs. 1,90,975. The year proved a most unfortunate one with regard to the staff. Lieut. C. G. Taylor, I.M.D., the resident medical officer, who had done duty for 17 years in the hospital had to take leave on account of ill-health and will not be able to resume his post; Assistant Surgeon V. G. Muttayya, who had served the hospital for 19 years died, and the loss of his valuable services is irreparable. Sub-assistant Surgeon A. K. Pillai, after 9 years service in the hospital, has been transferred.

Colonel Wright's report should be read in the original by everyone interested in ophthalmic work in India. It is too important a document to be regarded merely as an official publication.

ANNUAL REPORT FOR 1928 OF (I) THE NATIONAL ASSOCIATION FOR SUPPLYING MEDICAL AID BY WOMEN TO THE WOMEN OF INDIA (COUNTESS OF DUFFERIN'S FUND); (II) THE VICTORIA MEMORIAL SCHOLARSHIPS FUND; (III) THE LADY CHELMSFORD ALL-INDIA LEAGUE FOR MATERNITY AND CHILD-WELFARE. CALCUTTA: GOVERNMENT OF INDIA CENTRAL PUBLICATION BRANCH, 1929.

These three reports are incorporated in one volume. The first deals with the Countess of Dufferin's Fund and the Women's Medical Service in India. This records a rather disappointing year; not only was the

proposal to increase the permanent Government of India yearly subsidy refused, but even temporary help in the form of non-recurring grants was refused; two vacancies could not be filled in consequence and the W. M. S. doctor withdrawn from the Women's Hospital, Hyderabad, Sind. The Council feel so strongly the hopelessness of coping with the work of supplying well qualified women doctors in India without increasing aid from Imperial revenues that a memorandum on the subject was prepared and laid before the Indian Statutory (Simon) Commission in March 1929.

This memorandum (on p. 83 of the report) is one which should be read by every thinking medical man (and woman) practising in India to-day. It briefly sums up the history of the Women's Medical Service in India, its objects, its present, and its future. Provincial contributions have been exceedingly disappointing, and the income from central revenues is only Rs. 3,70,000. In conformity with the Lee concessions to other official services, in 1919 passage and similar concessions were granted to officer of the W. M. S., and a more liberal provident fund inaugurated (there is no pension in the service). The result was that in 1927, with a cadre of only 44, there was a deficit, and the cadre has now fallen to 42. But, as medicine is a transferred subject under the Montagu-Chelmsford reforms, the central Government consider that the expansion of the service is more a matter for provincial governments. It is estimated that at present about 400 women doctors with registrable qualifications are working in India; 42 in the W. M. S. and 15 in the junior branch of that service and its training reserve; about 90 under provincial governments and in local fund hospitals; about 150 under the different missionary societies, and some 100 in private practice. The female population of India is roughly 120 millions; and this provision works out at one qualified female doctor for every 300,000 of the female population of British India. Yet the gurdah system is almost universal, maternal mortality is fearfully high, there is the urgent necessity for medical teachers into the diseases of women in this country, female medical teachers are demanded, and even in ordinary medical and surgical cases female patients refuse to be attended to by a male doctor. Thus the W. M. S. is in a most difficult position; with medicine a transferred subject, the Imperial Government clearly feel that they can do no more for it than they are doing already; whilst the Provincial Governments are too poverty-stricken to take up the matter. It will be interesting to see what the Simon Commission makes of this matter; to those who know India there can be hardly any subject more vital than the supplying of medical aid to the women of India by well qualified women doctors. It is not a mere matter of advisability, but of necessity; the W. M. S. has in it the seeds of a very important future organisation; at present, however, its work has to be cut down for want of funds. Here, surely, there is an opening for generosity on the part of Indian philanthropists. With the present grant-in-aid by the Imperial Government, supplemented by large donations by Indian princes and merchants who realise what the W. M. S. means, there might be created a body on lines similar to that of the Indian Research Fund Association, and with even wider facilities for useful work.

To return to the main body of the report, a second disappointment during the year was the refusal of the Rockefeller Foundation to give a grant towards research work on maternal and infant mortality. Her Excellency Lady Irwin, however, sent out a special appeal in March 1928, and a sum of Rs. 15,431 was collected. This enquiry of Dr. Balfour's at the Haffkine Institute, Bombay, has often been referred to in our columns, and it is satisfactory to note that the sum raised was sufficient to enable a second research worker (Dr. Christine Thomson) to be brought out from Home, whilst the Indian Research Fund Association has added a third worker (Dr. Lucy Wills) to the enquiry at the expense of the Fund. Thus this vital investigation has been strengthened, and its results should be of cardinal importance with regard to maternal and infant mortality.

in India—(perhaps a more important problem than India's future political constitution of the defence of her frontiers).

During the year Dr. Mary O'Brien Beadon, w.m.s., was officially appointed to serve on the committee to consider the Age of Consent Bill now before the Imperial Assembly, a task for which twenty years of service in north India and the principalship of the Agra School of medicine for women specially fitted her. Many medical women in India, including members of the W. M. S. gave evidence before this committee.

"The universal cry from all W. M. S. doctors from Karachi to Calcutta," says the report, "is for more money to supply the barest necessities for their hospitals." Here we read that provincial governments, local bodies and the like take but a lukewarm interest in the institutions concerned and that "the Indian public will not give in charity to their support." (We wonder whether the last mentioned state of affairs cannot be remedied. Surely hospitals run by medical women for the women of India should be strongly supported by the Indian public. Indians are usually willing to give or bequeath the money to hospitals. The policy of fixing upon a sum of Rs. 500 to Rs. 5,000 to endow and name a bed, or of Rs. 50,000 to endow and name a ward was one of the most successful methods adopted by Sir Leonard Rogers in his up-hill fight for the Hospital for Tropical Diseases in Calcutta; and the ladies, with their free entry into the purdah, should surely be able to go one better. It is the personal touch that tells; letters are no use for raising money; a letter asking for an appointment and followed up by a personal visit often achieves the unexpected. The reviewer speaks from personal experience, for he once strolled down Clive Street after a morning of begging with cheques for Rs. 80,000 for the Carmichael Hospital for Tropical Diseases and the Calcutta School of Tropical Medicine in his pocket as the result of a morning round, and the promise of more to follow.)

Twenty-six scholarships were given during the year to lady students at the various medical colleges in India. Of the cadre of 41 officers in the W. M. S. at the end of the year, 19 had a European domicile and 22 an Indian domicile. "The Service has done good, steady and conscientious work during the year. In many hospitals doctors are fighting a difficult game, having to work in wretchedly constructed, rapidly deteriorating buildings, with poor equipment and an inefficient staff. The struggle to make both ends meet is a constant anxiety and adds enormously to the heavy responsibility entailed in the care and treatment of patients in considerable climatic difficulties and often great loneliness."

During the year 4 officers left the Service and 1 new recruit joined. The Lady Hardinge Medical College Hospital, New Delhi, treated 1,584 obstetrical and gynaecological cases during the year as in-patients. On the 12th September, 9 babies were born in the labour ward within 6 hours—a record for the institution. New departures are field block local anaesthesia with novocaine and adrenalin, intra-uterine injections of sterile glycerine in puerperal sepsis, and the present-day methods of treating pernicious anaemia. Admissions to the surgical unit numbered 493, and to the medical unit 909. Pathological examinations for the year totalled 5,330. An interesting finding was a pure culture of diphtheroid bacilli from the cerebro-spinal fluid of a case of meningitis in a baby; of 44 throat swabs 17 showed diphtheria bacilli, and the disease is not nearly as negligible in India as is usually supposed. The outpatient department attended to 12,027 patients.

A long series of local reports follow, from the Victoria Zenana Hospital, Delhi; the Lady Reading Hospital for Women and Children, Simla; Dera Ismail Khan; the Lady Sandeman Dufferin Hospital, Quetta; Madras; the Victoria Hospital, Vizagapatam; Bombay; Shikarpur; Karachi; the Dufferin Hospital, Calcutta, where the septic ward has been remodelled, and generous donations from the Calcutta Football Association are recorded; Agra; Lucknow; Cawnpore; Allahabad; Benares; Lahore; Rawalpindi; Nagpur; Jubbulpore; Chhindwara; Berar; Amraoti; Shegaon; Bettiah and

Gaya. This mere list of places alone shows what important and widespread work the W. M. S. is doing in India. The report then closes with financial statements and observations. The general financial statement for the Countess of Dufferin's Fund shows that the total income was approximately Rs. 41,620 and total expenditure Rs. 38,718; with a closing balance of invested securities of Rs. 7,50,444. The income of the Women's Medical Service was Rs. 4,14,955 as against an expenditure of Rs. 3,89,368; with a backing of Rs. 5,93,595 in investments. Annexure VII then gives details of hospitals under the W. M. S. in 1928, with regard to staff, nurses, work done, and statistical tables for obstetric, gynaecological, and other cases attended to, and operations performed. A nominal list of members of the Women's Medical Service follows (Annexure XI).

The second report included in the volume is the 27th annual report of the Victoria Memorial Scholarships Fund. Here the work chiefly carried out is the training of *dais* at very numerous centres throughout India and their subsequent examination. And here there appears to be some difference of opinion; is it better to get hold of local *dais* and try to train them, or to import properly trained midwives into the different centres of population? Really good teachers for the former class of pupil are scarce, and health visitors who are only partly trained themselves do not make good teachers. This line of work, however, was especially opened out during the year in Bihar and Orissa, and in the Central Provinces, whilst a beginning was made in Assam. In Assam the classes for selected young women from the tea gardens with no previous experience of midwifery work proved very successful and were eminently practical, under the supervision of Dr. Winifred Thompson of St. Luke's Hospital, Chabua.

The financial statement which accompanies this report shows that the Fund is in a sound condition, with an annual expenditure of Rs. 50,880 and reserve investments of Rs. 7,88,773.

The third and final report included in the volume is that for the Lady Chelmsford all-India League for Maternity and Child-Welfare for 1928. The work carried out by this League consists chiefly of the establishment of health schools, the work at different centres where *dais* are trained, and propaganda. The health schools are for the training of health visitors, and from very small beginnings ten years ago the organisation has now spread widely all over India, and the provincial governments of the Punjab and Bengal as well as of other provinces make contributions which render such schools completely or nearly self-supporting. The Lady Reading Health School at Delhi is the most important of these schools, and 13 students passed their final examination in July. These are already working at different centres scattered throughout India. The Bengal and Madras schools continued to do useful work during the year, and a new school was opened in Lucknow. The work at the different centres is concerned with the training of *dais* and the organisation of health weeks. Infant welfare centres are maintained all over India. The work on propaganda has diminished considerably, owing to the fact that provincial public health departments have largely taken over similar duties. Baby Week was celebrated during the year in many different centres in India.

This League again shows a satisfactory financial statement; an annual expenditure of Rs. 55,985, with investments of Rs. 8,77,831.

* * *

We have reviewed this report perhaps at some length, but that is because we are convinced that to a very large extent the future of medicine in India lies with the medical women in India. The Women's Medical Service in India may be no one's child; neither a legitimate object upon which imperial revenues may be expended—since medicine is a transferred subject; nor a matter of much interest to provincial governments who are trying their best to economise. Yet it is an organisation in being and one which is almost certain to expand to limits almost equivalent to those of the general civil medical organisation for India. It is interesting to note

that of recent years these three reports have now come to be combined in one annual volume, with a central office organisation for all three organisations. The reports appear to suggest some overlapping, and—to the uninitiated reviewer—it appears that a really strong and effective organisation might be built up by a combination of the three into one organisation. The one cardinal feature of the year is the memorandum presented to the Simon Commission. Will that Commission realise the tremendous present and future importance of medical attendance upon the purdah women of India by medical women, and what will it recommend?

Correspondence.

THE USE OF PNEUMOCOCCUS IMMUNOGEN COMBINED IN THE TREATMENT OF PNEUMONIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I was very interested to read the results of Dr. G. B. Bhaduri's treatment of lobar pneumonia with Pneumococcus Immunogen Combined (P. D. & Co.) in the leading original article of your June number.

It would be of interest to know the ages of these patients, a point which Dr. Bhaduri seems to have omitted.

The death rate from lobar pneumonia after the age of 45, as far as my experience goes, is invariably high, even with the newer forms of treatment which have been advocated from time to time, and it would be interesting in order to gauge the value of the new treatment, to have the mortality rate of the higher ages compared with the group who received ordinary treatment.—Yours, etc.,

A. R. D'ABREU, F.Z.S., L.M.S.S.A. (Lond.),
Civil Surgeon,
Mianwali.

MIANWALI (PUNJAB),
9th July, 1929.

STANDARDISED LIVES AND THEIR ASSESSMENT IN LIFE INSURANCE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the review on p. 292 of your issue for May 1929 of my handbook on standardised lives and their assessment in life insurance, whilst thanking the reviewer, there are a few points in his review with regard to which there is some misapprehension.

He writes: "It is rather surprising that in dealing with the subject of albuminuria, the author makes no reference to kidney efficiency tests." These are undoubtedly of great value, but in what is intended to be a small handbook on the subject it is hardly possible to include such details; to do so would be to make the book more bulky than a handbook should be. Large treatises on the subject already exist, and may be referred to for details of such tests. Both my *Pocket Guide to Medical Life Assurance* and the *Substandard Lives*, are intended for up-country medical examiners and may perhaps be more useful to them than large sized tomes.

With regard to "no mention being made of diastolic pressures," I may explain that blood pressure examinations are very difficult to carry out at up-country stations and remote *mofussil* towns where, oftener than not, the medical examiner, who generally happens to be a Sub-Assistant or an Assistant Surgeon or an L.M.P., does not possess the necessary instruments and very often lacks the experience for such an examination. Hence he often commits blunders in not correctly recording even systolic pressures, leave alone diastolic, which are much more difficult even for an experienced examiner to record with any exactitude. I have, therefore, not attempted to treat the subject more fully, as I should have otherwise done.

With regard to some of his other criticisms and suggestions, I certainly appreciate them and shall try to utilise them in the third edition of my *Pocket Guide*, which I hope to publish about the end of this or early next year.

The proofs, as he rightly says, have unfortunately not been carefully revised. But as the book was reprinted in *America*, from my articles contributed to the *Insurance Journal*, I had no opportunity of correcting them personally or even writing a foreword.—Yours, etc.,

JEHANGIR J. CURSETJI.

ORIENTAL GOVERNMENT,
SECURITY LIFE ASSURANCE CO.,
BOMBAY,
2nd July, 1929.

Service Notes.

APPOINTMENTS AND TRANSFERS.

LIEUTENANT-COLONEL H. W. ILLIUS, C.I.E., F.R.C.S.E., I.M.S., Civil Surgeon, Benares, is appointed to officiate as Inspector-General of Civil Hospitals, United Provinces, during the absence of Colonel Sprawson.

Major P. F. Gow, D.S.O., M.B., I.M.S., officiating Professor of Midwifery, Medical College, Calcutta, and Obstetric Physician and Surgeon to the College Hospital, was appointed to act as Second Professor of Midwifery of the institution, in addition to his own duties from the 22nd March to 18th April, 1929, both days inclusive.

The services of Major J. M. R. Hennessy, I.M.S., are placed temporarily at the disposal of the Government of the Central Provinces, with effect from the termination of his present leave.

The services of Major J. C. Bharucha, I.M.S., are placed temporarily at the disposal of the Government of Burma for employment in the Burma Jail Department, with effect from the date on which he assumes charge of his duties.

The services of Captain R. T. Advani, I.M.S., are placed temporarily at the disposal of the Government of Bombay for employment in the Bombay Jail Department, with effect from the date on which he assumes charge of his duties.

The services of Captain C. L. Pasricha, M.B., I.M.S., officiating Civil Surgeon, Burdwan, are placed temporarily at the disposal of the Governing Body of the Calcutta School of Tropical Medicine and Hygiene Endowment Fund under conditions attaching to deputation to foreign service, with effect from the 14th January, 1929, the date on which he assumed charge of his duties under the fund.

To be Lieutenants.

Dr. P. N. Gokhale, M.B., F.R.C.S.E. Dated 1st August, 1928, but with seniority from the 21st November, 1927.

Lieutenant Chandra Mani, M.B. Dated 1st August, 1928, but with seniority from the 19th August, 1927.

Lieutenant Lakshman Das, M.B. Dated 2nd August, 1928, but with seniority from the 18th August, 1927.

Lieutenant P. C. Dutta, F.R.C.S.E. Dated 7th August, 1928, but with seniority from the 25th November, 1927.

To be Lieutenants (on probation).

Patrick Joseph Walshe, M.B. Dated 29th April, 1929.

Arthur Manus Sheridan, M.B. Dated 29th April, 1929.

Joseph Hugh Boulbee, M.B. Dated 29th April, 1929.

LEAVE.

Colonel C. A. Sprawson, C.I.E., M.D., F.R.C.P., V.H.S., I.M.S., Inspector-General of Civil Hospitals, United Provinces, is granted leave on average pay for 1 month and 13 days combined with leave on half average pay for 1 month and 17 days, with effect from the 16th July, 1929, or any subsequent date from which he may avail himself of it.

Lieutenant-Colonel D. P. Gail, I.M.S., Civil Surgeon, on leave, is granted leave on average pay for 1 month, with effect from the 3rd July, 1929, in extension of the leave granted to him under Government Notification No. 71T.Medl., dated the 26th April, 1929.

Lieutenant-Colonel S. J. Bhatena, I.M.S., Civil Surgeon, Surat, has been granted leave on average pay for 1 month, with effect from 22nd May, 1929.

PROMOTIONS.

Major A. A. C. McNeill, I.M.S., to be Lieutenant-Colonel from 28th January, 1927 to 21st October, 1927 whilst commanding No. 33 Field Ambulance Shanghai Defence Force.

The promotion to his present rank of Major J. M. Mitchell, O.B.E., M.B., I.M.S., notified in Army Department Notification No. 1619, dated the 31st December, 1926, is antedated from the 13th December, 1926 to the 13th June, 1926.

The promotion to his present rank of Major W. C. Spackman, M.B., as notified in Army Department Notification No. 1085, dated the 7th August, 1925, is antedated from 26th July, 1925 to 26th January, 1925.

Captain (now Major) E. S. Goss, M.C., I.M.S., is granted the acting rank of Major from the 21st September, 1918 to 28th May, 1919, whilst serving with the Mesopotamia Expeditionary Force.

Captains to be Majors.

N. M. P. Dotivala, M.C., M.B., I.M.S. Dated 23rd December, 1928.

D. P. McDonald, M.B. Dated 9th January, 1929.

Amar Nath Sharma, M.B., I.M.S. Dated 12th January, 1929.

Lieutenants to be Captains.

E. G. Montgomery. Dated 22nd July, 1928.

G. F. Taylor. Dated 29th April, 1929.

W. A. Khan, M.B. Dated 10th May, 1929.

Lieutenants to be Captains (provisional).

J. Acheson. Dated 25th June, 1928.

R. A. Haythornthwaite. Dated 18th February, 1928.

RETIREMENTS.

Colonel A. Spitteler, O.B.E., M.B., I.M.S. Dated 10th June, 1929.

Lieutenant-Colonel G. Fowler, I.M.S. Dated 29th April, 1929.

Lieutenant-Colonel F. A. F. Barnardo, C.I.E., C.B.E., M.D., F.R.C.S.E., I.M.S., from the 4th June, 1929.

Lieutenant-Colonel L. E. Gilbert, C.I.E., M.D., I.M.S., with effect from the 20th January, 1929.

Lieutenant-Colonel J. K. S. Fleming, C.B.E., I.M.S. Dated 5th July, 1929.

NOTES.

WATSON'S INSTRUCTIONS TO PATIENTS.

MESSRS. H. K. LEWIS, the well known firm of medical publishers, 136, Gower Street, London, W.C. 1, have drawn our attention to these leaflets, of which they are the publishers. Medical treatment is not simply a question of the "bottle"—despite an almost unanimous belief to the contrary in this country; advice with regard to diet, habits, exercise, etc., is as important or more important than the prescription.

The leaflets are 6 × 4½ inches in size, and cover a very wide range of subjects. They are simple and give the patient exactly what he wants, clear and simple instructions. Sixteen of the series have been published; and include such subjects as how to give hot fomentations; gonorrhœa; the alkaline treatment of gastric and duodenal ulcer; exercises for constipation; how to

cleanse the eye; nasal douching; diet in obesity; after-care in dental extractions; poultices; syphilis; the treatment of constipation; breathing exercises; scabies; advice to pregnant women; pulmonary tuberculosis; and the management of febrile cases.

These leaflets have been designed by T. T. B. Watson, M.B., B.Ch. (Camb.). They are issued in sets of 25 in a folding cover at 1s. per set of 25. A holder is also supplied at 9d. which will take a supply of several of the "Instructions" which may be selected to suit the needs of individual practitioner or specialists.

The use of such a system as this should save the general practitioner many hours of talk and worry.

HYGIENIC LININGS FOR GOGGLES.

THE British Hanovia Quartz Lamp Co., Ltd., Slough, Bucks, England, have recently placed on the market an ingenious lining of porous paper for use with goggles. In the x-ray and electrotherapy room these linings overcome the risk of spreading disease from one patient to another by using the same pair of goggles. The linings are placed on the inside of the goggles and are held in place by slits, cut in the sides, through which the elastic band is passed. It is claimed that with these linings goggles remain clean and hygienic for a longer period, and the leather will no longer adhere to the heated skin. They are produced in two sizes; No. 1 for adults at 15s. per 1,000; and No. 2 for children at 13s. 6d. per 1,000. An enamelled stand to hold 500 such linings threaded on nickelled pins is also sold at 3s.

The same firm have also recently introduced hygienic guard rings of paper for attachment to the cork ring of the Sollux lamps and the Kieffer localisation tube. The new guard rings prevent contamination of the cork, and therefore safeguard the patient from risk of contagious diseases. These are sold at 15s. for 100 for attachment to the Sollux lamp, and 10s. 6d. per 100 for attachment to the Kieffer localisation tube.

THE QUARTZ LAMP.

THIS is a small brochure of some eight pages published monthly by the Alpine Press, Inc., U. S. A., of which we have received the issues for March, April, and May 1929. It consists chiefly of abstracts of papers published in other journals or read at medical conferences, together with a bibliography each month of the papers published in heliotherapy and actinotherapy. The range of subjects covered is considerable, and these three numbers include papers on the quartz lamp in rickets and spasmophilia; the treatment of psoriasis; the effective dose in treating erysipelas with the quartz lamp; the treatment of tuberculosis of the cervix uteri; heliotherapy in pulmonary tuberculosis; an editorial from the *British Journal of Actinotherapy* on the Medical Research Council's report on ultra-violet radiation; and the hatching of eggs under ultra-violet light. The journal is one which may be of interest to radiologists and general practitioners.

BRAND'S ESSENCE OF CHICKEN.

MESSRS. BRAND AND Co., London, whose advertisement of their essence of chicken appears elsewhere in this issue, have been invalid food specialists for nearly ninety years, and during the whole of that time have held the appointment to supply their products to the royal household. Brand's Essence of Chicken is a well known and reliable product, and is of special value where hardly any other diet can be tolerated in cases of gastric disorder, fevers, impaired digestion, and neurasthenia of whatever cause. The tins for India are overprinted in red ink "specially manufactured for the Indian market."

The India representative of the firm, Mr. A. H. P. Jennings, Block F 4, Clive Buildings, Calcutta, will be pleased to supply literature and price lists at any time on application to him.

NEW MATERIALS FOR MOULDS AND CASTS.

"NEGOCOLL," "HOMINIT" AND "CELERIT."

A new process for taking moulds and casts of the human body or any inorganic object has been invented and developed by Prof. Dr. A. Poller of Vienna and is causing considerable interest on the continent amongst medical authorities, criminal police branches, etc. This system is based on different principles from those which have been in use up to the present and it presents new possibilities in research work with regard to the plastic reproduction of any interesting phenomenon.

The fundamental principle of the process lies in the new moulding material, called "Negocoll," which differs entirely in its composition, as well as in its application from the materials which have hitherto been employed. "Negocoll" is a hydrocolloidal moulding material, clean and simple to use and practically indestructible. A further advantage consists in the fact that objects to be copied do not need to be prepared in any way, even if they are covered with hair. The smallest details are faithfully and accurately reproduced.

"Negocoll" melts at 210°F., forming a thick pulp. After the "Negocoll" has cooled down sufficiently and whilst it is still in a liquid state (much below 210°F.), it is applied over the object to be copied by means of a brush, spatula or the fingers. As the "Negocoll" is free from germs, it can be used straight away over wounds or for mouldings of interior organs. Owing to the exceptional elasticity of "Negocoll" even in the cold state, it is possible to mould objects with deep undercuts, without the necessity of reproducing the object by means of separate piece moulds.

In order to obtain from the "Negocoll" negative the corresponding positive object, it is essential to use the special positive masses "Hominit" and "Celerit." These compositions are extremely hard and melt at about 240°F. As the molten "Hominit" becomes practically as liquid as water, it penetrates into all the pores of the "Negocoll" negative and thus reproduces the most minute details of the negative form. The positive masses can be reinforced by means of gauze or fibre material, whereby the resulting form becomes not only exceedingly hard, but is also practically unbreakable. A further advantage of the "Hominit" and "Celerit" objects, compared with the usual wax and paraffin mixtures, is that they can support high temperatures and therefore easily resist the hottest climates. This is of particular importance for research work in hot countries, as it gives a means of reproducing accurately and permanently certain phenomena occurring in many tropical diseases.

Owing to the practically unlimited field in which "Negocoll," "Hominit" and "Celerit" can be used with the greatest advantages, they have already been adopted for standard use not only by many leading medical institutes, hospitals, laboratories, etc., on the continent, but they have also largely been introduced in universities, schools, criminal police investigation departments, etc.

The British agents for these products are Apotela, Ltd. (England), 65, Moorgate, London, E. C. 2.

HICKS' CLINICAL THERMOMETERS.

We have been asked to draw the attention of our readers again to Hicks' clinical thermometers, an advertisement of which appears on p. xlvii of this issue. We need hardly emphasise the necessity for the medical man in India to use clinical thermometers which are absolutely reliable, for the Indian market is flooded with cheap and spurious thermometers, which may be as much as 2° to 3° F. out. They may be cheap, but even so they are bad value.

Hicks' thermometers have a reputation of very many years of sound workmanship behind them. Every thermometer issued is fully tested by an expert before it leaves the factory and is reliable. The firm, in brief, can well claim to be the premier thermometer makers of the world.

The representative for India is Mr. A. H. P. Jennings, Messrs. Allen & Hanburys, Ltd., Block F 4, Clive

Buildings, Calcutta, who will be glad to forward price lists on application.

NUMOTIZINE.

We are requested by the manufacturers of "Pneumophthysine," a medicated emplastrum, to bring to the notice of our readers that they have changed the name of this preparation to "Numotizine, Inc.," in order to bring the name of the product into line with modern ideas regarding nomenclature of pharmaceutical preparations. The new name is simply a simplified spelling of the old, and there has been no change in the product or its packing.

It is claimed that this emplastrum contains 2.6 parts of guaiacol, 2.6 of formalin, 13.02 of creasote, 2.6 of quinine, 2.6 of methyl salicylate, to 1,000 parts of glycerine and aluminium silicate. It is therefore obviously eminently suitable for application as an emplastrum in all cases of pneumonia, rheumatism, or other inflammatory conditions.

The agents for India are The Indian Alkaloidal Co., Princess Street, P. O. Box No. 2062, Bombay, No. 2, who will be glad to send specimen containers on application.

AN INEXPENSIVE STOP-WATCH.

In order to count the pulse beats accurately, a watch with a centre-seconds hand is almost an essential to the medical practitioner. And in this connection the Arnold stop-watch, which has been commented on favourably by *The Motor* for January 15th, 1929, and *The Electrical Times* of January 31st, 1928, is of interest. Whilst this watch is primarily designed for engineers, umpires at races, etc., it is also of medical interest. The watch is of the usual 30-hour type with lever movement, and carries a centre-seconds hand reading to one-fifth of a second. This centre-seconds hand can be stopped at any instant by pressing a knob at the side. The watch is guaranteed for twelve months. It is manufactured by Messrs. A. Arnold & Co., 17, Elmcroft Avenue, Golders Green, London, N. W. 11; and is sold at 7s. 6d., plus postage. The same firm also manufacture a special minute and seconds watch for races, and a chronograph guaranteed for five years.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers, relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India, Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

NOTES ON THE NEW CONCEPTIONS OF SCIATIC PAIN AND ON ITS TREATMENT.

By J. B. HANCE, O.B.E., M.A., M.D. (Cantab.), F.R.C.S.E.,

MAJOR, I.M.S.,

Rajkot,

N. C. MODY, M.D., B.S.,

Radiologist, West Hospital, Rajkot,

and

SHIVA DATTA UJWAL, I.M.P. (C. P.),

Officer-in-Charge, Radiology and Electro-Therapeutics,
Hewson Hospital, Jodhpur.

THE pathology of sciatica, which has hitherto remained obscure, has recently been illuminated by the observations of Professor Putti and others, a summary of which was placed before the profession by the eminent Italian orthopaedist in his Lady Jones lecture of 1927.

As a result, not only has the pathogenesis of the condition been placed upon a more orderly basis, but an avenue has been opened up for its rapid and successful attack, as opposed to the symptomatic treatment hitherto employed, which can be described neither as rapid, nor as particularly successful.

Putti arranges his pathological classification of sciatic pain under three heads:—

- (i) *Primary sciatica*,
- (ii) *Secondary sciatica*, and
- (iii) *Idiopathic or rheumatic sciatica*.

Primary sciatica is expressive of a true peripheral neuritis, caused by generalized toxæmias such as alcoholism, lead-poisoning, diabetes or syphilis; while *secondary sciatica* is caused by irritation of the nerve in its course from local causes; neoplasms, vertebral or pelvic, malunited fractures, or syphilitic or tuberculous granulomata.

These form the minority of the cases seen; by far the greater number are of neither of these types, but belong to the third category, idiopathic or *rheumatic sciatica*, whose pathology has hitherto been indeterminate.

Putti claims that these cases are an expression of variations from the normal in the intervertebral foramina of the lumbar column, from causes anatomical or inflammatory, and usually from both in combination, the effect of which is to expose the nerve fibres to compression and irritation.

The objects of this paper, which is based on observations on a series of 15 cases of sciatica and lumbago treated by the senior author in collaboration with one and other of the junior writers, are to add, for what it is worth, their testimony to that of Putti regarding the

pathogenesis of so-called "idiopathic sciatica" and to bring forward suggestions as to its treatment.

Sciatica and its precursor, lumbago, is one of the commonest complaints of hospital practice in India, and, in the experience of the writers, such are cases in which treatment on hitherto accepted lines, analgesics, massage, counter-irritants, injections of so-called "specifics," nerve stretching, etc., yields results which are very far from satisfactory.

If, as the writers believe, Putti's conceptions of the pathogenesis of the condition are correct, this failure of treatment is not surprising, since it is based on faulty pathology, and leaves the cause untouched, if it does not, as in the case of nerve stretching, do actual harm.

Considerations of space forbid any but the briefest summary of Professor Putti's brilliant exposition; but a short review of points relevant to the writers' clinical findings is unavoidable.

They comprise consideration of:—

- (i) The anatomy of the spinal nerve in the intervertebral foramen.
- (ii) The anatomy of the intervertebral foramen.
- (iii) The normal character of the posterior intervertebral articulations of the lumbar region, with the more common variations from the normal, Putti's "anomalies of tropism," and
- (iv) The effect upon the intervertebral foramen and the nerve it contains of inflammatory changes in the posterior intervertebral joints.

(i) The spinal nerve, carried by the foramen, is the complete spinal nerve, i.e., that part formed by the junctions of the anterior and posterior roots, and which on emerging divides into anterior and posterior divisions.

This part of the nerve has been designated the funiculus; it is extra-arachnoid but intradural, and carries with it a funnel-shaped prolongation of the dura mater, which eventually blends with the sheath of the nerve trunks. In contrast to the intraspinal portions it has no protective bath of fluid, but is surrounded by a rich venous plexus, which is much influenced by mechanical and inflammatory conditions outside the funiculus.

(ii) The intervertebral foramen is bounded *above* by the intervertebral notch; *in front* by a small portion of the body of the vertebra above, the intervertebral disc and a small portion of the body of the vertebra below; *below* by the neural process of the vertebra below and *behind* by the posterior intervertebral articulation, any change in which must therefore intimately affect the foramen and its contents (Fig. 1). Further, the foramina in the lumbar region vary in size, the 5th being the smallest of all, but carrying the 5th lumbar nerve, the largest in size and the main constituent of the sciatic nerve (Fig. 1).

(iii) Normally the plane of the articular surfaces in the posterior intervertebral articulations in the lumbar region is the sagittal plane, with

Fig. 1.—(After Putti).

the exception of those between the 5th lumbar vertebra and the sacrum, which are usually disposed in the coronal plane (Fig. 2).

Fig. 2.—(After Putti).

But variations in this "tropism" are common, especially in the lower lumbar vertebrae, where one of a pair may be found normally disposed, while its fellow may be tending towards, or actually in, the coronal plane (Fig. 3).

These changes are especially marked and frequent in the lumbo-sacral articulations (Fig. 4).

It will be seen that any such anomalies of "tropism" will tend to constrict the intervertebral foramen and, possibly, to compress its contents, and where these changes are associated, as is not infrequently the case, with sacralization of the 5th lumbar transverse process, constriction of the foramen will be still more marked.

Both the normal articulations and variations from the normal are demonstrable by the x-rays; but skiagrams of a very high technical quality are

necessary for the purpose; and Figs. 2 and 4 are diagrammatic representations of the x-ray appearances.

Fig. 3.—(After Putti).

Radiogram 1 also illustrates the normal, the line of articulation on the left side being clearly visible,

Fig. 4.—(After Putti).

that on the right being partially obscured by the arrow point.

(iv) The changes consequent on infective arthritis of the intervertebral joints are those of infective arthritis elsewhere: swelling, effusion, erosion and ankylosis; and their x-ray appearances are those of arthritis, "fluffing" of the outline of the articular cartilage and blurring of bony margins. Ankylosis is indicated as elsewhere by absence of articular outline. These changes are demonstrable in the intervertebral joints by radiograms of a high technical quality and the appearances are diagrammatically represented in Fig. 5, the left side showing arthritis and the right ankylosis. Such changes will also obviously tend to constrict the lumen of the intervertebral canal and to compress and irritate its contents. Further, constriction from whatever cause will tend to obstruct the venous outflow from the plexus, and still further to compress the nerve funiculus in consequence, while the inflammatory factor will add its quota to the concomitant venous congestion.

On these observations, and on the results of treatment directed to them, Putti bases his thesis that the so-called idiopathic sciatica is a symptom

of a neuritis of a specific nature; a neuralgia caused by pathological conditions of the intervertebral foramina and articulations. It is a symptom of irritation of the nerve in the bony canal through which it passes—"neurodocitis"—

Fig. 5.—(After Putti).

and of lumbar arthritis; and Putti advocates the substitution of "arthritic" or "vertebral" for "idiopathic" in the designation of the disease.

Clinical Features.

Putti has shown that there is no pathognomonic sign or symptom in cases of sciatica, and few which are even constant; but there are certain features which, taken together, suggest the diagnosis; and skiagrams, if sufficiently good, establish it. The suggestive features are:—

- (1) Preliminary lumbago.
- (2) Rigidity of the lumbar spine with spasm of the erectores spinæ.
- (3) Scoliosis.

(1) *Preliminary lumbago*.—This symptom receives no attention from Putti, but was a constant feature in all but one of the cases here recorded; in this one case of sciatica followed a violent spring to one side when jumping a ditch.

In all the others, each attack was heralded by preliminary pain in the back, aggravated by any but the slightest movement. This phase varied in duration from a few hours to one to three days, after which the pain adopted the typical sciatic character.

(2) *Rigidity of the lumbar spine*.—This was a constant feature in our series, and Putti states it to be invariable in idiopathic sciatica, thereby differentiating the latter from sciatica due to inflammation of the nerve roots, and from all forms of secondary sciatica. On examining the patient in the sitting position the erectores spinæ are found to be in spasm, hard and board-like. The patient, if asked to lean forward does so from his hips, while the lumbar and lower dorsal vertebræ remain fixed as in spinal caries; and any attempt on the part of the examiner to overcome this rigidity meets with instant and heart-felt protest from the patient on account of the

aggravation of his pain. This symptom is earlier in appearance than scoliosis and persists throughout the course of the disease, marked during attacks, less accentuated between them.

(3) *Scoliosis*.—This was a frequent, though not invariable physical sign in the present series of cases. It may be said that it was a feature of the more acute cases and was not so marked in those less severe. Examples occur of both homolateral and contralateral scoliosis, the latter, as stated by Putti, being the commoner.

No case of alternating scoliosis occurred in our series, although cases showing intervertebral arthritis of both sides—the condition which Putti considers the causative factor in alternating scoliosis—did occur.

Accepting, as we do, Putti's views on the pathogenesis of idiopathic sciatica, we consider that these three symptoms are the logical outcome of intervertebral arthritis.

The scoliosis is the fixture of the joints in a position of ease; the homolateral deformity results in the separation of the inflamed joint surfaces and the opening up of the intervertebral foramina, the contralateral is the fixation of the joints in the relaxed position and also relaxes the nerve cords as they pass through the foramina. The muscular spasm is identical with the protective spasm over any inflamed joint, and, as in the case of other joints, is the cause of the faulty position and, as in other cases, is diminished or abolished, with resultant diminution or abolition of the deformity by successful treatment. *Vide Case I.*

The lumbago is exactly analogous to the localized pain in arthritis of other joints. Indeed, if one considers the hip joint, affected with chronic progressive osteo-arthritis with periodical exacerbations, we observe the same phenomena except that we call them local pain, protective spasm, and fixation in the position of abduction or adduction; and the sciatica is exactly comparable to the pain often seen along the distribution of the anterior crural nerve, caused by pressure on its divisions as they pass over the deformed and distorted femoral head.

Diagnosis.

The diagnosis of idiopathic sciatica depends upon the exclusion of the other varieties, primary and secondary sciatica, and upon positive x-ray evidence. Careful history-taking and a meticulous clinical examination are essential; and special attention should be paid to such points as the Wassermann test, the passing of a finger into the rectum, and the presence or absence of rigidity of the erectores spinæ and scoliosis.

The writers would venture to emphasize the importance of the two former measures, which should be a routine, but which in practice they do not find to be so. Syphilis may cause sciatica of the idiopathic type by lumbar intervertebral arthritis, and an appreciation of the fact will bear materially on its treatment; while the practitioner who neglects to examine the rectum will one day

incur the chagrin and loss of prestige of failing to recognize the presence of a rectal carcinoma or other pelvic neoplasm.

Having excluded other causes by consideration of the history and appropriate examination, the diagnosis of idiopathic sciatica is established by the *x*-rays. It is important to take both antero-posterior and lateral radiograms, as well for appreciation of the extent of the disease, as for gauging the results of treatment. The technical details of milliampèreage, kilovoltage and exposure time must necessarily vary with the build of the patient and the calibration of the individual *x*-ray unit used. The results at present illustrated were obtained with a transformer of the "Snook" type, a 30-milliampère fine focus Coolidge tube and the factors of current, kilovoltage, exposure and distance for patients of average build as tabulated below:—

Position.	Distance.	K-V. M. A.		Time.
Anteroposterior	25 inches	88	10	6 sec.*
Lateral	.. 25 inches	88	10	30 sec.*

With Potter Bucky Diaphragm.

*Time is for patient of average build, and is the only variable factor.

Treatment.

Putti summarizes the treatment of idiopathic sciatica in the phrase: "active hyperæmia and immobilization." He outlines his system of applying it, which consists of daily hot air baths extending over a period of 18 to 20 days, combined with an immobilizing (*not* corrective) plaster jacket which is followed by a celluloid jacket which "may be required to be worn for over a year."

Such a course of treatment, radical and admirable though it be, is out of the question for the Indian hospital patient, who would never submit to it even were a celluloid jacket within his reach, and is a severe handicap to the European patient, even of the leisured classes, of whom there are few in India. To most of them a degree of activity, greater rather than less, is an essential to the gaining of their livelihood, and few can afford to be laid up or partially inactivated for considerable periods.

The writers, therefore, had to cast about for some less exacting form of treatment, and one less restricting to the activities of the patient; and they wish to place on record their very deep sense of obligation to Mr. R. W. Armstrong of the Victor *x*-ray Corporation, who, in the course of a discussion on means of applying active hyperæmia, suggested diathermy.

Theoretically, the treatment is ideal, since, while the high-frequency current will generate heat impartially throughout the area of interest, this will be rapidly dissipated from the soft parts through the ordinary mechanism of heat dispersion, but from the denser, less vascular bony and ligamentous structures, its dissipation will be very

much less rapid. In other words, diathermy theoretically provides the means of applying a hot fomentation to the inflamed joints, and one whose effects are much more lasting than those of the more usual variety. That it carries out in practice what it promises in theory we hope to show in this paper.

In the series of cases under report the line of treatment followed has been to confine the patient to bed during the acute stages, except, of course, for the necessary transport to and from the radiological block, and to give a course of diathermy, alternating with the galvanic current with the negative pole at the site of interest, the so-called "dispersive" galvanism. To begin with, treatment of one or other variety is given daily, the patient thus receiving diathermy and galvanism on alternate days.

The writers were fortunate in having as their first patient an electrical engineer, who was as interested in the details of the course as he was anxious to be rid of a disease which had in the past rendered his life a misery for considerable periods; and they owe much to his constructive criticism, as well to his familiarity with electricity which gave them very useful information as to tolerance and dosage.

They find with diathermy, as Putti found with hot air baths, that the first effect is an aggravation of the pain, which, however, rapidly passes off giving place to marked relief. The aggravation of the pain lasts for an hour or two after the first application, for a much shorter period after the second, and is usually entirely absent after the third. Regarding the effects of galvanism, the writers cannot dogmatize, but the patient referred to definitely stated that the relief experienced from diathermy is greater when it is allied with galvanism than when it is applied alone. This may possibly be ascribed to the effect of chlorine ionization from the normal saline in which the electrodes were moistened or simply to the hyperæmia produced in the area of interest by the passage of the galvanic current.

After a period of daily treatment which varies from a week to ten days, the patient may be allowed up with crutches or sticks, and usually requires these aids for a further week, after which they are no longer necessary, while after the third week all pain and discomfort have usually disappeared.

By this time daily attendances may be dispensed with and the patient need only attend on alternate days, still receiving each variety of treatment alternately. The interval may be gradually lengthened to attendances twice a week and so to weekly visits until they cease altogether.

The effects of treatment should be gauged by periodical skiagrams which are most instructive, and which will be discussed in detail when considering individual cases; but it may here briefly be stated that in each case they show a progressive clearing up of the condition; joint outlines reappear, lateral views show clearing of the intervertebral foramina; scoliosis progressively lessens

and disappears, while clinical examination reveals a diminution in lumbar spasm which finally ceases.

So much for treatment directed to the site of the disease. But there is another consideration which in our experience is of the greatest importance, eradication, where possible, of the cause.

The very name infective arthritis postulates an infective focus, and the most painstaking efforts to trace and eradicate such foci should be made. In our experience the majority are dental or intestinal, but all possible localities, tonsils, nasal sinuses, middle ear, urine, and, where possible, duodenum, should be investigated.

Two of our European patients revealed dental foci which gave pure cultures of non-hæmolytic streptococci, while a third, after a lengthy investigation, gave positive cultures of *B. flexner* from his stools.

Autogenous vaccines were prepared and administered in each case with beneficial results.

Indian patients of the hospital class, however, while they usually carry in their mouths obvious possible foci, have a strong objection to dental extraction for the purpose of culture, and treatment has often to be confined to diathermy and galvanism. But in two cases extraction of teeth, shown to be faulty by the x-rays, revealed short-chained non-hæmolytic streptococci, while in a third similar organisms were recovered from the urine, and in the case of a female patient catheter specimens of urine gave a pure growth of *B. coli*.

The resultant vaccines were administered in each case.

Details of Cases.

Considerations of space preclude a detailed discussion of each case in the present series; a summary of them is given in the attached table and the writers have confined themselves to a brief description of a few cases which may be accepted as typical of the clinical features and results of treatment.

Those of our readers who are experienced in radiology are aware that the lumbar spine is one of the most difficult subjects in the whole body as regards the production of radiographic detail. They will need no reminder from us that in such cases details which are perfectly clear in a 14 ins. by 17 ins. film when viewed in a viewing box may not be by any means so obvious in a 3 ins. by 4 ins. reproduction on a printer's block. The writers feel that much credit is due to the makers of the blocks of the radiograms published with this article for having reproduced with such clarity fine points of radiographic detail concurrently with so marked a reduction in size.

Case I. (Radiograms 2-7.) Mr. C. H. W., European, at. 48 years, Electrical Engineer. Left-sided sciatica. November 1927.

Trouble dated from active service in Mesopotamia, since when patient had had four or five attacks becoming progressively worse. Last two had crippled him and necessitated the use of crutches for weeks on end. When

seen was crippled and on crutches, unable to get relief either sitting or lying except when pain was controlled by aspirin and caffeine. The pain extended from left gluteal region to left heel.

Examination.—Wassermann reaction negative; rectum normal; urine normal; wears denture with two remaining teeth, x-rays of which were pronounced healthy by dental surgeon. Marked lumbar spasm and exquisite tenderness of sciatic nerve at gluteal fold. Muscles of thigh and calf wasted by 1½ and 2 inches respectively as compared to other side.

X-rayed, 5th November, 1927 (Radiograms 2 and 3). Contralateral scoliosis, joints between 4th and 5th lumbar vertebrae and between 5th and sacrum obscured. Filling of 5th lumbar intervertebral foramina with inflammatory exudate. Diathermy daily for 5 days, followed by diathermy and galvanism on alternate days. Marked immediate relief; aspirin abandoned after 3 days and slept normally. After 15 days walked easily with stick. After 3 weeks discarded stick. After one month climbed a hill to examine cable.

5th February, 1928. Slight recurrence of pain.

X-rayed again (Radiograms 4 and 5). Contralateral scoliosis present but less marked, joints and foramina much clearer, but still remains of exudate in 5th foramen. *B. flexner* isolated from stools and vaccine prepared. Diathermy and galvanism resumed on alternate days with immediate relief. Twice weekly after a fortnight for one month, thereafter weekly for one month.

11th May, 1928. X-rayed again (Radiograms 6 and 7). No scoliosis, joints and foramina clear. No lumbar spasm. Has performed all duties with entire freedom from symptoms and has indulged in a weekly small game shoot throughout the cold weather 1928-29.

Had slight twinge May 1929, which disappeared with purgative.

(*Note.*—Since going to press information has been received from the author that this patient has had a severe return of symptoms confining him to bed. *B. coli* have been isolated from the urine, and it is hoped that a combination of autogenous vaccine with diathermy and galvanism will once more give complete relief.—EDITOR. I. M. G.)

Case II. Mr. H. S. H., European, male, at. 42, Civil Engineer. November 1927.

Slight sciatica cold weather 1926-27 which disappeared with massage and rest. Return in aggravated form November 1927. Primary and secondary sciatica excluded. Marked lumbar spasm. X-rays showed contralateral scoliosis, fluffing of joints and foramina (Radiogram 8). Dental x-ray; apical infection of upper molar.

Diathermy and galvanism alternate days for 14 days. Complete relief and proceeded to dental surgeon. Molar tooth extracted and cultured. Non-hæmolytic streptococcus grown and vaccine prepared. Diathermy and galvanism bi-weekly for 1 month after return from dentist, then discontinued. Has remained free of trouble.

Case III. Mr. J. P., European, male, at. 40, Civil Engineer.

Acute right-sided sciatica following a side-ways jump. January 1928.

No evidence of primary or secondary sciatica.

X-rayed, 26th January, 1928 (Radiograms 9 and 10). Homolateral scoliosis, fluffing of joint outlines and filling of 4th and 5th foramina. Diathermy and galvanism alternate days for 1 week with rest in bed for 4 days. Left for dental surgeon who extracted and cultured suspicious bicuspid. Non-hæmolytic streptococcus isolated and vaccine prepared. Returned to own station and continued diathermy and galvanism for 6 weeks at increasing intervals. Has remained free of trouble since.

Case XI. M. S., Mahomedan, male, at. 65, Faqir, April 1928.

Had fallen from a horse a year previously and had pain resembling renal colic at intervals for some 12 years back. After his fall was able to walk, but soon developed slight pain in back, which later settled into left-sided

sciatica and became progressively worse. Teeth foul, extraction declined. Primary and secondary causes excluded.

X-rayed, 13th February, 1928 (Radiograms 11 and 12). Stone in right kidney. Fluffing of left intervertebral joints between 3rd, 4th and 5th lumbar vertebrae and between 5th and sacrum. Narrowing of 4th and 5th foramina. Diathermy and galvanism on alternate days for 3 weeks. Complete relief and insisted on leaving hospital.

X-rayed, 11th March, 1928 (Radiogram 13). Joints much clearer.

Treatment of stone in kidney declined. Discharged relieved, and not since heard of.

Case XIII. Mrs. P., Hindu, female, at. 35, April 1928.

Acute sciatica at intervals of years, both sides, worse at periods. Hysterectomy some years previously but pain persisted. Poor general health. Primary and secondary sciatica excluded. Teeth foul, extraction refused. Urine cultured, pure growth of *B. coli*; vaccine prepared.

X-rayed, 23rd April, 1928. Slight left-sided scoliosis. Fluffing of intervertebral joints both sides, 4th and 5th lumbar foramina narrowed.

Diathermy and galvanism alternate days for 3 weeks with relief, then bi-weekly. After 1 week took discharge against advice, alleging herself cured.

Case XV. Z. S., Hindu, male, at. 20, zemindar, weight 20 stone. November 1928.

Acute sciatica, right side, developed spontaneously. Crippled, and can only hobble with stick, unable to stand upright or straighten right leg. Pain from buttock to ankle.

X-rayed, 15th November, 1928. Anteroposterior only, patient so bulky that nothing seen with lateral. Contralateral scoliosis with joints badly fluffed. Diathermy and galvanism alternate days, with immediate relief. After 3 weeks no symptoms, walks easily without stick. Diathermy and galvanism bi-weekly for a month, and then weekly for 3 months. Returned home. Radiographed 2 months later: joint outlines markedly clearer. Is leading an active life, entirely free from pain.

Technique.

For the information of those of our readers who may be inclined to check our results and adopt our line of treatment, we give the following brief description of the technique used by us:—

Diathermy.—The instrument used is the Victor vario-frequency Diathermy Unit made by the Victor X-ray Corporation, Chicago. Treatment can be given either in the sitting or the recumbent position as the convenience of the patient dictates. The electrodes used are made from lead- or tin-foil (the wrappers of photographic films serve admirably for the smaller ones). The "indifferent" electrode is large, at least 6 inches square, preferably 6 by 8 inches, and is placed upon the abdomen, while the "active" electrode which measures about $3\frac{1}{2}$ by $2\frac{1}{2}$ inches, is placed snugly over the area of interest, the centre of which corresponds roughly to the posterior inferior iliac spine. The electrodes are secured in position by a rubber bandage which should be as tight as the patient can tolerate without discomfort, for intimate contact is essential, if prickling and burns are to be avoided as the current rises.

The current is then turned on, and gradually increased till the limit of the patient's tolerance

is reached, when it is maintained for 10 minutes and then gradually decreased.

The application may be summarized as "five minutes going up, ten minutes at the top, five minutes coming down."

Soon after the current is turned on, the patient experiences a sensation of warmth which is not unpleasant and which increases as the current rises. The summit is reached when the sensation of warmth gives place to one of burning, when the current is slightly decreased and there maintained.

Provided the contact of the electrodes is good, no inconvenience is felt; but a loose electrode will cause a disagreeable prickling sensation, which will diminish tolerance, and the summit will be lower than could be borne with good contact.

Regarding tolerance, the highest level borne with comfort by any patient in our series has been 1,750 ma. (*Case I*).

Usually the tolerance rises with treatment; at the beginning 1,000 ma. is the average limit, while later currents up to 1,400 and 1,500 ma. are borne with comfort.

The higher the tolerable maximum the quicker and more marked the relief; and, fortunately, sciatica patients are so anxious for easement that they are not nervous, while they appreciate the warmth generated by high frequency current.

Galvanism.—Here the instruments used by the writers have been variously a Watson pantostat, a Newton and Wright pantostat, and a Victor multiple wave generator, in each case connected to the main supply, the instrument imposing the necessary resistance. The anode is connected to a foot bath, while the kathode, moistened with saline, is applied to the site of interest as in the active electrode in diathermy. The current is then switched on, and gradually increased up to the amount which it is desired to give, usually about 5 ma. As for diathermy, the increase and decrease is gradual, and the time occupied by treatment does not as a rule exceed 20 minutes.

Discussion.

Through the kindness of the Director, Central Research Institute, Kasauli, the senior writer was enabled to look up the recent literature on sciatica in the fine library of the Institute. He could only discover two references to the use of electrotherapy in sciatica. The first was by Kowarschik in a Berlin paper and was not available, while the second was by Dattner (1927) of Vienna in which that author states that of recent years electrotherapeutics, and especially galvanism, have gained for themselves a permanent place among therapeutic agents; and he prophesies that they will be more extensively used because of their surprisingly rapid action. More recently O'Meara (1929) mentions that electricity in the form of galvanism and diathermy has been successful in obstinate cases.

It is apparent, therefore, that others besides the present writers have successfully treated sciatica with diathermy and galvanism, though they can find no reference in the literature to

the checking of the efficacy of these agents by serial radiograms, and their curative—as opposed to palliative—effect recorded. Consequently they do not feel that they can claim originality for this article; nor do they consider the point of any importance compared with the main object in publishing it, which is to bring before the profession in India a line of treatment which has enabled them to give relief—and, they hope, permanent relief—to a number of sufferers from a hitherto most intractable complaint.

The writers desire to record their great sense of obligation to the Victor X-ray Corporation of Chicago, and especially to their Bombay representatives, who have been of the greatest assistance, not only in preparing the blocks of the radiograms herewith reproduced, but in supplying advice which has been of the utmost value in developing technique, both radiological and therapeutic.

Summary and Conclusions.

(1) The present series of cases tends to confirm Putti's claim that idiopathic sciatica is caused by an infective arthritis of the lumbar intervertebral articulations, with or without "anomalies of tropism."

(2) The physical signs of the conditions are identical, *mutatis mutandis*, with those of infective arthritis elsewhere.

(3) Diathermy, in association with "negative" galvanism, gives excellent immediate results both as regards relief of symptoms and amelioration of their causal arthritis; and if, as seems probable, its promise of permanent relief be fulfilled, it would appear to be the treatment of choice, since it is available to all classes of case within the reach of a radiological department, and, moreover, is free from the inconvenience to the patient which is inseparable from any form of retentive appliance.

(4) The search for, and if possible eradication of, the infective focus or foci is a most important step in the treatment of the condition, and should not be overshadowed by the more spectacular results of physiotherapy.

Tabular Summary of Cases.

Serial No.	Name.	Class, sex and age.	Date.	Complaint and duration.	X-ray findings.	Treatment.	REMARKS.
1	Mr. C. H. W.	E. M. 48	Sept. 1927.	Recurrent left-sided sciatica, 6 attacks in 10 years. Later attacks had crippled him.	5-11-1927. Obliteration of articular outline 4th and 5th lumbar intervertebral joints. Partial filling 4th lumbar foramen. 5th foramen filled with exudate, contralateral scoliosis. 5-2-1928. Joint outlines reappearing. 4th lumbar foramen nearly clear. 5th clearing. Scoliosis less. 11-5-1928. Joints and foramen clear. No scoliosis.	Diathermy and negative galvanism. <i>B. flexner</i> autogenous vaccine.	Complete relief except for twinge in May 1929 when constipated, which disappeared with purge.
2	Mr. H. S. H.	E. M. 40	Nov. 1927.	Right-sided sciatica 4 days. Slight attack winter 1926-27.	Contralateral scoliosis. Fluffing of joints and foramina.	Diathermy and negative galvanism. Non-hæmolytic streptococcus autogenous vaccine from dental focus.	Complete relief.
3	Mr. J. P.	E. M. 40	Jan. 1928.	Acute left-sided sciatica following jump.	Homolateral scoliosis. Fluffing of joint outlines. Filling of 4th and 5th foramina.	Diathermy and negative galvanism. Non-hæmolytic streptococcus vaccine from dental focus.	Complete relief.

Tabular Summary of Cases—Contd.

Serial No.	Name.	Class, sex and age.	Date.	Complaint and duration.	X-ray findings.	Treatment.	REMARKS.
4	G. J.	H. M. 35	Jan. 1928.	Left-sided sciatica for 15 years off and on. Lumbago constant	Fluffing of joint outline, filling of 4th and 5th foramina. Partial obliteration of 3rd. Contralateral scoliosis.	Diathermy and galvanism. N. A. B. Bismotab.	Wassermann positive. Discharged against advice after 4 weeks alleging complete relief not since traced.
5	K. A.	M. M. 45	Feb. 1928.	Right-sided sciatica 3 weeks.	Fluffing of joint outlines right side. Blurring of 4th foramen, obliteration of 5th.	Diathermy and galvanism.	Discharged after 1 month alleging complete relief. X-rays showed restoration of outline of joints and foramina. Not since traced.
6	K. K.	M. M. 67	Feb. 1928.	Right-sided sciatica 1 year.	Fluffing of joints between 3rd, 4th and 5th lumbar and sacrum. Constriction of 4th and 5th foramina.	Diathermy and galvanism. Short - chained non-haemolytic vaccine (isolated from urine).	Discharged completely relieved. Not since traced.
7	A. G.	M. M. 40	March 1928.	Right-sided sciatica every cold weather for years. Lumbago constant.	Fluffing of 3rd, 4th and 5th lumbar joints. Homolateral scoliosis.	Diathermy and galvanism. Vaccine of "short-chained" non-haemolytic streptococcus from dental focus.	Complete relief.
8	S. L.	H. M. 30	March 1928.	Right-sided sciatica, 25 days. Following on appendicectomy.	Contralateral scoliosis. Tropism of 4th right lumbar joint anomalous, 5th joint outline fluffed, filling of 4th and 5th foramina.	Diathermy and galvanism.	Complete relief.
9	N. M.	M. M. 45	March 1928.	Left-sided sciatica 15 days.	Fluffing of 3rd, 4th and 5th lumbar joints with filling of foramina. Contralateral scoliosis.	Diathermy and galvanism. Autogenous short - chained streptococcus vaccine from dental focus.	Discharged against advice after 3 weeks alleging himself cured.
10	Mrs. S. N. M.	H. F. 23	March 1928.	Alternating sciatica. 4 months.	Fluffing of 4th and 5th joints both sides and 3rd joint right side. Filling of 3rd, 4th and 5th foramina. 15-5-1928. Joints clear. 3rd and 4th foramina clear. 5th almost clear.	Diathermy and galvanism.	Leucorrhoea. Retroversion uterus. erosion of cervix. Complete relief.
11	M. S.	M. M. 65	April 1928.	Left-sided sciatica intermittent 1 year.	Fluffing of 3rd, 4th and 5th lumbar joints. Constriction 4th and 5th foramina. Stone right kidney. 11-5-1928. Joints much clearer.	Diathermy and galvanism.	Declined nephrolithotomy. Left against advice after 1 month's treatment, alleging himself cured.

Tabular Summary of Cases.—concl.

Serial No.	Name.	Class, sex and age.	Date.	Complaint and duration.	X-ray findings.	Treatment.	REMARKS.
12	S.	H. F. 40	April 1928.	Left-sided sciatica. 3 weeks.	Homolateral scoliosis. 3rd, 4th and 5th joints fluffed on left side. 4th and 5th foramina constricted and obliterated respectively.	Treatment declined.	Unrelieved.
13	Mrs. P.	H. F. 35	April 1928.	Intermittent alternating sciatica for some years.	No scoliosis. Fluffing of all lumbar intervertebral joints 4th and 5th lumbar foramina narrowed.	Diathermy and galvanism. <i>B. coli</i> vaccine from urine.	Discharged against advice after a month, alleging himself cured.
14	G. L.	H. F. 40	May 1928.	Right-sided sciatica.	Contralateral scoliosis. 4th and 5th joints fluffed. 4th and 5th foramina constricted.	Diathermy and galvanism. N. A. B. Bismotab.	Wassermann positive. Discontinued treatment after 6 weeks being free from symptoms. Not since traced.
15	Z. S.	H. M. 20	Nov. 1928.	Right-sided sciatica.	15-11-1928. Antero-posterior only. Contralateral scoliosis. Joints badly fluffed. Outlines much clearer.	Diathermy and galvanism.	Complete relief. Is leading active life. Weighs 20 stone.

WEBSTER'S OPERATION FOR ENTROPION OF THE UPPER LID.

By R. E. WRIGHT, C.I.E., M.D.,

LIEUTENANT-COLONEL, I.M.S.,

Superintendent, Government Ophthalmic Hospital, Madras.

It needs no apology on my part to claim the attention of those readers of the *Gazette* who are interested in ophthalmology to the above procedure, if amongst them there is anyone to whom it is unfamiliar. The operation mentioned in the title was described by MacRae in the *British Journal of Ophthalmology*, January 1928. It was devised by Webster in Beyrout over thirty years ago, but apparently had remained comparatively unknown, although no doubt similar procedures were employed in various parts of the world from time to time. As MacRae points out, numbers of different methods have been devised of operating for the relief of entropion of the upper lid, but this is "superior to them all." He described it in the hope that "what he considered the best operation for this condition" might find its way into the textbooks and displace many of the old (some of them barbarous and mutilating) procedures which are still described. He goes on to say that the operation is practically "fool-proof," even should it fail no harm is done, but in his hands it has been uniformly successful. When one considers the number of procedures

described in the textbooks for this condition, the claims which the author makes for this operation seem almost too good to be true. When I read MacRae's article, this was my first impression, but the author's simple dogmatic statements were somehow convincing and I determined to give it a trial; for, after a considerable experience of other operative measures for the relief of entropion of the upper lid, I had come to the conclusion that there was not one of them really satisfactory in hospital practice. Over a year's experience of the method has convinced me that the claims made by MacRae are fully justified, and in the interests of ophthalmological science, I consider that any surgeon who does not know the operation ought to become familiar with it. A really good method of treatment such as this can bear repetition in the medical press in order to emphasize its value just as a bad procedure deserves criticism. Dr. Webster deserves great credit for its evolution, and although MacRae claims no share in having invented the operation, he justly merits the thanks of ophthalmologists for having brought it to notice.

For the convenience of those who have not got ready access to the paper above quoted perhaps I cannot do better than give the essentials of the technique in the author's own words.

"A Snellen's entropion clamp is used reversed; the left-sided clamp being used for the right eye and *vice versa*. The flat plate of the clamp is applied to the skin

surface of the lid, the open arm to the conjunctival surface, and the lid everted. The outer end of the lid is grasped with toothed forceps and pulled outwards until the punctum is just visible in the portion of the lid included in the clamp. The clamp is then screwed tight. An incision is now made in the conjunctival surface of the lid parallel to the lid margin and about 3 mm. from it. This incision goes from end to end of the lid and goes right through the tarsal plate. It is not advisable to go so deep as to button-hole the skin surface but no great harm is done if this accident happens. The important point is that the tarsal plate must be completely divided. At each extremity of the lid the incision is curved a little forwards towards the lid margin, but it must stop short of the actual margin, or the cosmetic result will not be so good. At the inner extremity this forward curve should end just external to the punctum. It may not be possible, even if a large clamp is used, to complete the outer end of the incision without moving the lid in the clamp, but this is easily done by grasping the lid with toothed forceps, the clamp being slightly slackened meanwhile.

"On completion of the incision the wound is carefully inspected to see that no hair roots have been left in the proximal part of the lid. If the incision is made 3 mm. from the border there should be none; but if at any point it has got too near some may be left and in any case it is wise to look for them. If any are seen they are carefully dissected out.

"The clamp is now removed; the lid is replaced and a large moist pad pressed on it. Bleeding is at first free but has stopped by the time it is necessary to proceed with the final stage of the operation on the lid.

"If both eyes are affected the other lid is incised in the same way and in its turn covered with a pad.

"The inner surface of the lower lip is now cleansed by an assistant and held everted. The operator picks up a point of mucous membrane towards the angle of the mouth with toothed forceps held in his left hand, and with scissors, preferably curved on the flat, rapidly cuts a strip of mucous membrane of somewhat more than the length of his lid incision and 4 mm. or 5 mm. broad. The wound in the lip is immediately sutured by an assistant with a continuous suture. If no assistant is available it may be clamped and dealt with later. The strip of mucous membrane is now laid on the palmar surface of a finger of the operator's left hand, raw surface exposed. From the raw surface the fat and submucous tissue are carefully removed, with iris scissors curved on the flat, until the strip is so thin that it is difficult to tell which surface is which. This is the most troublesome and tedious part of the operation, as it is easy to button-hole the delicate graft, and so render it useless, necessitating the cutting of another graft. It is important to perform it thoroughly, as the thinner the graft the better apposition can be got with it, and the more certain it is to 'take.' When sufficiently thin its sides are trimmed parallel and the ends pointed. The graft may now be transferred, till wanted, to a bowl of warm saline lotion or may be kept on the finger if the operator is not likely to forget it and let it be rubbed off during the next stage. Keeping it on the finger with the raw surface exposed saves one straining one's eyes later on to make out which is the raw surface.

"The pad is now removed from the eye, blood wiped away and the lid everted. The line of the incision will be found filled with clot. The bulk of this is very gently removed by forceps or by swabs so as not, if possible, to restart the hæmorrhage. The graft is then placed in position, convenient instruments for this purpose being a pair of fine-pointed, light, dissecting forceps and an iris repositor. If found to be too long it is shortened. Finally, it should lie in, and covering the groove made by the incision, the pointed ends lying in the two curved ends of the groove, care being taken that it is pressed well down on to the lid and that its edges are not curled in. It does not matter if the sides of the graft overlap the sides of the groove, in fact it is probably better that they should; but the points must lie in the groove, as otherwise they are apt to get out of position on closing the eye. If any bleeding has restarted on removing the clot, it will cease as soon as the flap is in position.

"The lid, which has been everted, is now gently replaced. The lid margin is then cautiously raised with the finger and the conjunctival surface inspected to make sure that the graft has not been displaced in the act of replacing the lid. If it has, it is smoothed into position by the iris repositor without again everting the lid. A pad and bandage are then applied."

Possibly every surgeon of experience will vary the details to suit his fancy. MacRae does not carry out the various steps of the operation exactly as demonstrated to him by Webster, but this is a small matter.

MacRae uses general anaesthesia. I personally prefer local anaesthesia. The fact that local anaesthesia is satisfactory places the operation within the reach of numbers of operators who would not otherwise adopt it for want of time or assistance. An infiltration of the upper lid with 2 per cent. novocaine containing a drop or two of adrenaline per c.c. and a similar infiltration of the submucous tissue of the mouth opposite the lower incisors on the side from which it is proposed to take the graft, gives excellent anaesthesia. As a dressing I use a piece of lint well smeared with boracic ointment and change it once or twice in the first six days without disturbing the eye. On the seventh day the eye is released.

It would only confuse the issue to mention other modifications adopted here. They are not essential. The operation can be employed in eyes mutilated by other methods, e.g., where there is shortage of palpebral conjunctiva and drawing up of the upper lid.

MATERNAL MORTALITY IN INDIA: A PRELIMINARY STUDY.*

By CAPTAIN N. R. UBHAYA, L.R.C.P. & S., D.P.H.,
Acting Director of Public Health, Madras Presidency,

and
R. ADISESHAN, B.S.Sc., Dip. Hyg. (Camb.),
Assistant Director of Public Health, Madras.

A DIFFICULTY frequently experienced by the public health officials and workers in charge of maternity relief and child-welfare organizations in this country is in getting reasonably correct statistics of maternal mortality. The extraordinary variations in the maternal death-rates recorded in the different provinces and in cities in the same province are so incredible that little value can be attached to these figures. The following is an example:—

TABLE I.

	Variation in Maternal Death-rates in 1925.
(a) Provinces—Bengal, Bombay, Central Provinces and Madras	2.03 to 5.27
(b) Cities in United Provinces	3.0 to 17.5
(c) " in Madras Presidency	9.0 to 32.8
(d) " in Bombay	5.8 to 53.2
England and Wales	3.6 to 4.3

*Being a paper read at the Medical and Veterinary Section of the Indian Science Congress held at Madras in January 1929.

The causes of these abnormal variations are:—

(a) Maternal mortality rates being expressed as a ratio to live births, the rates will be inflated or lowered to the extent of the defects in the enumeration of births and maternal deaths respectively.

(b) Errors in the compilation of returns resulting from the registrar's ignorance of the nomenclature of diseases—hæmorrhage and eclampsia for example being classified as "other causes."

(c) Under the existing rules, it is only those deaths that occur during or within 14 days of child-birth that are assigned to maternal mortality. This is a very serious cause of under-statement. For instance, in the investigation of puerperal mortality registered in Saxony during the period 1901 to 1904, it was found that only 70 per cent. of deaths occurred in the first two weeks, the corresponding ratio in the present investigation being approximately 60 per cent.

When the total maternal mortality statistics are so defective, it is almost impossible to determine the share of the several diseases responsible for the mortality. In order to surmount this difficulty, attempts have been made from time to time to get this information by indirect methods. One of these is by applying to the general population the experience of maternity hospitals. This method, however, is open to serious objection as the hospital population is an adversely selected one.

The method commonly adopted by the Public Health Department of this Presidency is based on the trend of mortality in the two sexes at different ages. Unlike the case in other countries, the death-rate in women in the ages 15 to 30 in this Presidency; and probably in the rest of India, is markedly higher than in men; in the other age periods, the male mortality is higher as in other countries. This may be seen from the following statement:—

presumed that the excess mortality in women represents maternal deaths. Even then, these figures are an under-statement as no allowance is made for the greater viability of the female in these ages as in other ages and for maternal deaths in the ages 10 to 15 and 30 and above.

As such estimates are after all attended with the risk of a certain amount of speculation, an investigation was started in order to determine by actual field study the maternal mortality rate and the various factors associated therewith as they obtain under ordinary conditions. This paper is a summary of the preliminary statistical analysis of the histories of over 7,000 confinements registered in Madras, Madura, Trichinopoly and Coimbatore during the period October 1927 to September 1928. These confinements correspond approximately to a population of 183,000, the great majority being Hindus who form the preponderating element in this Presidency. The field work was entrusted to members of the Public Health Department of these four cities chosen in consultation with the Health Officers. The different points on which information was elicited are shown in the questionnaire form, published as an appendix. Apart from the fact that the population under enquiry consisted of Hindus and is mainly urban in character, the only other selection, if it can be considered a selection at all, consisted in confining the investigation to such portions of the cities which, on account of their compact situation, facilitated the conduct of investigation. Subject to the limitations inevitable in a field study of the present kind, the results of the preliminary statistical analysis are briefly discussed below:—

(i) *Age at the time of Confinement.*—Out of 7,324 confinements one was at the age of 12, four at age 13, and 38 at the age of 14. The proportion of confinements below 15 was 0.59 per cent. One of the items of information ascertained in the present investigation in the case of confinements under 18 years of age was the age of the

TABLE II.

IN THE AGE INTERVAL.

Ages.	Male.	Female.
0-5	87.23	78.01
5-10	9.5	8.9
10-15	5.7	5.6
15-20	8.2	11.8
20-30	10.2	12.0
30-40	12.7	12.6
40-50	18.6	14.5
50-60	29.4	24.8
60 and above	75.4	75.4

In the absence of any other causes excepting greater risks of maternity to explain the higher incidence of mortality in the ages 15 to 30, it is

mother at the time of consummation of marriage. In some instances, information of this has been furnished even for higher ages. The sub-joined

statement compiled from nearly 900 consecutive cases in which the last confinement was below 20 years of age gives an idea of the proportion of marriages at the earlier ages:—

TABLE III.

Mother's age at consummation of marriage.	Number of marriages.	Proportion per cent. to Total.
12	120	13.82
13	153	17.63
14	192	22.11
15	215	24.77
16	116	13.36
17—19 ..	72	8.29
Below 20 ..	868	99.98

Although early marriages are fairly frequent, it is a matter for surprise that the ratio of confinements below 15 to the total at all ages is only 0.59 per cent.

The ratios of confinements in the different ages to the total are shown in the following statement:—

TABLE IV.

Age interval.	Number of confinements.	Proportion to Total.
Under 15 ..	43	0.59
15—19 ..	1,811	24.73
20—24 ..	2,289	31.25
25—29 ..	1,748	23.87
30—34 ..	934	12.75
35 and above ..	499	6.81
All ages ..	7,324	100.00

(ii) *Plural Births.*—These amounted to just 1 per cent. of the total confinements. Excepting one triplet, the rest were twins.

(iii) *Proportion of Normal and Abnormal Confinements.*—For purposes of this investigation, it is only those confinements in which instrumental delivery or other surgical interference was necessary, that are classified as abnormal. The proportion of these to the total at all ages was 3 per cent. The maximum was in the ages 15 to 24 and 30 to 34 and the minimum in the age period 25 to 29 (excluding the ages under 15 in which the proportion was nil).

TABLE V.

Age period.	Total confinements.	Number of abnormal cases.	Ratio of column (3) to (2).
(1)	(2)	(3)	(4)
Under 15 ..	43	0.0	0.0
15—19 ..	1,811	63	3.47
20—24 ..	2,289	79	3.45
25—29 ..	1,748	37	2.12
30—34 ..	934	29	3.10
35 and above ..	499	14	2.81
All ages ..	7,324	222	3.03

In the experience of the Madras Government Hospital for Women and Children, the proportion of instrumental deliveries during 1910—27 varied from 7 to 14.7 per cent., the corresponding figure in the Norway Hospitals for the year 1917-18 being 3.48 per cent.; the latter figure conforms more or less with the rate arrived at in the present investigation.

Ordinarily, on account of defective registration of still births, the maternal death-rate is represented as a ratio to every 1,000 live births. In the present investigation, however, the number of confinements at risk being definitely known, the death-rate has been calculated with reference to the total births including still births.

Among the 7,324 confinements, there were 131 deaths directly or indirectly attributed to child-birth. This corresponds to a maternal death-rate of 17.89 per 1,000 births. This is in marked contrast with the corresponding rates in other countries:—

TABLE VI.

Countries.	Maternal death-rate per 1,000 live births.
Cities under investigation (1927-28)	18.45
Denmark— 1920 ..	2.35
Holland ..	2.42
Sweden ..	2.58
Japan ..	3.53
Union of South Africa ..	4.10
England and Wales ..	4.33
Germany— 1920 ..	5.15
France ..	6.64
U. S. A. (White) 1921 ..	7.99

Maternal mortality in relation to still births.—In confinements which resulted in still births, the maternal death-rate was 90.36 as compared with 16.20, the death-rate per 1,000 confinements which resulted in live births.

Maternal Mortality according to age at Confinement.—The mortality rate is highest when confinement occurs before 15 years of age, and drops by nearly 50 per cent. in the ages 15 to 19. In the ages 20 to 24, the death-rate corresponds to the rate at all ages. Details for the different age periods are shown in the following statement:—

TABLE VII.

Age.	Number of confinements.	Deaths.	Death-rate per 1,000 confinements.	Deaths at all ages: 100. Proportionate mortality figures.
Under 15	43	2	46.51	260.03
15—19	1,811	43	23.74	132.73
20—24	2,289	41	17.91	100.13
25—29	1,748	25	14.30	79.95
30—34	934	13	13.92	77.82
35 and above	499	7	14.06	78.61
	7,324	131	17.89	100.00

The comparative risks of maternal mortality at the different age intervals will be more readily seen from the last column of the statement, the mortality at all ages being taken as 100.

For purposes of comparison, the age period maternal death-rates in the U. S. A. for 1921 are shown in Table VIII.

Order of Confinement.—This appears to exercise a marked influence on maternal mortality. The risk to the mother at confinement is at its maximum in the first birth order, the mortality-rate being nearly twice that in all birth orders

Order of birth.

Thirteenth	14.01
Fourteenth and over	7.70

Maternal mortality according to Age and Birth Order.—It will be seen from the two preceding

TABLE VIII.

Maternal death-rates per 1,000 births.	Under 15	15-19	20-24	25-29	30-34	35-39	40-44	45 and above.
	20.0	6.8	5.0	5.6	7.4	10.3	13.1	19.2

and is at its minimum in the second and the sixth confinements. The maternal death-rates in the different birth orders are shown below:—

TABLE IX.

Birth order.	Confinements.	Deaths.	Death-rate per 1,000 births.
First	1,553	51	32.84
Second	1,364	13	9.53
Third	1,223	24	19.62
Fourth	953	12	12.59
Fifth	771	13	16.86
Sixth	491	4	8.15
Seventh	414	4	9.66
Eighth	233	5	21.46
Ninth and above	212	5	23.58
TOTAL	7,324	131	17.89

The corresponding figures for New South Wales in this connection may be found to be of interest:—

TABLE X.

Maternal Mortality Rates. By Order of Birth: New South Wales, 1893—1898.

Order of birth.	Maternal mortality per 1,000 births.
First	8.82
Second	4.40
Third	5.11
Fourth	5.27
Fifth	6.60
Sixth	6.19

paragraphs that the maternal death-rate is highest in the first birth order and in ages under 15. From this, a very pertinent remark may be raised, viz., that the high death-rate in early ages is due not so much to age as to the order of confinement, the great majority of confinements in the earlier ages being first confinements. This argument does not, however, seem to be in consonance with the results of the present enquiry as may be seen from the following statement:—

TABLE XI.

PRIMIPARÆ.

Age.	Maternal death-rate per 1,000 births.
Under 15	51.28
15—19	33.04
20—24	30.69
25—29	27.78
30 and above	45.45
All ages	32.84

It appears therefore that the risk to the mother at the first confinement is greatest when it occurs before the age of 15 and it is almost as dangerous at the age of 30 and later.

As regards the second and later confinements, there does not appear to be any correlation between the birth order and the age of the mother at confinement.

Cause of Death.—Sepsis and septicæmia (a large part of which is preventable) caused nearly

60 per cent. of the total mortality. Eclampsia and difficult labour caused about 9 per cent. and 8 per cent. of the deaths:—

TABLE XII.

Causes of death.	Number of deaths.	Percentage of Total.
Puerperal sepsis and septicaemia	77	58.78
Eclampsia	12	9.16
Difficult labour	11	8.40
Hæmorrhage	5	3.82
Other causes	26	19.84
	131	100.00

Attendance at Labour.—For purposes of the present study, confinements which at any stage were handled by untrained midwives are classified as such, although skilled aid might have been summoned at a later stage. According to this grouping, the proportion of confinements attended by trained agency was 36.37 per cent. and by untrained agency 63.63 per cent. These figures for four of the most important cities of the Presidency are ample proof of the insufficiency of skilled maternity aid for attendance at confinement.

A most disconcerting feature in the present study is the maternal mortality rate in the cases attended by trained midwives. Until a more detailed analysis is made, it is not possible to state whether this feature is due to a larger proportion of abnormal and complicated cases in this group or to any other cause. No definite conclusion can therefore be drawn at the present stage.

Economic Conditions.—A rough classification of the confinements was made according to the income of the households. The results are shown in the following tables:

TABLE XIII.

Average household monthly income.	Number of confinements in the group.	Maternal death-rate per 1,000 confinements.
Under Rs. 25 ..	3,200	19.06
Rs. 25—49 ..	2,750	17.09
Rs. 50 and above	1,274	18.05

According to this grouping economic factors do not seem to influence maternal mortality.

Besides maternal mortality, the present investigation was utilized to collect information regarding still births and neo-natal deaths. The results of the analysis are set forth below:—

(i) *Still Births.*—Among the confinements analysed, there were 7,176 live births and 166 still births. The proportion of the latter to the

former is 2.31 per cent. The rate of still births appears to be at its highest when the mother's age is 15 to 19 and 30 and above. Details are shown in the following statement:—

TABLE XIV.

Age group.	Live births.	Still births.	Proportion of still births to 100 live births.
Under 15 ..	43	0	0
15—19 ..	1,771	47	2.65
20—24 ..	2,248	46	2.05
25—29 ..	1,722	29	1.68
30—34 ..	909	29	3.19
35 and above ..	483	16	3.31
All ages ..	7,176	166	2.31

In relation to birth orders, the ratio of still births to live births is lowest in the third birth order. There is a progressive decline in the ratio from the first to the third birth orders, after which there is a steady increase.

TABLE XV.

Birth order.	Ratio of still births to 100 live births.
First	2.51
Second	2.40
Third	1.66
Fourth	2.03
Fifth	2.39
Sixth and above ..	2.74
Total for all Birth Orders ..	2.31

(ii) *Neo-Natal Mortality.*—As all the children in the present investigation were exposed to risk of dying during the first month of their existence, neo-natal mortality in some of its aspects may be considered.

Out of 7,176 children born alive and with respect to whom information regarding survival or death has been furnished, 780 died in the first month of life. This represents a neo-natal mortality rate of 108.70. As approximately 50 per cent. of infant mortality occurs within the first month of life, this neo-natal rate of 108.70 corresponds to an infant mortality rate of 217.40 per 1,000 live births.

The incidence of mortality of infants is at its maximum in the first birth order and when the mother is under 20 years of age. It decreases in the later birth orders and as the age of the

mother at confinement increases. The details are shown in the following two statements:—

TABLE XVI.

Neo-natal Mortality in Relation to the Age of the Mother.

Age of the mother.	Live births.	Neo-natal deaths within one month.	Death-rates per 1,000 births.
Under 15 ..	43	8	186.05
15—19 ..	1,771	227	128.17
20—24 ..	2,248	240	106.76
25—29 ..	1,722	173	100.46
30—34 ..	909	88	96.81
35 and above ..	483	44	91.10
All ages ..	7,176	780	108.70

TABLE XVII.

Neo-natal Mortality as per Birth Order of the Child.

Birth order.	Live births.	Deaths within one month.	Death-rate per 1,000 births.
First ..	1,515	231	152.48
Second ..	1,332	144	108.11
Third ..	1,203	110	91.44
Fourth ..	934	86	92.08
Fifth ..	753	75	99.60
Sixth ..	485	47	96.91
Seventh and above.	954	87	91.19
All orders ..	7,160	780	108.70

(iii) *Economic Conditions.*—Unlike maternal mortality, neo-natal mortality seems to be influenced to some extent by economic conditions. The death-rate per 1,000 births in the first month of life was 120 in families whose income was below Rs. 25 per mensem, 105 when the income was between Rs. 25 and 49, and 84 when the income was Rs. 50 and above.

Conclusions.

From a preliminary statistical analysis of 7,324 confinements in four cities in Madras Presidency, the following conclusions are established:—

(1) Although marriages before the age of 15 are of frequent occurrence, the number of confinements occurring before this age comprises only 0.6 per cent. of the confinements at all ages.

(2) The proportion of plural births was about 1 per cent. of the total.

(3) The proportion of abnormal confinements, to the extent that instrumental delivery or other surgical interference was necessary, was 3 per cent. of the total confinements.

(4) The maternal death-rate in the confinements investigated is 17.89 per thousand births, which compares very unfavourably with the corresponding figures in most other countries.

(5) The maternal death-rate in the case of confinements resulting in still births was a little over $5\frac{1}{2}$ times the death-rate in the case of confinements resulting in live births.

(6) The maternal mortality is at its maximum in the earliest ages. In relation to the order of confinement, the maternal mortality rate is highest in the first confinement. Also in the first birth group, the earlier the age of the mother, the greater is the risk of maternal death. As regards the later birth orders, age does not appear to have any appreciable influence on the mortality.

(7) More than 60 per cent. of the puerperal deaths were due to sepsis and septicaemia which are preventable to a large extent.

(8) Economic conditions do not seem to have any relation to maternal mortality.

(9) Skilled maternity aid was available in only about a third of the confinements, which shows the extreme inadequacy of suitable maternity relief even in important cities.

(10) The ratio of still births to live births was 2.31 per cent. This ratio is highest at the two extremes of the child-bearing age of the mother and in the earlier and in the later birth groups.

(11) The mortality rate among infants in the first month of life was 108.70 per 1,000 births.

(12) The incidence of neo-natal mortality is greatest in the first birth order when the mother is under 20 years of age.

(13) Economic conditions seem to have an inverse relationship to neo-natal mortality.

It should be pointed out that in the present analysis, the relationship of two variables alone has been considered.

It is proposed to continue the enquiries for another year in these four cities and to start similar investigations in other places (urban and rural) in order to get a more representative sample of the population which will ensure greater accuracy when the detailed statistical analysis is undertaken. The present enquiry being probably the first of its kind in this country as far as the general population is concerned, it would be of great advantage if investigations on more or less similar lines are carried out in other parts of the country so that the results may be comparable and the schemes for the improvement of maternity relief may be worked out on more scientific lines than hitherto.

In the present investigation and the tabulation of results, the Health Officers of the four cities, Captain Hesterlow, Professor of Hygiene and his staff, and Dr. Subramanyam, Health Propaganda Officer, have been of invaluable help and our most cordial thanks are due to them.

MICROSCOPIC DIAGNOSIS OF MALARIA ON A GROUP OF TEA ESTATES.

By R. A. MURPHY, I.R.C.P. & S.I.,
Medical Officer, Tea Estates, Luskopore Valley,
South Sylhet.

WHILE the high spleen index, sometimes as high as 80 per cent. on most of the estates in the practice under consideration, shows that the endemicity of malaria is heavy, it is a matter for conjecture as to what extent this disease accounts for the long list of reported fever cases. An accurate and timely diagnosis by the microscope, or even by the temperature chart, of every individual patient is for various reasons not possible, communications being bad, the labour largely scattered in outgarden lines and *bastis*, and the coolies refusing to come indoors or attend regularly. Moreover, the number of films which would require examination from thirteen gardens is a serious obstacle, and for some months, under somewhat primitive conditions, microscopic work can only be done without much discomfort in the early morning hours, on account of the damp heat and the worrying attentions of *Siphonella funicola*, the eye-fly of Assam. Diagnosis, consequently, depends usually upon the sub-assistant surgeons on the estates, and one of the objects of this investigation was to ascertain to what extent the returns supplied by men of some experience, but dependent on the slight clinical evidence available, could be relied on to estimate the number of malarial cases.

Instructions were given on six estates, comprising seven gardens, that blood films should be taken from all patients showing a rise of temperature, irrespective of their complaint. These estates had joined in an anti-malarial scheme, and on most of them some field work had already been carried out, and on three of them in the Managing Agency of Messrs. Duncan Bros., where operations have been in progress some time with the advice of Dr. Strickland, a more than 50 per cent. reduction in the number of fever cases has been effected, and in some instances a very definite lowering of the spleen rate, so that the figures given below must not be taken as representing the full incidence of fever on the estates in the valley generally.

In the course of twelve months, from a population of approximately 9,000, there were 2,166 films made and examined. As there were 2,929 cases of fever returned under the heading of malaria alone, there was a disconcerting paucity of films compared with the number that should have been expected, and the discrepancy largely detracted from the value of the findings. The explanation was that a large number of coolies attended the dispensaries in the morning, and although their temperature was then normal, complained that they had suffered from fever during the night. As the coolie puts most minor ills down to *bokhar*, most of these cases probably have some small indisposition, constipation, or a headache, often well-earned, but as it is impossible to affirm fever has not been present, they are

written up as malaria. An attack of the latter, it might be added, usually comes on here in the two to three hours before noon. There was also difficulty in getting films from many of the *basti* cases.

Of the 2,166 films, malarial parasites were found in 1,167. The results showed, as might be expected, that casual dispensary diagnosis is practically valueless. It was to be expected that many fevers would be called malarial which were not, but it was surprising to find the number diagnosed as other diseases which were in reality malaria. A very striking group, mostly autumnal, showing catarrhal and bronchitis symptoms, with a continued temperature of about 101°F., were logically diagnosed as influenza or feverish colds, but were found to have heavy *P. falciparum* infections. It can be argued in these and the abdominal cases that the finding of parasites is merely accidental, but judging by individual cases coming under treatment malaria is the primary cause, and the massive infections frequently found reinforce this view.

The figures from one estate, with a sub-assistant surgeon rather above the average, show how fallacious returns are—

Diagnosed malaria and parasites found	380
Diagnosed malaria and parasites not found	200
Diagnosed other diseases and parasites found	107
Diagnosed other diseases and parasites not found	110

Some allowance must be made for possible errors due to bad films, parasites missed, etc., but such would not materially affect the findings, for with a reasonable good thick film—and these are easier to make and not subject to the same vagaries of staining as the thin—if parasites are not seen after a ten to fifteen minutes search, malaria may be excluded with tolerable certainty as the cause of the present fever. This is not to say that there may not be an existing latent malaria. When parasites are present the possibility of some other superimposed infection must be borne in mind.

P. vivax parasites were found in 417 films, *P. falciparum* in 739, *P. malariae* in 49, giving in round figures percentages respectively of 35, 61, 4. Crescents in 68. The preponderance of the malignant tertian species is not associated with the malignancy seen in some places. In seven years there has been no case of blackwater fever in a European, nor is the bilious remittent type of fever seen. A very occasional case of blackwater fever occurs amongst members of the educated Indian staff. Malarial coma is rarely seen. High fever with convulsions and death were formerly rather frequent in infants, but, with the inculcation of more vigorous treatment at the onset of fever, even these are becoming few, and the average infant death-rate per 1,000 births for all estates for five years is 116.

A 60 per cent. to 70 per cent. spleen index may be accompanied by a general death-rate of only 12 to 15 per 1,000. With the prevailing *P. falciparum* infection more dire effects would be expected. The coolies are for the most part old settlers, well acclimatized and must possess considerable immunity, and it is possible that recurring passage of the parasite through partially immune hosts may weaken its virulence, nor does it seem unreasonable to suppose that some immunity may be received by the child from its parents.

Films were not taken from patients returning with fever within one month, but 38 returned after a longer interval with a different species of parasite, and 47 with the same parasite. Considering that treatment was only taken while the patient was actually ill, or at the most for a few days after, the number of recorded relapses is very small. The same immunity to relapse is seen to some extent in the long-resident European, but bought with many years of ill health, and those new to infection suffer with certainty from frequent relapses, unless receiving a long course of quinine. A short course is ineffective, and experience does not bear out the results of experiments in a temperate climate. A factor in the failure of the shorter courses of quinine may be that the patient does not rest for long, and as soon as he has shaken off the fever returns to fairly arduous work, and the drug fails to be effective. Young coolie children, also presumably new to infection, would be expected as a general rule to have relapses, and their infrequency supports the suggestion that resistance to the toxins of the parasite may be inherited.

Nevertheless, malaria has far-reaching results for evil on health, and it would be a mistake to rely on treatment (supplemented by swatting mosquitoes in houses) for its mitigation. The residents on tea estates in Assam have for years enjoyed prompt and efficient treatment, better than it would be possible to make available to the general population of most malarial countries, and by this treatment malarious tracts have been rendered habitable, yet the toll is still heavy, deaths occur, miscarriages and still-births frequently originate in a bout of fever, and the loss to estates in working days is large. Moreover, even when the infection does not cause actual fever, nor incapacitate the sufferer, it is the cause of much anæmia, and lowering of vitality, both mental and physical.

The number of positive films each month was as given below. The figures for January are deceptive as 50 of these came from one estate.

Jan.	Feb.	March	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
64	17	53	54	50	93	227	192	137	135	92	53

The films were made and stained in the easy way recommended by Sinton, a thick and thin film being made on the same slide, divided by a

grease pencil line, and after the addition of water to the Romanowsky stain on the thin film it is drawn over on to the thick. In these thick films young rings stain well and are true to type, but older parasites require some revision of previous views, although when sporulating are excellent, even being occasionally seen in this stage. A great help in picking up the older parasites is the pigment, which stands out sharply; the contrast in this respect to the thin film almost raises a doubt as to whether the teaching that hæmozoin is insoluble in pure alcohol is correct. In the rains a thick film may appear thoroughly dry, but if stained on the day it is taken is liable to wash off the slide. This may be avoided by very slightly warming the slide before staining.

A MALARIA SURVEY OF MADARIHAT AND ITS ENVIRONS.

By DR. S. N. SUR, M.B. (Cal.), D.P.H. (Lond.),
D.T.M. (Liverpool),

Assistant Director of Public Health, Malaria Research,
Bengal,

and

DR. BANAMALI GHOSH, M.B. (Cal.), D.P.H. (Cal.),
Assistant to the Assistant Director of Public Health,
Malaria Research, Bengal.

THIS paper has been written chiefly for the purpose of showing those who are interested in the malaria problem the importance of a mosquito survey before launching any scheme to reduce malaria in a locality. To improve the health of Madarihat a proposal was made by the local authority under concern to connect the borrow pits alongside the Bengal Dooars Railway line and drain into the nearest river. This proposal being referred to the Public Health Department for opinion, a malaria survey was conducted in the month of May 1929 by the junior writer under the guidance of the senior writer to find out the actual conditions regarding the breeding of anopheline mosquitoes which are responsible for malaria at Madarihat. The survey was undertaken in the month of May because hospital records showed that the malaria incidence begins to rise by about May at Madarihat and reaches its highest point in July or August. A thorough search was made over an area of about one square mile.

Madarihat is within the Jalpaiguri Dooars. It is a small place located at the terminus of the Bengal Dooars Railway. The open ground on which this colony is located has been the result

of afforestation. It has a bazaar close to the railway station. The charitable dispensary, the police outpost and inspection hungalows, etc., are

all grouped around this *hāt*,* as will be evident from the sketch map. There are two bustees as well, one on the west and the other on the north of the bazaar. The population of the area is about 200 only, consisting of a mixed type of people, viz.—

- (1) Paharis,
- (2) Beharis,
- (3) Marwaris,
- (4) Chinamen,
- (5) Bengalees, and
- (6) Bilaspuris.

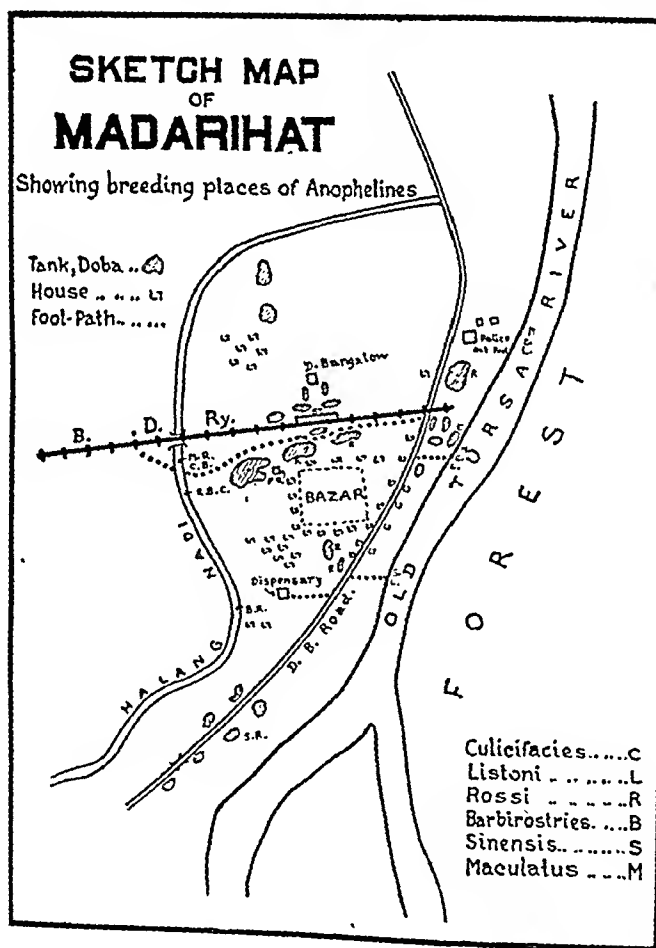

In the *hāt* most of the inhabitants live single for trade or business purposes; only a few live with their families.

forest extends from this stream right up to the present main stream of the Tursa, which is about two miles from this.

On the western side of the *hāt*, beyond the bustee mentioned before, a dry bed of a *jhora* was seen. This was fairly deep in some places and contained a certain amount of water, forming pools. The overgrown jungle on its sides was so thick that the bed was apt to escape notice.

There are open fields between this *jhora* and the bustee. Some of them lying on the west are under paddy cultivation, while others on the south are lying fallow.

On the north there are a number of borrow pits, and beyond them are situated the Bengal

The *hāt* is situated on the right bank of the abandoned bed of the Tursa river, which is overgrown with scrub jungle and *kush* grass. But, further to the north, close to the charitable dispensary, big trees are found with dense jungle underneath on the abandoned river bed. During our visit a fairly strong current was noticed in this old bed close to the police outpost, which was winding through the overgrown *kush* grass on its edge, but further south, the current gradually slowed down into a big swampy pool. Dense

* *Hāt*, means market or bazaar; usually a bazaar held weekly.

Dooars Railway station and the railway embankment with a number of borrow pits on its side, close to the inspection bungalow.

The breeding places of mosquitoes may be grouped under the following headings:—

- (1) The old bed of the Tursa.
- (2) The stream on the western side of the *hāt*.
- (3) Pools, either natural or artificially made by digging up stones for roads and railway purposes.
- (4) Borrow pits—
 - (i) along the railway embankment,
 - (ii) along the District Board roads,

(iii) within the *hāt* compound.

(5) The paddy fields.

(1) *The old bed of the Tursa*.—After search along the edges of the stream on the abandoned bed of the Tursa and the natural pools in connection with the stream, the following species of anopheline larvæ were found:—

- (i) *A. listoni*,
- (ii) *A. culicifacies*,
- (iii) *A. maculatus*,
- (iv) *A. sinensis*.

From local enquiry it was ascertained that usually at this time of the year no water runs in the old bed of the Tursa near the police outpost, where the current was noticed to be fairly strong this year during our visit. Usually only pools, big or small, form in other years. A big swampy pool is found in the bed of the river all the year round opposite the charitable dispensary. The local inhabitants informed us that owing to early rains this year the stream did not dry up and had been running all the year round.

(2) *The jhora on the western side of the bazaar*.—The bed of the jhora was dry in most places but water collections in the form of pools hidden by jungle were searched and the larvæ of the following species of anophelines were found:—

- (i) *A. rossi*,
- (ii) *A. barbirostris*,
- (iii) *A. culicifacies* (two only),
- (iv) *A. maculatus* (one only),
- (v) One pupa hatched out to be *A. minimus*.

(3) *Pools, in the old bed of the Tursa*.—An excavation just on the right side of the terminus

freshly made, just by the side of the District Board road and only a few yards off from the above-mentioned excavation. There were also pools formed of seepages.

(4) *The borrow pits*.—

(i) Those in connection with the railway line are mostly dry, except the two on the northern side of the railway station.

The anopheline larvæ from the dirty and foul water in them belonged to the species—

A. rossi,

A. vagus along with a large number of *Culex* larvæ.

(ii) There are a number of borrow pits on both sides of the District Board road and there were rain-water collections in most of them. The anopheline larvæ collected from them were of the following species:—

A. rossi,

A. vagus.

(iii) Other borrow pits, within the *hāt* compound. One of them was rather deep and contained a comparatively large amount of water. This was found to breed *Culex* and *A. rossi* larvæ.

5. *The paddy fields*.—They were quite dry during the visit, so no definite opinion can be given about them.

Spleen Census.

The spleen census was taken from the *hāt* and the bustees, around it, in order to find out the intensity of malaria. The number of available children under 12 years of age was only 56, as stated below:—

	Total children examined.	Children with enlarged spleen.	Spleen index.
1. <i>Hāt proper</i> .—			
(a) Among the Paharis	7	5	71%
(b) Children examined from the remaining mixed type of population	38	27	71%
2. <i>Bustee</i>	11	7	64%
Total	56	39	70%

of the Bengal Dooars Railway line, made by digging up stones for road and railway purposes formed into a small pool of about 3 square feet with sandy bed and clear water. On examination innumerable *A. culicifacies* were found in the larval and pupal stages, each dip showing some hundred specimens. Similar excavations are fairly numerous and some of them were being

It is therefore seen that malaria in the locality is in a hyperendemic condition.

Relation between these breeding places and the prevalence of malaria at Madarihāt.—The Madarihāt charitable dispensary figures show that the incidence of malaria fever begins to rise in May and is at its height by about July and August, after which it begins to decline.

Malaria Incidence at Madarihāt Charitable Dispensary.

	Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
1924	72	81	182	172	245	257	300	315	225	213	255	297
1925	183	143	152	203	287	249	190	324	250	262	216	109
1926	118	134	151	179	342	324	395	316	201	159	252	252
1927	242	188	159	174	487	381	443	460	359	433	249	214
1928	245	229	265	300	442	342	372	267	251	152	119	172

Hence the mosquitoes responsible for the new infections in the locality which occur in May must be in their larval stage of development at least some five or six weeks before this yearly rise. This fact becomes quite evident when it is kept in view that:—“When anyone develops an attack of malarial fever, for the first time in any season, it may be assumed (i) that he was bitten by an infected anopheles at least ten days or possibly a fortnight previously, (ii) that the infected anopheles that bit him lived as an adult insect for a period of at least 12 or 14 days, for the development of parasites in its stomach and salivary glands, and (iii) prior to that it had spent another 10 or 12 days in passing successively from egg to larval stage and eventually from pupal to adult form.”

The place was visited in the month of May and most of the railway borrow pits were dry, with the exception of a few which had been breeding *A. rossi* and *A. vagus* only. Hence the source of mosquitoes responsible for the malaria at Madarihat must have been some place other than these borrow pits.

The actual findings showed that the small stream in the abandoned bed of the Tursa and the pools either natural or artificially made in the bed were the chief breeding places of at least three dangerous species of anopheline mosquitoes, viz.—

- (i) *A. culicifacies*,
- (ii) *A. listoni*,
- (iii) *A. maculatus*.

Thus in the opinion of the authors these breeding places are mainly responsible for the malaria at Madarihat, and until and unless the stream and pools in the old bed of the Tursa are carefully dealt with, no amount of attention to the borrow pits only will help matters much. If anything is intended to be done in the way of dealing with the breeding places, scrub jungle should first be cleared to bring into view all the hidden pools where mosquitoes are breeding. It is not the intention of this article to suggest the solution of the problem.

PATHOLOGICAL LAUGHING AND CRYING.

By J. NORMAN PACHECO, M.R.C.S., L.R.C.P.,
Acting Medical Superintendent,
Ranchi European Mental Hospital.

In few textbooks on medicine is pathological laughing and crying described as a sequela of certain cerebral lesions, and the condition is so rarely met with that a description of the following case is not without interest. A European, aged 38, was admitted on the 4th February, 1929, with paresis of the left arm and leg. His previous history showed that he contracted syphilis in 1915, for which he was treated with a full course of mercury and salvarsan. In 1919 his Wassermann reaction was still positive and he had a further course

of salvarsan. Up till 1927 he was quite fit and active. Since May 1927 he suffered from severe and continuous headache which ceased only at night and was accompanied by vomiting. The area of pain was just over the right eyebrow. Three days before admission he felt dizzy and reeled to the right side. Vertigo was constant and at the same time he noticed that his left eye grew weaker, and when reading he experienced a crescentic halo to his left. The day previous to his admission while typing letters he noticed that his left arm was cold, numb and weak. When he awoke the next morning he found his left arm and leg were paralysed. He was admitted soon after and on examination it was found that in addition to the arm and leg the left side of his face was paralysed. He could however smile on both sides equally on emotion.

The left hand lost its grip and all the deep reflexes of the arm were exaggerated, but there was no loss of tactile or postural sensibility.

The leg was less paralysed and could be raised off the bed for six inches. The deep reflexes were exaggerated. Babinski's sign (plantar extensor) was present, plus ankle and patellar clonus and no anæsthesia to pain, pressure or temperature.

The right arm and leg and sphincters were unaffected. Jaw clonus was present and the speech was slightly dysarthric.

On examination of the optic discs the right side was normal, but the left in addition to being “choked” had a small dark crescent in the lower and outer quadrant. The pupils were equal and active to light and accommodation. All other cranial nerves were unaffected. He was treated as a case of simple hemiplegia, and on 16th February, 1929, as his Wassermann reaction was positive, 0.45 gm. novarsenobillon was injected intravenously. The next morning he was found to be completely paralysed on both sides and had developed signs of acute bulbar paralysis. He was completely aphasic, had great difficulty in breathing and was unable to swallow, but no fluid regurgitated through the nose. The palate was also paralysed.

The plantar response was extensor on both sides. Throughout his illness the patient never had a rise of temperature.

The most marked feature of the case at this stage was the appearance of uncontrollable fits of laughter. He laughed heartily, incessantly, without cause, and without feeling any emotion whatever, and this in spite of the serious condition he realized he was in. Any stimulus, even the most serious topic, was sufficient to evoke peals of laughter which he could not control even when alone. His mental state was quite clear, and he experienced no pleasure or elation, but rather felt annoyed and expressed the opinion that it was

a positive nuisance. He cried on two occasions without cause and without experiencing any appropriate emotion. The next day (18-2-29) he regained some power in his left arm and left side of his face, and though there was considerable incoordination, he was able to raise his left hand and touch his nose. The power in both limbs gradually returned and in a fortnight he was able to use them, though weak, quite freely.

As he was still aphasic, he was only able to communicate by writing, which he did a good deal most of the day. The arms were the first to regain power. The legs followed gradually and then the face. A second injection of novarsenobillon was given and in a week's time he was able to pronounce a few labial consonants like P. B. M., but not linguals. Two days after the second novarsenobillon injection he complained of an uncontrollable impulse towards crying. He used to cry silently, and again without cause or any accompanying emotion. This however did not last long, and laughter reappeared. He was discharged on 20th February, 1929, by which time he had completely regained the power of his hands and was able to pronounce a few words and name common objects, though with a nasal twang, and could walk several steps but with some ataxia. He is now able to walk quite steadily and can talk a great deal but with a slight slurring and a nasal intonation. The laughter, however, still persists but is decidedly less noticeable.

Apart from its clinical interest the case affords an excellent proof of the fallacy of the James-Lange theory of the emotions, for here we have the exact opposite, i.e., vasomotor disturbance with the consciousness of the characteristic bodily changes, yet without experiencing the appropriate emotion. Numerous examples of this syndrome associated with pseudo-bulbar paralysis have been described by continental writers—the *Zwangslachen* and *Zwangswainen* of German writers and the *rire et pleurer spasmodiques* of the French.

Kinner Wilson in an article in the *Journal of Neurology and Psychopathology* quotes a patient who "went off in a torrent of laughter on the slightest provocation or on none" and others who laughed on the receipt of grave news.

The question that is important in this problem is where is the lesion? According to Head and Holmes the thalamus is the seat of the emotions, but thalamic lesions are not always found at post-mortem in these cases, and, again, lesions of the thalamic and sub-thalamic regions do not always produce pathological laughing or crying. According to Brissaud the integrity of the thalamus is essential to life and the causative lesion is one involving the anterior limb of the internal capsule, where he places his *faisceau*

psychique or fronto-thalamic tract of control over thalamic centres, but for pseudo-bulbar palsy he places the centres for involuntary expressions of the emotions in the basal ganglia. Several other authorities place the lesions in different areas but no precise information is given as to how these act. Kinner Wilson suggests that "lesions of the geniculate bundle anywhere in its course will impair volitional control over the musculatures concerned with expression of the emotions and as pseudo-bulbar paralysis is a disease of the geniculate bundles, lesions affecting it are particularly prone to be accompanied by the phenomenon of *rire et pleurer spasmodique*." He also lays stress on the fact that "corticifugal paths to the facio-respiratory centres in the pons and medulla are independent of the voluntary cortico-ponto-bulbar tracts to the same nuclei," that excitation will "modify the facio-respiratory synkinesis in the direction of either laughter or the reverse."

Now it is a well known fact that if a patient with a lesion, say of the right optic thalamus, is told a joke he smiles only on the right side, but when he assumes a smile both sides of the face act equally. But in a lesion of the right Rolandic area he smiles equally on both sides in response to a joke and an assumed smile occurs only on the right side, showing therefore that the motor element of emotion crosses to the opposite side. Now the only bundle which crosses from the mesencephalon to the opposite side is Monakow's rubro-spinal bundle. I suggest that this bundle subserves the function of the motor part of emotion that is involuntary. In addition there is a cortical portion of the system of motor neurons subserving the function of emotion connecting the cortex with the nucleus rubra. M. and Mme. Dejerine describe such a system, the fibres of which they state originate from all parts of the cortex, especially the parietal lobe. They skirt the thalamus just above the radiations of the internal geniculate body, enter into the formation of the tegmentum and reach the red nucleus at its antero-supero-external part, forming an upper segment of the emotional motor system.

I venture to suggest that the cause of pathological laughing and crying in cases of pseudo-bulbar palsy is to be found in the vicinity of the red nucleus, the lesion stimulating the rubro-spinal tract of Monakow, which may be considered the involuntary tract for emotion, and thus producing involuntary laughter or crying, and at the same time cutting off the cortico-rubral tract described by Dejerine, which tract may be considered to exercise a voluntary control over Monakow's rubro-spinal tract.

The result is that when the voluntary control of Dejerine's cortico-rubral fibres is cut off, stimulation of the lower rubro-spinal

tract produces involuntary laughing and crying without the registration in the association areas of the affective tone of emotion.

CHAULMOOGRA OIL IN THE TREATMENT OF TRACHOMA.

By R. GUBBAY,

Superintendent, Zenana Hospital, Jammu, Kashmir.

OF the very large number of patients who attend our out-patient eye clinic, by far the majority are suffering from trachoma or granular lids.

I have tried many different remedies for this condition, expression, various operations, silver nitrate, and other drugs. Two years ago, however, I commenced to use chaulmoogra oil (obtained from Messrs. Smith, Stanistreet & Co., Calcutta), and the results have been so encouraging that I now use it almost to the exclusion of other applications. With the very first application there is immense relief, the lids feel lighter, the gritty sensation is less troublesome, the sticky discharge decreases, and vision is clearer.

Mode of Application.—A swab stick is soaked with the oil, and, the eyelids being everted, this is well rubbed into the surface, taking care to go as far back as possible into the fornix, at the same time protecting the cornea with the lower lid. The tears combining with the oil form a soapy substance. There is generally intense irritation for a few minutes and much watering of the eyes, but no more than occurs with copper sulphate or silver nitrate. This passes off very quickly, and I have never observed any injury to the cornea or conjunctiva, and have used the method successfully in hundreds of cases.

The application may be made daily, or—if this is found too irritant—every alternate day. About ten to fifteen applications suffice to clear up the condition; but I have given a longer series of applications with no cauterising effects. Scarring is much less with chaulmoogra oil than with other remedies. As to how the oil acts, I cannot say. Early cases react best to treatment, and in these three or four applications are enough to check the progress of the disease.

In acute cases after the first application there may be much swelling and oedema of the lids. This, however, is very rarely the case and does not occur if ordinary measures are used, such as hot fomentations, protargol drops, etc., until the acute symptoms subside.

One case treated was a child one year old. The lids were everted with huge granulations and could not be closed naturally. After four applications there was voluntary closure of the lids. The patient was brought to the hospital for a month, and thereafter was not seen again, so I conclude that there was no further trouble.

Chronic cases do very well indeed. In cases of affection of the margin of the lid with redness, the oil is rubbed well into the margin of the lids—about two or three applications are sufficient. I have treated babies a few weeks old with this

remedy and the results are excellent, with no ill effects.

(*Note.*—We have shown the above article to the Superintendent of the Eye Infirmary, Medical College Hospital, Calcutta, who gives it as his opinion that the chief trouble about the treatment of trachoma and granular lids in India is the almost universal application of too irritant remedies, with bad results. Possibly chaulmoogra oil may represent a happy mean. The microbic cause of trachoma is almost certainly a filter-passing organism, and until something more is known about the ætiology of the disease than is at present the case, treatment is bound to remain empirical. Many of the acute cases are complicated by secondary infections, a Koch-Weeks' bacillus infection, gonorrhoeal conjunctivitis, etc., and the treatment of these should not be neglected.—Ed., I. M. G.)

CHEMOTHERAPEUTIC INVESTIGATIONS WITH ANTIMONY PREPARATIONS IN THE EXPERIMENTAL KALA-AZAR OF THE HAMSTER.

By THE LATE WILHELM ROEHL, M.D.,
*Elberfeld.**

THE production of a general kala-azar infection in different laboratory animals, especially in dogs and mice, was a task which succeeded very rarely, until Smyly and Young (1924) discovered that in the Chinese hamster (*Cricetus griseus*) infection occurred in practically 100 per cent. Thereafter M. Mayer (1926) showed that also in the European variety of the hamster (*Cricetus frumentarius*) a positive result could always be obtained.

The present writer examined the chemotherapeutic properties of different antimony compounds in infected hamsters. The leishmania strain used was obtained through the kindness of the Institut. f. Schiffs-u. Tropic-hygiene, Hamburg.

First of all the toxicity of each compound per kilo body-weight was ascertained. The injections were given subcutaneously. For treatment a single weekly injection was found to be the best possible method. The efficiency of the different compounds was estimated by puncturing the liver of the hamster once weekly and examining a smear for leishmania after staining with Giemsa's stain.

(**Note by the translator:*—Dr. Wilhelm Roehl was an assistant of Professor Paul Ehrlich from 1907 to 1909 and took part in the investigations concerning the new preparations 606 and 904. From those days he devoted his life to chemotherapeutical research, the methods of which he had been taught by the originator himself. In 1911 he became Superintendent of the Chemotherapeutical Research Laboratory of Messrs. F. Bayer in Elberfeld. An important part in the history of the discovery of "Bayer 205" is due to his research and only lately he carried out all the numerous trials connected with the discovery of "Plasmoquine." The method of administering certain quantities of the chemical compound to a bird infected with *Plasmodium relictum* by means of the stomach tube is due to him. And only with this method it was possible to work out the exact chemotherapeutic effects of the different compounds of the Plasmoquine group.

His last work was connected with antimony research, but was not finished. He died suddenly of septicæmia, at only 48 years of age.)

It was possible to keep the animals, which were under permanent microscopic control, free from parasites for several months if efficient compounds were employed, whereas control animals, which were left without treatment, always showed a heavy infection.

By this method the smallest effective doses were ascertained and comparative trials made possible. There were interesting differences as regards tolerability and efficiency among the compounds under examination.

Out of their number we will publish only the results of those which have already been tried clinically and which consequently may have special interest.

(1) *Tartar emetic* (36 per cent. Sb III).

The compound produced after hypodermic injection—the only one which could be taken into consideration in the hamster—severe superficial necrosis.

As tartar emetic was not suitable for therapeutic experiments, another well-tolerated trivalent antimony compound was employed:—

(2) *Antimosan* (12 per cent. Sb III).

Tolerated dose 1.0 gm. per kilo body-weight of hamster (or 0.125 Sb per kilo).

Smallest efficient dose 0.2 gm. per kilo (or 0.025 Sb per kilo).

Chemiotherapeutic Index.—1 : 5.

The two following preparations are pentavalent compounds:—

(3) *Stibosan* (31 per cent. Sb V).

Tolerated dose, 0.7 gm. per kilo (or 0.21 gm. Sb per kilo).

Lethal dose, 1.0 gm. per kilo (or 0.31 gm. Sb per kilo).

Smallest constantly efficient dose, 0.15 gm. per kilo (or 0.046 gm. Sb per kilo).

Sometimes efficient dose, 0.1 gm. per kilo (or 0.03 gm. Sb per kilo).

Chemiotherapeutic Index.—1 : 5 up to 1 : 7.

(4) *Neostibosan* (42 per cent. Sb V).

Tolerated dose, 1.0 gm. per kilo (or 0.42 gm. Sb per kilo).

Lethal dose, 2.0 gm. per kilo (or 0.84 gm. Sb per kilo).

Smallest efficient dose, 0.02 gm. per kilo (or 0.008 gm. Sb per kilo).

Chemiotherapeutic Index.—1 : 50.

These experiments show that "Neostibosan," which was also found to be of very low toxicity in mice after hypodermic injection, differed from the other antimony preparations and had a very high therapeutic index in kala-azar.

The trials of antimony preparations in other experimental diseases like nagana or dourine of mice have not given any definite clues as to the value of various preparations as a kala-azar remedy (Uhlenhuth, Kuhn and Schmidt, 1925). Consequently these measures were of no use in the investigations with "Neostibosan" (Schmidt, 1928).

However, the results in experimental kala-azar of the hamster confirm the clinical findings of Napier (Napier and Mullick, 1928) who has tried "Neostibosan" in human kala-azar and who has ascertained that high efficiency of this preparation combined with the absence of the hitherto experienced antimony by-effects.

A COAT EFFECT OBSERVED IN MICE WHEN FED WITH FATS UNDER CERTAIN CONDITIONS.

(A PRELIMINARY NOTE.)

By T. C. BOYD, F.R.C.S.I., D.P.H., F.I.C.,

LIEUTENANT-COLONEL, I.M.S.,

Chemical Examiner to Government, Bengal,
and

A. C. ROY, M.Sc.,

Biochemical Research Worker under the Indian Research
Fund Association.

We have been experimenting for some time with various dietaries on monkeys on the following general lines:

(1) To produce an avitaminosis by the use of a polished rice diet.

No. 1.—Control.

(2) Feeding with samples of rice which had undergone various degrees of decomposition with the possible production of toxins.

During the course of these experiments we had at times occasions to add fat to the diet and for this we used a vegetable ghee. While the animals were receiving this diet we noticed a peculiar effect on their coats, the hair assuming a rough straight appearance almost as if the animal had been dipped in fat. To verify our observations we repeated the experiments on mice.

We first prepared a basal diet consisting of 100 grams of powdered polished rice, 20 grams of blood albumin, and 4 grams of common salt. A litter of young mice were taken and divided into three batches. To batch (1) was given the basal diet with the addition of 2 to 3 drops of cod liver oil and two or three grains of germinating gram; batch (2) were given the same, with the addition of 0.5 gram of vegetable ghee; and batch (3) with the same amount of pure cow's ghee.

After about six days on the above diets it was noticed that the mice receiving the vegetable ghee developed the peculiar appearance in their coats (this appearance may be well seen in the photograph).

The same peculiarity also developed in the batch to which cow's ghee had been added, while the control set remained normal. After about two weeks the diets were reversed, that is to say the

No. 2.—Fed on a diet containing ghee.

control batch were given vegetable ghee in their dietaries and the vegetable ghee batch were placed on the basal diet. In the course of a week the coats of the mice on the basal diet returned to normal, while the former controls developed the peculiarity in their coats. The experiment was repeated on several batches of mice, always with the same effect. We also tried the effects of the addition of olive oil and 'til' oil and found that the same abnormality occurred, but the effect was not so pronounced.

We are not at present in a position to assign any reason for this phenomenon, but further work is in progress. In the meantime, however, we consider this peculiarity worthy of note.

NERVOUS MANIFESTATIONS IN TUBERCULOUS INFECTIONS.*

By DR. P. V. GHARPURÉ, M.D. (Bom.),

Grant Medical College, Bombay.

In an address on tuberculosis and the nervous system by Sir Farquhar Buzzard, published in the *British Medical Journal* of 11th May, 1929, a number of conditions are referred to in connection with tuberculosis and the nervous system. In a subsequent number of the same journal, perhaps prompted by the publication of this address, some case reports have been published. I have with me case notes which I propose to embody in this note as I think they are of some interest.

The following cases are worth recording:—

Case No. 1.—A girl, aged 15, was seen by me in 1925 with a history that she gradually developed inability to attend to her school work and later developed inability to walk. When I first examined her she exhibited a slight squint and a dazed appearance. She did not show the same intelligence as before (I knew her since her birth). On examination it was noted that her speech was affected and it was of a monosyllabic character (scanning type). Her heart and lungs were normal. Her build and development were fairly good. Born of healthy parents, she was one of several children all of whom were quite fit. The examination of the nervous system showed vague signs. Her memory was not clear, so much so that she occasionally was unable to tell the name of the place she came from. She could not describe the onset and progress of her ailment; the deep reflexes were exaggerated; ankle-clonus was present on both sides, she used to get regular convulsive attacks starting from the face and spreading to the whole of the right side. There was some defect in vision. Thus at first sight the signs pointed to disseminated sclerosis. I advised that she be kept under observation and brought and kept in Bombay. Not clearly being able to make out what the matter was I consulted a prominent physician of Bombay who diagnosed the case as one of hysteria and prescribed a line of treatment including electrical treatment. I was not quite satisfied but continued the treatment in all its details and again submitted her to further examination by the same physician who still was of the same opinion. After keeping her under my care for one month I sent her back to her parents with no change in her condition. Later her doctor informed me that the girl developed typical symptoms of acute meningitis and died of hyperpyrexia fifteen days after she returned from Bombay. The total period of her illness was eight months. No cerebro-spinal fluid examination was done, no blood examination was done, and no post-mortem was possible.

One can speculate about the cause of the disease, but I was nearly sure that it was a case of tuberculosis. The exact nature of the lesion I was not sure of. I only kept the case before my mind for subsequent observations, thinking that the so-called "hysteria" might have been nervous symptoms of a latent tuberculosis.

Case No. 2.—Later, about the middle of 1925, a girl, aged about 13, was brought to me for regular twitching movements of the right hand and forearm. It was such a typical picture of chorea that I dealt with it at length and showed the patient to the students around me in the out-patient department as an ideal case of chorea. She was admitted to the hospital; on admission her temperature was 102°F. and she had a tendency to drowsiness. I was somehow reminded of the former case and thought that this might be another manifestation of tuberculosis. I did a lumbar puncture, the fluid was clear, cells increased, mostly mononuclears, tubercle

* A paper read before the British Medical Association, Bombay Branch, on 19th July, 1929.

bacilli present. Seen the same evening, she showed definite signs of increased pressure in the meninges, Kernig's sign was marked on both sides, the temperature had gone up and I warned the relations that the case might end fatally. Next morning lumbar puncture was repeated and the same type of clear fluid under pressure came out. This puncture was done to relieve the pressure. The second afternoon, i.e., the third day after I saw her first, the temperature went to 106°F. and the girl died. Here again no post-mortem was available.

Case No. 3.—A girl, aged 14, was in a private hospital for some trouble with her ankle joint presumed to be of tuberculous origin. On examination there were no signs of tuberculosis. She was reported to be subject to hysterical fits. She was a child widow. With the experience of the former two cases in mind I was interested in this case and kept her under observation and attended her when she was in the fits. The fits were of an epileptic type and generalized throughout the whole of the body. She used to scream and had a marked aura in the form of twitching of the face muscles, upper extremities or lower. I watched a succession of fits one night. At first I told the father of the girl that she was a subject of hysteria, but later changed my opinion, being reminded of the former cases above referred to. Examination revealed that she had slight exaggeration of all deep reflexes and a faintly positive Kernig's sign. She was put under observation and her temperature was showing signs of rising. At this stage with 102°F. temperature a lumbar puncture was done. The fluid came out under pressure. It was clear, with cells increased, mostly mononuclears. Tubercle bacilli were found in it. After this examination I gave a grave prognosis and warned the house surgeon of the hospital and the parents that the commencing attack was probably the final stage in a tuberculous infection and that she might die of hyperpyrexia. Suitable treatment for hyperpyrexia was given. On the third day after the cerebro-spinal fluid was examined her temperature went up to 107.2°F. and she died. Here again a post-mortem was not available.

Case No. 4.—This case was that of a patient under Dr. Kohiyar's care at the J. J. Hospital. The patient was admitted with fever and signs of meningitis, and was for a couple of days only in the wards.

His temperature chart showed a persistent rise. The cerebro-spinal fluid showed lymphocytes and tubercle bacilli. After death a post-mortem was done. No tubercular lesions were seen anywhere. The sub-arachnoid space was tense with fluid, the fluid was collected and examined and it showed tubercle bacilli.

Case No. 5.—One more case may be cited of an adult male, aged about 32, brought down from Nasik by his relatives to Bombay. The history given by the relatives was that they considered him insane and a dangerous person and wanted me to certify him a lunatic. I examined him carefully. I noticed in him exaggerated knee-jerks and signs of meningitis and warned the relatives of a grave prognosis. The doctor who accompanied him was kind enough to give me details later. This man died of hyperpyrexia, developing signs of acute meningitis.

These are the cases I have come across which in my opinion may throw some light on nervous manifestations in tuberculous infection. The termination in all has been a typical acute tubercular meningitis, but I particularly wish to point out the initial signs and symptoms; the hysterical, the choreiform and epileptic manifestations. I am led to believe that the cerebro-spinal fluid is an unfavourable medium for tubercle bacilli, and this may explain the comparative absence of tuberculous lesions of the central nervous system and meninges even in cases which show generalized acute miliary dissemination. I have by now examined several cases in the post-mortem room.

Another suggestion I may venture to make. I believe that there are only some particular strains of tubercle bacilli which affect the central nervous system and an ordinary case of tuberculosis is quite free from nervous symptoms and has comparatively a very hopeful temperament. It may be that a particular strain gives off a neurotropic virus. It certainly would require experimental evidence to substantiate such a proposition.

On the other hand, to find tuberculous lesions in the central nervous system in very advanced and generalized tuberculosis cases in the post-mortem room is unknown so far as my experience goes.

X-RAY WORK IN BALUCHISTAN. (THE NEW X-RAY AND ELECTROTHERAPY DEPARTMENT OF THE C. M. S. HOSPITAL, QUETTA.)

By J. H. BARRETT, D.M.R.E.,

CAPTAIN, I.M.S.,

Quetta.

ONE is not often fortunate enough to have either the opportunity or the funds to erect and equip a department designed solely for radiological and electrotherapeutic work. I have had the good fortune to be associated with Dr H. T. Holland, C.I.E., and Dr K. W. Mackenzie, D.S.O., M.C., in the planning and designing of the new x-ray and electrotherapy departments of the Mission Hospital, at Quetta; and it has been no small pleasure to me to realize that the actual building plan submitted by me has been adopted by them. It is through the courtesy of the above that I now describe certain aspects of the new x-ray department which I hope may be of use to others who are confronted with the difficulty of erecting a similar department with semi-skilled labour, and where economy is a *sine qua non*. Incidentally it is no longer the fate of the unfortunate radiologist to be allotted a cell in the basement of a hospital where the darkness accentuates the difficulties of his work. The great advances that radiology has made in the recent years deserves something better than the cellars, and the Mission at Quetta has given a progressive lead in this direction.

THE MAIN X-RAY OPERATING ROOM

The whole finished building is designed so as to occupy three sides of a square. Funds at present only allow two sides to be completed, one for x-ray work, and one for electrotherapy. The third side will be used, when constructed, for stores and ultra-violet rays, etc.

The main x-ray room (indeed the whole building) is built of kacha brick cemented over. Both ceiling and floors are constructed of wood. The dimensions of the room are as shown (see building plans). The back windows face north, and it communicates directly with the electrotherapy room and

ELECTRO- THERAPY

LIGHT TRAP

G.I. IRON SHEET

XRAY DE POT

with the dark room, access to the latter being obtained by means of a special light-trap (not the cumbersome double door).

The ceiling is stained light mahogany.

The wall colours for the x-ray room, dark room, and the electrotherapy room are arranged as follows:—

X-ray Room.

The wall is light stone colour in the middle, with 2½-inch belts of dark green, 3½ ft. from the floor and 1 ft. from the ceiling. The lower 3½ ft. of wall is light green and the upper foot near the ceiling is white.

Dark Room.

Light blue.

Electrotherapy Room.

Light blue in the middle with 2½-inch belts of black, 3½ ft. from the floor and 1 ft. from the ceiling. The lower 3½ ft. is coloured grass green, and the upper foot the same blue as the middle.

The High Tension Wiring System.—The overhead system was designed with an eye

to simplicity and economy. A glance at diagram No. 2 shows the arrangement. It is merely a system of ordinary brass tubes (diameter ½ inch) supported on brackets. As high tension switches are expensive they have been omitted. The deficiency has been made up by the arrangement of the tubes and

brackets so that three pieces of x-ray apparatus can be used, so the cost of the high

PLAN of X-RAY DEPARTMENT C.M.S. MISSION HOSPITAL QUETTA.

tension switch is saved. The special shape of the brackets, one limb longer than the other, enables correct spacing of the spring leads to obtain during operation.

Light Exclusion.—In the main x-ray room this is effected by using external sliding galvanized iron shutters. These shutters can be operated also from inside the room. The "roshan dans" (windows near the ceiling) are occluded by a special cap, operated from the room but opening outwards (see diagram No. 2).

Earthing.—Efficient earthing of the apparatus is facilitated by two large steel plates buried below the floor, one at each end of the room, and connected by a long steel bar down the centre, and also below the floor.

THE DARK ROOM.

Easy access to the dark room is effected by the light trap door previously mentioned. An arrangement has been made to enable films to be passed easily in and out of the dark room (see diagram No. 2).

Safe Light.—By means of a simple arrangement films may be developed, using either screened daylight, electric light, or the light of an ordinary hurricane lamp.

A point not lost sight of was the possibility of the dark room being also required for transilluminations and for ophthalmic work.

ELECTROTHERAPY ROOM.

This room will also be used as an office. The bay windows at the end ensure efficient lighting so that the office work can be done at that end. The old idea of the combined x-ray room-office is bad from all points of view. The necessary number of wall plugs have been inserted to enable different types of apparatus to be used.

EQUIPMENT.

The equipment is modern and includes a Victor high tension transformer; a combined screening-stand and couch (Schall), metalix tubes, and Potter-Bucky diaphragm. The electrotherapy equipment includes a pleurostadt (Cox-Cavendish) and Schnee's baths. As soon as funds are available the building will be extended and also a further increase in apparatus will be made. The actual cost of the apparatus alone (not including delivery, freight charges, etc.) is approximately £750.

The erection and equipment of the above X-ray and Electrotherapy Department was made possible as a result of a munificent donation of Rs. 11,000 (to the C. M. S. Hospital, Quetta) by his Excellency the Khan of Kalat State.

A Mirror of Hospital Practice.

A CASE OF VARIOLA TREATED BY VACCINATION.

By C. D. CHATTERJI, B.Sc., M.B., B.S.,

Medical Officer, Kapurthala Dispensary, Lucknow.

Mr. F. came to Lucknow with a son aged five years and a daughter aged eight years. The son got an attack of fever on the 16th May, 1929, and developed rashes on the 19th May. The rashes developed into a severe confluent type of variola and the child died on the 29th May. His sister aged eight years was brought to my dispensary on the 31st May, suffering from fever (temperature 104°F.). Her face was flushed but she showed no other symptoms, except slight pain in her joints. I diagnosed the case as one of smallpox and advised immediate vaccination. She was vaccinated the same evening. From that date the temperature never went below 104°F. and an ice cap was constantly applied. On the 3rd June (the fourth day following vaccination), pimples appeared on her face, forearms, hands, legs and feet which two days later developed into typical variola, but in a milder form. On the 6th June, the pimples appeared on the sites of vaccination and her fever came down to 102°F. Henceforth her convalescence was rapid and uninterrupted, the fever leaving her on the 7th June; the pustules quickly dried up and she was able to leave her bed after a week. The pustules of the vaccination took the usual time to dry up.

The point to be noted in this case was that the child was not previously vaccinated. This suggests that if cases of smallpox are vaccinated in the earliest stage, the attack becomes milder and the patient may be saved; however, the advisability of vaccinating a patient when the system is already under the reaction of an acute infection cannot be settled unless numerous experiments of this nature are made with favourable results. The patient may not be able to tolerate the effects of vaccination over and above the severe reaction of variola.

A CASE OF AN ABSCESS OF THE BRAIN.

By SURESH CHANDRA DAS GUPTA, L.M.S.,

Senior Surgeon, Bir Hospital, Nepal.

In October 1928, R. N. S., a male aged 20 years, was brought to the Bir Hospital in an unconscious state for depressed fracture of the skull caused 3 days previously by direct violence with a heavy piece of stone hurled against his head by an insane man. The patient was comatose, passing urine and stools in bed, and with the right hand and left side of the face paralysed.

On examination it was found that the scalp was lacerated, the wound being situated just below and a little anterior to the parietal eminence, and there was a compound fracture of the skull with much depression. But, as the pulse was very weak and the respiration almost stertorous, I decided to wait till the condition improved, and in the meantime ordered antiseptic dressings to be applied every 6 hours. However, there was no change for the better in the course of next 48 hours, on the other hand the temperature rose to 104°F. Therefore, I thought that delay was dangerous, and with the consent of the members of his family I made up my mind to operate at once. After the usual preparations the patient was anaesthetised lightly as he was almost insensible to pain, a semilunar incision was made and the infected margins of the wound were cut away after careful sterilization. Then the skull was laid bare and trephined, and all the in-driven fragments of bone from the depressed area were removed, when

the membranes were seen to be torn, and as soon as they were separated there was a gush of pus from the brain. I then gently probed the cavity. It measured about an inch and a half in depth. Next, I had the cavity washed out with tepid sterilized saline solution and left a drainage tube in the cavity which was fixed to the scalp by means of two stitches, shown in Fig. 1. On the second day of operation the tempera-

Fig. 1.

ture came down, but the patient was still unconscious. I then administered urotropin. After a week of stupor he began to regain his senses and exhibited signs of feeling the pain at the time of depressing, and when he was asked to open his mouth or protrude his tongue he would do so. After the second week he regained consciousness completely, and though he could not utter a single word he could explain his motive by signs; he indicated that he wanted paper and pencil and actually wrote down the names of a variety of foods which he wanted. On the 17th day I removed the drainage tube, the cavity having been in the meanwhile nearly filled up. After three weeks I tried to teach him to utter words after me, but he could not succeed. I then asked him to imitate me by looking at my face and copying the movements of my mouth, and expressions. I explained to him the different sources of pronunciation of various letters, such as, lips, teeth, plate, and so on, and just like a baby he began to pick up new words daily.

After 4 weeks when the gap in the membrane was nearly filled up in order to cover the gap in the skull I had a thin silver plate made with 2 holes at either end for the purpose of suturing it to the scalp. Then in order to fix the plate and close the wound the patient was again put under chloroform, an incision was made on either side of the wound and the uneven margins were removed. Next, another incision was made $1\frac{1}{2}$ inches away from and parallel to the former wound, and the flap between the cuts was raised by undermining the skin leaving the pericranium intact, and then the plate, having been sterilized, trimmed to fit the aperture and its edges smoothed, was applied on the base of the

scalp-flap and fixed in position by silkworm gut stitches. The original gap was closed by bringing the edges of the primary wound in apposition over the silver plate by the bridge-flap method; by doing this a gap was produced on the outer aspect, above the ear, but this wound healed up very quickly.

Fig. 2 was taken 3 months after the patient's discharge from the hospital. The only defects he has now are

Fig. 2.

physical ones, such as slight weakness of the right forearm and hand, and slight incoherence of voice, but his mental condition is quite good.

A CASE OF ACCIDENTAL SUFFOCATION IN A WELL.

By J. F. HENRIQUES, L.M. & S., F.C.P.S., B.M.S.,
Medical Officer, Bulsar.

THE interesting letter from Dr. Rajandra Prasad on the above subject in the May number of the *Indian Medical Gazette* was found by me a very opportune one, as similar cases occurred in Bulsar.

On 16th June, 1929, in the afternoon I was sent for to render artificial respiration to 3 patients. The history was as follows:—A rice mill had a disused well in its compound, which for some reason or other was discarded and was being filled with husks which were also gathered in a large heap alongside the well. After some time it was decided, as the rains were setting in, to clean up the well and utilize the water for the mill machinery. The well was a deep one; the water was probably waist deep. A labourer went in but soon after shouted for help. It was thought that he had hurt himself. A second labourer went in to his rescue and did not return. A third then went in to the rescue of the other two, but also did not return. A fourth went in roped and immediately shouted to be drawn up, as he was feeling suffocated. The dragging out of the

three corpses was a difficult problem. A fifth man then went in, and very hurriedly and dexterously managed to strap one of the corpses to a hook which was at once drawn out; but he felt distressed in breathing for a short time and I had to get him into the fresh air away from the large crowd. He went in subsequently and brought out the other two corpses in the same way, though he felt distressed in the same manner each time. Artificial respiration was of no avail, as the bodies were in the well for nearly two hours. They were cyanosed. There was white froth coming from the mouth of one and food from another.

A lantern was then put in the well after the corpses had been dragged out. The light went out. Silver and brass ornaments were not tarnished.

According to Lyon's Jurisprudence carbon dioxide gas is produced by stored grain which has become damp; similar cases of dioxide gas poisoning are described in this book. I presume it was this gas which caused the tragic death of these three persons. It was germinated, in my opinion, from the husks.

A CASE OF RAT-BITE FEVER.

By M. A. KRISHNA IYER,

Medical Officer, Jammalamadugu, Cuddapah District.

A HEALTHY young man, aged about 26, a villager and a friend of the writer, was bitten by a bandicoot on his foot while returning from a hotel on a dark night in Madras. Some antiseptic dressings were applied to the wound and nothing was thought about it for some time. He is employed in a Government office and attended his office as usual. For about 6 months the ulcer did not heal. About October 1927 I happened to meet him at Madras. Then he showed me the ulcer in an unhealthy state with a good deal of inflammatory infiltration of the surrounding tissues. He told me how six months previously he had been bitten by a bandicoot and further added that he was getting irregular fever now and then, and that he felt very weak. I too noticed a change in his constitution. As I myself was ignorant of the characteristic symptoms that develop in a rat-bite case then, I could not help him much in the way of treatment. However, I asked him to have complete rest and proper treatment for the ulcer and to take some tonics for the general improvement of his health.

Soon after the publication of the article on rat-bite fever in the *Indian Medical Gazette* of September last, I got a note, that the condition of the patient was getting worse and that he had been reduced to a skeleton (a person who had appeared for police sub-inspector's selection for 2 or 3 years, and had had an excellent constitution with the necessary height, weight, girth, etc.), and that his disease had been diagnosed as, and was receiving treatment for, tuberculosis of the lungs.

On my suggesting to him the diagnosis of his condition, he approached his doctor with the object of getting injected with Neosalvarsan. For some reason or other the doctor did not give the injections and he had to go to another doctor, who gave him 2 or 3 injections.

He was cured and within the period of 3 to 4 months he regained his old constitution, and again appeared for police selection.

ASCARIASIS SIMULATING ABDOMINAL TUMOURS.

By J. F. HENRIQUES, I.M. & S., F.C.P.S., B.M.S.,
Medical Officer, Bulsar.

A HINDU, male child, age 5 years, had a number of masses easily felt within the abdomen. Duration of condition: 2 months. The child looked anæmic. A diagnosis of tumour had been made elsewhere, and the patient had been advised to come to the dispensary for operation. I felt about 4 or 5 masses on palpating the abdomen; one especially seemed unduly prominent and fairly superficial. It was felt above the right Poupart's ligament. I suspected malignancy and advised the patient that operation was out of the question, but as always happens when the doctor does not desire to do anything in a case the patient wants him to operate; in this case the child's father was very disappointed that I was not going to operate. As a *placebo*, I prescribed salol with *mistura sodii compound* and as the patient lived some miles away I gave medicine for four days. During this time the patient had 6 grains of salol. This drug has some slight anthelmintic action and four days after the child was again brought to the dispensary, having passed during this interval 25 worms. The lumps had all disappeared and the abdomen was flat. I then gave a *santonin powder*; the child only passed a few more worms.

Though the man, who belonged to the illiterate classes, was happy to see his child all right after taking my medicine and thought very highly of me, still I felt very insignificant to think how poor my diagnosis had been.

This case shows the importance of giving *santonin* as a preliminary measure to abdominal operations in tropical countries.

A RADICAL CURE FOR HYDROCELE BY QUININE INJECTION.

By B. L. SHARMA, I.M.P.,

Medical Officer, Chumar, District Mirzapur, U. P.

THE following method for the treatment of hydrocele has been tested by me and found successful in several cases during the last two years. During this period cases of hydrocele of different size and duration have been treated by me with this method, and in no case was there any re-accumulation of fluid.

The method is very simple, painless, without any bad after-effects, and takes only a few minutes to perform so that the patients can be sent home soon afterwards, and attend to their ordinary pursuits of life.

The Technic of the Operation.

Articles required:—

- (1) An all-glass 10 c.c. syringe with a needle, $2\frac{1}{2}$ inches long.
- (2) An hydrocele trocar and cannula.
- (3) Ten c.c. sterilized solution, containing 20 grains of quinine bi-hydrochloride and 1 grain of acid salicylic.

The scrotum is well cleaned and painted with tincture of iodine while the patient is sitting on a chair.

With all the necessary antiseptic measures the surgeon taps the hydrocele with the trocar and cannula, drains the fluid thoroughly, and leaves the cannula *in situ*.

The hypodermic syringe is filled with the quinine and acid solution, and emptied into the sac by inserting the needle into the cannula. (The solution should be slightly warm.)

The needle and the cannula are removed, the puncture wound rubbed well with the fingers, and painted with tincture of benzoin. The patient is then discharged with a suspensory bandage to be used for some days.

On account of slow absorption of the solution, the scrotum remains larger for about 15 days, but without any pain or inconvenience of any kind; it then becomes reduced to its normal size.

A PERSIAN TREATMENT FOR ORIENTAL SORE.

By SORAB BAPPJI VATCHAGHANDY, L.M. & S.,
82, Nepan Sea Road, Malabar Hill, Bombay.

IN September 1928, a month and a half before I left Persia, where I was in charge of the Sir Ratan Tata Medical Hall, Yezd, a Zoroastrian boy of 6 or 7, was brought to me for some ordinary ailment. He also had a big oriental sore, a little larger than the size of a rupee, on his face, situated at the corner of the right ala nasi. His father, who accompanied him, had recently returned home with the boy from Teheran to visit his family. The boy had contracted the trouble in Teheran some four months previously. As they did not turn up next day I forgot all about this case. After three weeks the boy was again brought to me for cough, and to my surprise I saw the ulcer healed up, leaving a thin scar without much disfigurement. On inquiry I was informed that he had been taken to a fruit-seller in the bazar who had a specific ointment which cured this trouble in a week. Promising some monetary reward, with great difficulty, my friend, Arbab Shapoor Goostasp, a landlord and a merchant, persuaded the son of the fruit-seller, who also knew the remedy, to

give me the prescription of this ointment. He brought me two powders. One was red oxide of mercury; the other "aishnoo." Aishnoo is the Persian name of a local plant which is dried, powdered, and extensively used, particularly in Yezd by the poor, as a substitute for soap for washing clothes. According to the man it is more important than the mercury salt. He told me "on the third day you will see that it brings out the roots of the disease from the ulcer." I weighed the powders he gave me, separately. The proportion was approximately one of red oxide and four of "aishnoo." In this proportion I used them for a case to be described below. The powders are triturated and a small quantity is mixed with the yolk of an egg, sufficient to make an ordinary paste, neither too thin nor too thick.

Oriental sore was not prevalent in Yezd at the time. I saw only two cases during my stay of 18 months. I am told that at times it is so very prevalent that even persons over 70 do not escape this infection. That it is common there can be easily verified by the number of patients attending the dispensary with scars, generally on the face. So, to verify the specificity of the ointment myself, with difficulty I obtained one case. The patient was a maidservant in a family. She was a girl of 13 and had contracted the sore some six months previously at her village, Allahabad, 8 to 10 miles from Yezd. The sore was situated on the extensor surface of the mid-forearm, was oval in shape, and nearly two inches in long diameter. I smeared vaseline on the healthy border, and applied the ointment on a piece of lint just the size of the ulcer. On application the burning was very severe, but it did not last long. Next day there was some pus, and, in spite of vaseline, the surrounding skin was a bit inflamed. I cleaned the ulcer with spirit and changed the dressing every day, applying freshly-prepared ointment. On the third or fourth day the ulcer, though rough, was clean, with a number of tiny white spots on its surface. These constituted "the roots" spoken of before. On being closely examined they resembled the heads of guinea worms protruding from a broken surface. When I tried to pull out one it would give way leaving a very thin white thread-like piece, about one-twentieth of an inch, on the forceps. After the sixth day I was nervous lest the ointment would be too strong for a healthy wound, but I went on with the dressings as usual, and on the tenth day the ulcer was completely healed.

(Note.—Ointments containing mercury, copper and arsenic are commonly used by the barbers in northern India in the treatment of oriental sore. Their action, so far as is known, is chiefly to cause irritation and inflammation with sloughing of the diseased tissue. There is no specific action. "Aishnoo" would appear to be some substance of the nature of soap-nut which contains large quantities of irritating saponins.—Editor, *Indian Medical Gazette*.)

Indian Medical Gazette.

OCTOBER.

THE PARASITOLOGY OF INDIAN MALARIA: UNPUBLISHED INFORMATION.

IN our issue for August 1929, we published an appeal for information with regard to the parasitology of Indian malaria. Previously to that we had circularised the different Directors of Public Health in the provinces of India, the Directors of major laboratories, and others whom we knew to be interested in the subject. The position briefly was that—with the exception of certain well-known papers of outstanding merit—but little has been published in the journals with regard to malaria in India during the present century, but we knew that exhaustive investigation and very many surveys had been carried out. The question at issue was, Where was all this mine of information buried?

The result of our appeal has been as amazing as it has been gratifying. We owe our deepest debt of all to Major J. A. Sinton, V.C., I.M.S., Director, Malaria Survey of India. Major Sinton recently spent two years in collecting and digging into the buried files in the various Public Health Departments, offices of the provincial Surgeons-General, and the major laboratories in India. The result was that in every province he was able to unearth stores of buried—and often forgotten—information, unavailable to the outside world. He proceeded to compile a *Bibliography of Malaria in India*, which is now in press, and which gives an exhaustive list of all these published and unpublished documents, chiefly from 1896 to 1926. This will shortly be issued as the first number of a new publication financed by the Indian Research Fund Association, entitled *Reports from the Malaria Survey of India*.

Major Sinton was kind enough to lend us an advance copy of the manuscript of his *Bibliography*, and, armed with this information, we wrote to various public health officials and others, asking for a loan of the various documents which we now knew to exist in their offices. The reply has been cordial and generous in the extreme.

The outside world may think that malaria has been but little studied in India since Sir Ronald Ross and the Italian workers made their famous discovery of the method of transmission of malaria. A study of the journals would certainly lead one to such a conclusion. But the true facts are entirely different. India contains within her

borders almost every conceivable variety of climate in the world, and malaria has been studied in them all, with special reference to its parasitology and epidemiology. Of the wealth of information which has passed through our hands during the past three months, about 15 per cent. are papers published in well known and readily accessible journals, about another 15 per cent. have been published as local governments reports—some of which are very difficult to procure, and many out of print, and few or no copies available; the remaining 70 per cent. or so are still typed or hand-written documents. But the information which they contain covers India from north to south and east to west, and constitutes a mine of entirely untapped information already in existence with regard to the epidemiology of Indian malaria.

Let us take a few examples to show the true position of affairs:—

(i) Malaria in the North-West Frontier Province is dealt with in the journals chiefly in papers by Acton in 1910, and Adie in the same year; also in a paper by Sinton, dealing with Kohat. But there are many unpublished reports by Lieut.-Col. H. G. Stiles-Webb, I.M.S., when Sanitary Commissioner in that province, dealing with several areas; a series of annual reports on Peshawar city by Capt. Richmond, R.A.M.C.; and, above all, an invaluable report by Lieut.-Col. H. Stott, I.M.S., on a two years' survey of the Tochi valley, which gives a detailed account of the epidemiology of malaria in an almost rainless area in the North-West Frontier Province. Apparently Peshawar was relatively free from malaria until about twenty years ago, when an enterprising general decided that officers resident in the city should start gardens in their compounds and introduce irrigation. To-day Peshawar apparently shares with Dera Ismail Khan the notoriety of being the most malarious station in the province.

Col. Stott's paper is one of the most striking that we have seen. It is very fully mapped and illustrated with magnificent photographs of the type of scenery encountered on the frontier; it deals with malaria in barren outposts and rocky mountain areas. It is a document of intense interest, but at present it exists only in manuscript form.

(ii) The Punjab is fairly well dealt with in accessible publications. There is the classical memoir by Christophers on the terrible epidemic of 1908 and its aftermath, and there are several recent reports by Gill, as well as older ones by Adie. But there must be many unpublished documents. Still, taken as a whole, information about the Punjab is that most readily accessible and most generally known.

(iii) The United Provinces present a most interesting state of affairs. There is only one paper in the journals that we have been able to find; published in this journal by Phillips in 1924,

recording the results of anti-malarial measures in five towns. He gives the following figures:—

		Spleen-rate.	Endemic (parasite) rate.
Lucknow,	1913 ..	2.2	7.4
	1923 ..	1.6	6.1
Nagina,	1909 ..	79.10	44.4
	1923 ..	13.49	6.0
Meerut,	1911 ..	5.9	6.0
	1923 ..	1.3	3.0
Saharanpur,	1909 ..	78.8	53.8
	1923 ..	7.3	10.3
Kosi,	1910 ..	81.3	26.0
	1923 ..	42.5	6.5

These are concrete results; they have been achieved on a minimum of expenditure wrung from the hands of unwilling District and Municipal Boards.

But the unpublished reports are innumerable; earlier work by Lieut.-Col. J. C. Robertson and Colonel J. D. Graham, I.M.S.; in recent years no end of survey work by Lieut.-Col. J. A. S. Phillips, I.M.S., recently Assistant Director of Public Health (Malariology), United Provinces. From Nepal to the Ganges, from extreme west to extreme east, and in the notorious Terai, malaria has been extensively studied, recommendations made, and precautions taken. Even the lake region of Bhim Tal and Sat Tal has been investigated. This is the most densely inhabited province in India, and here the problem has been fully tackled, but there is not a hint of this wealth of buried information in the journals.

(iv) Imperial Delhi is represented in the journals and Government of India publications, by Christophers' *Malaria in the Punjab* and in a recent report by Christophers, also published by the Imperial Government. The most important paper, however, is that by Hodgson which determined on Raisina as the most healthy and suitable site for the Imperial capital. Yet there is much other unpublished work, especially a recent survey by Senior-White, now, we understand, in press. Imperial Delhi indeed is not without a controversial aspect, for a member of the Legislative Assembly states that Delhi is (or shortly will be) an example to all-India and indeed to the Empire of a malaria-free enclave within a malaria-ridden country; whereas Mr. Senior-White's report shows that the European residents and their Indian servants suffer severely from the disease. There are hundreds of wells in the old city and its environs breeding *A. stephensi*, whilst the annual flooding of the Bela by the Jumna river leads to intensive breeding of *A. culicifacies*. The remedy which he suggests for the Bela is to remove the electric standards which cover it and to dust it with Paris green from an aeroplane. The latest *Annual Report of Health of the British Army* to hand states that Delhi is the third most malarious station in India.

(v) We had become accustomed to receiving enormous parcels of reports by post, but when we

received the consignment for the Bombay Presidency, through the kindness of Dr. J. Munsiff, Director of Public Health, Bombay Presidency, we got rather a shock, for it was a packing case sent by rail.

The early local government publications by Hunter and by Bentley on Bombay city are well known, though copies are almost unavailable now. Marjoribanks in 1913 has a paper on malaria and mosquitoes in Salsette Island; Chalam has recorded his control work in connection with the Back Bay reclamation scheme in our columns; Powell in 1904 gave figures for two years' malaria in the Bombay police. Covell's 1928 survey was published by the Central Press, Bombay, but we have unfortunately not yet seen a copy. Yet there are very many additional unpublished returns—a report of a committee appointed by the Parsi Zoroastrian Association to enquire into the special prevalence of malaria among the Parsis; of another committee reported to investigate the prevalence of malaria among the nurses and patients of St. George's Hospital; reports of the general Bombay Anti-Malaria Committee.

Turning to the Presidency outside Bombay city, there is much information with regard to Sind and the Sukkur barrage, which we understand has been submitted for publication. There are several surveys of different areas, of Kathiawar by Major Sinton, of other areas by Dr. J. Munsiff, Dr. J. L. Pinto, Dr. J. Mello, and other Assistant Directors of Public Health (Malariology) all over the province.

The most important investigation of all, however, and the one which accounted for the packing case, is a survey of Kanara district by Dr. K. S. Mhaskar, lasting over three years. This is still in manuscript. It is a very fine piece of work. It begins with a thin fascicle containing the results of a preliminary and rapid survey. Then follow 12 big fascicles; these deal with the whole district village by village and hamlet by hamlet; everything is mapped, houses, breeding sites, nullahs, etc. Finally, there is a bulky final summary report, which is a model of what a report on the epidemiology of malaria should be. In contrast to what is observed in Burma, Dr. Mhaskar reports that the coastal plain is relatively healthy and malaria-free; the sub-montane tract is more malarious, but here the rivers descend in such spate that there is little chance for anopheline breeding; on the hill tops and the ghats malaria becomes intense, and is largely due to the inhabitants irrigating gardens and plantations by damming streams. This very fine summary report should be published; it is too important a piece of work in malariology to be buried.

(vi) Coorg is dealt with in the journals by Hassel Wright, and in McCombie Young and Baily's recent survey. The Andamans are dealt with in the *Government of India Scientific Memoirs* by Christophers, and in the *Indian Journal of Medical Research* by Covell and Baily, also in a government publication by Covell

separately. Ceylon is partly dealt with in the journals, but by far and away the most important report is a local government publication by Carter, published as a Ceylon sessional report in 1927. This shows the predominant position of *P. malariae* as a cause of malaria in the mountain massif in the south of the island. It is the result of a two years' survey, village by village, and hamlet by hamlet, in a travelling motor laboratory. As an essay on malaria as studied in a tropical and densely forested island close to the equator it is of very great interest; an epidemiological study which certainly deserves wider publicity than it has yet obtained.

(vii) For Mysore State we have received much valuable information from Dr. W. C. Sweet of the Rockefeller Foundation, Health Consultant to the State. There is nothing in the journals for this area as far as we know. The only information for Hyderabad, Deccan, that we have been able to unearth is a series of papers by Surgeon-Major Lawrie in this journal in 1900; in that year he was diagnosing malaria species by examination of fresh blood, relying chiefly on the characters of the pigment observed; and he tabulates his findings down the left hand side of his paper, with corresponding freehand drawings on the right hand side beside each; clearly he was a little doubtful about the diagnosis. The Central Provinces is regrettably blank, though there is one paper by Kenrick in the journals, and Powell in Bombay quotes figures given by Buchanan for that area.

(viii) For the Madras Presidency there are first the very early work by Sir Ronald Ross himself at Sigur Ghat, and later numerous local government reports by Lieut.-Col. W. C. Ross, I.M.S., to which we have not had access. There is an early paper by James on Ennore, just north of Madras city, and Hodgson's survey of Madras city itself. Yet the Malaria Diagnosis Units, based on the King Institute of Preventive Medicine, Guindy, have carried out numerous surveys—chiefly under the direction of Dr. Menon—and their records cover the presidency fairly thoroughly, in all types of terrain, from the Western and Eastern Ghats to the flat seashore of the Bay of Bengal. The notorious Agency Tracts, north of Vizagapatam—probably the most intensely malarious area in the whole of India—are dealt with in Perry's reports in *Paludism* and the *Indian Journal of Medical Research*, and in a paper by Senior-White on malaria as a railway problem in this journal in February 1928. Here, again, however, we have been able to study much unpublished information. This area contains considerable quartan malaria among the indigenous hill tribes; but *P. falciparum* is the all-dominant species, and blackwater fever is very prevalent. (In Ceylon, where *P. malariae* is almost predominant, blackwater fever is said not to exist.) The present importance of this area is very great, for, with the decision of the Government of India to make Vizagapatam a first class harbour, the

Bengal Nagpur Railway are driving a line through from the Central Provinces across a country which consists chiefly of undulating plateau land densely forested, full of aboriginal tribes, and saturated with malaria.

(ix) For Bengal there are the early reports in 1900–1902 by Stephens and Christophers to the Royal Society. Calcutta city is dealt with in this journal by Lukis, Rogers, and Megaw. A report (original unaccessible) by Dr. Laura Hope is quoted by Sir Leonard Rogers in his *Fevers in the Tropics*, which goes to show that quartan malaria is predominant in Eastern Bengal. Our own experience in five years' malaria in out-patients in the Calcutta School of Tropical Medicine is entirely different; quartan malaria only constituted 7 per cent. of the total infections encountered. So amazed were we at this report that we had 100 films taken from dispensary patients with "fever" at Pabna, and studied them; the incidence of quartan malaria worked out at only 10 per cent. of the positive findings obtained.

For malaria in rural Bengal outside Calcutta city, there is but little accessible information; Bentley and Christophers' well-known report on blackwater fever in Bengal, and a paper by Armstrong dealing with malaria among Gurkha troops in the Teesta valley. But here we have to acknowledge the kindness of Dr. S. N. Sur, Assistant Director of Public Health (Malariology), Bengal, in placing at our disposal figures for almost every town in the province; also of Capt. B. S. Chalam, Malariologist, Eastern Bengal Railway, for full information with regard to that railway system. Dr. R. B. Khambata, officiating Director of Public Health, Bengal, has also kindly lent us a number of reports. In all we have details for 19 different towns and districts in Bengal. These all go to confirm the importance of *P. falciparum* (and not of *P. malariae*) in Bengal.

(x) For Assam there is the early report by James on kala-azar and malaria in that province; reports by Shortt and by McCombie Young on malaria in Shillong; and Christophers' report on Nalbari in the journals. But Dr. R. Murphy has sent us his findings for two years in South Sylhet; Dr. G. C. Ramsay his for Cachar; whilst we are very much indebted to Major H. E. Shortt, I.M.S., for figures collected by the Kala-azar Commission in Golaghat and in Gauhati over some years. Lieut.-Col. J. Morison, I.M.S., from the Pasteur Institute, Assam, has also kindly sent us many unpublished manuscripts, and Assam can be mapped fairly thoroughly. These reports make it clear that, whilst *P. malariae* contributes some 7 to 10 per cent. of the malaria in Assam, it is *P. falciparum* which is the predominant species. Quartan malaria is chiefly encountered among the hill tribes.

(xi) For Burma there are early papers by Fink and Lator; also one by Stott, written in Mandalay, but of purely clinical interest, and containing no epidemiological or parasitological details. From a study of the journals one would

think that malaria had been scarcely studied at all in Burma.

The actual facts are entirely different. The epidemiology of malaria has been studied in Burma almost more exhaustively than in any other part of the world. In the first place there are a complete set of reports on surveys by Lieut.-Col. N. P. O'Gorman Lalor, I.M.S., and a later present-day series by Military Assistant Surgeon E. S. Feegrade, I.M.D., D.T.M. (Bengal), now Special Malaria Officer, Burma. These cover almost the entire country and afford a wealth of information. Lalor's reports are models of what reports on malaria surveys should be, yet they are all still in manuscript and unpublished. He has even investigated and reported on the ectoparasites of adult anopheline mosquitoes. Malaria in Burma, he writes, is hyper-endemic in three different types of country: (a) the coastal littoral where salt swamps occur; (b) submontane areas densely clothed with forest and fed by perennial streams; and (c) areas in the beds of large rivers where swamps occur fed by perennial streams. There is only one factor common to all three areas—the presence of perennial streams leading to swampy conditions. In this series of unpublished reports lies a wealth of years of careful scientific investigation by a most reliable and careful worker.

The most malarious spot in Burma, he writes, is the island of Ramri, thirty miles from the Arakan coast, and the only safe harbour at all seasons of the year between Rangoon and Akyab. Until 1882 this island appears to have been healthy, then a local Oil Company imported extraneous coolie labour, and with it malaria. Government constructed a big embankment, which added to the local malarial incidence. By 1895 the town was recognised to be intensely malarious. In 1912, when investigated, the local spleen rate in children was 69.6 per cent. and the endemic (parasite) index 65.5 per cent. All three species of malaria parasite were prevalent, but at different seasons of the year. This unpublished report is one of the most interesting and detailed that we have as yet the pleasure of reading.

Even from the extreme north of Burma comes an unpublished report by Mr. E. S. Pinfold, a geologist in the employment of an Oil Company at Indaw in the Chindwin region, which shows that one need not be a medical man to study malaria. He gives a series of tables which show how the American oil drillers go down with attack after attack of malaria, and frequently die of blackwater fever; so severe is the disease in this sparsely inhabited country that the oil drillers have to be taken away from it during the rains. The chart for annual incidence of malaria is a most unusual one, for the heaviest incidence of malaria occurs *before* the rains, in April and May, and not after the rains. The report is accompanied by a very fine series of photographs showing the character of the country, broad rivers and densely forested hills, oil wells, mud volcanoes

and the like—what one would take to be typical *A. maculatus* country. This report certainly deserves to be rescued from oblivion. And from northern Burma the story can be continued into French Indo-China where the French observers have studied malaria in every province in that country. Further, although the information is scanty, Faust's important paper for China gives the incidence of *P. falciparum* infection as heavy in the southern corner adjacent to Burma and Tonkin.

Now we understand that the Indian Railway Board has sanctioned the driving of the railway from Assam into Burma through the Hukong valley, and that operations on this project will shortly be commenced. From every report that we have seen it may be concluded that this almost unsurveyed tract of territory is intensely malarious, that *P. falciparum* infections predominate and that blackwater fever is extremely prevalent. We trust that the Railway Board will not lose sight of the grave importance of malaria in connection with this scheme.

(xii) From Burma also the survey may be continued into the Federated Malay States. There is Sir Malcolm Watson's book on the *Prevention of Malaria in the Federated Malay States*, and a few papers in the journals dealing with Kuala Lumpur. We know that extremely important work has now been carried out for many years on the control of malaria in Singapore, but we have been unable to find any report on this work in the journals available.* By way of contrast the tiny group of islands in the Riou archipelago, in the narrow strait between Singapore and Sumatra, is the subject of two important papers by Dutch workers.

* * * * *

We have attempted, briefly and cursorily, to summarise this amazing position. There are several deductions to be drawn from it. In the first place India owes a debt of gratitude to Major Sinton for his revelation of this mine of unpublished information in existence with regard to the epidemiology of malaria in India. It was a very laborious, but not a thankless task. Its results have been of the utmost importance.

In the second place, something ought to be done about these innumerable unpublished papers, for the outside world has no idea at all of the immense amount of study of malaria which is going on all over India. To give an example, the classical memoir by Christophers on malaria in Singbhum district—a paper of the utmost importance to every student of malaria—was first published as a local government publication. Only later, when a demand for copies arose, was it republished in the *Indian Journal of Medical Research*, and made generally available to malaria workers all over the world.

* Since this was written, we have received full information and a most valuable report from Dr. P. S. Hunter, Municipal Health Officer, Singapore.

Several of the more important reports which we have referred to have been printed as local publications, and we would urge Directors of Public Health in the different provinces to send copies of these, if available, to the *Tropical Diseases' Bulletin* and the *Bulletin of Hygiene* as a first measure towards publicity. We understand that the Indian Research Fund Association is about to commence the publication of a series of special memoirs dealing with the epidemiology of malaria in India, and that Major Sinton's compilation of a complete bibliography of malaria in India is but the first step towards the "release" of many of these buried records for general information. We are delighted to receive this news. Some months ago we suggested that the congestion both in the *Indian Medical Gazette* and in the *Indian Journal of Medical Research* was now so acute that the former journal *Paludism* should be resurrected. The history of that journal may here be recalled. At the time when the late Sir Pardey Lukis was one of the most efficient and able Director-Generals that the medical services in India have ever had, all-India malaria congresses were held in successive years at Simla, Madras and Lucknow, provincial malaria committees were appointed, anti-malaria policy was defined, and *Paludism* was published as a journal to deal with anti-malaria work in India. Five consecutive numbers of *Paludism* were published in 1911-1912, and contained many abstracts of papers published by local governments, etc. Then in 1913 the Indian Research Fund Association was inaugurated by Sir Pardey Lukis; this Association commenced the publication of the *Indian Journal of Medical Research*, and *Paludism* lapsed.

The Malaria Commission of the League of Nations is at present touring India. (We have seen a part of the very strenuous programme which lies ahead of this Commission, and can only express the hope that the members of it will escape contracting malaria themselves, for they will study several intensely infected tracts of territory.) We believe that they will be amazed at the amount of anti-malarial work and organisation that is going on all over India; they will come to the conclusion that the malariologists of India are too shy; they work steadily and quietly, and give the world at large no idea of the extent or importance of their work; their light is effectually hidden in locally published or even unpublished reports. Yet the position is an extremely promising one. With the creation of the Malaria Survey of India, and the commencement of publication of a special series of memoirs on malaria in India, the outside world may gain some idea of the enormous amount of successful anti-malarial work which is being carried on in every province in India.

India has recently entertained a distinguished malariologist—Sir Malcolm Watson—as her guest. During the course of his brief cold weather tour in this country, he passed certain strictures on the anti-malarial work which is being carried on

in India. Still later he has suggested in the public press in India and England that medical men in India should proceed to the Ross Institute near London to be trained in anti-malaria work. We believe that Sir Malcolm Watson is of necessity in entire ignorance of this immense mine of unpublished information (indeed we ourselves were ignorant with regard to it until Major Sinton came to our help.) Also, we confess that we cannot see how studying mosquitoes on Putney Heath is going to help the malaria workers in India to grapple with their problems. There is an admirably conducted class for malariologists in existence at Kurnal under the Malaria Survey of India, where malaria is studied in the field in India. It is nonsense to say that India is not grappling with her immense problem of malaria—the most important of all public health problems in this country; the truth probably is that there is more investigation of malaria going on in this country than in any other in the world, *when the funds available are considered*; whilst both the Indian Research Fund Association and the military authorities in India are fully alive to the importance of India's malaria problem.

On the other hand we are informed that Mr. Andy Gump, a philanthropist in the United States, has promised a reward of five million dollars for "the last mosquito." Unfortunately, we are afraid that his money is safe.

As far as the parasitology in these unpublished reports goes, we have abstracted such information as they contain with regard to the geographical and seasonal distribution of the three species of human *Plasmodium* in India, and hope to include this information, with due acknowledgments, in the forthcoming memoir. But there is a whole wealth of general epidemiological information in these reports which should be surveyed, edited, and published, for the information of malaria workers throughout the world in general. Italy has her *Rivista di Malariologia*; we trust that shortly India will have a corresponding malaria journal or series of memoirs.

In the meantime, the present note has been written, in the first place to thank the very numerous officials and medical men who have come to our assistance, in the second place to draw attention to the existing state of affairs.

THE EIGHTH INTERNATIONAL CONGRESS OF DERMATOLOGY AND SYPHILOLOGY.

This Congress is to be held at Copenhagen from August 5th to 9th, 1930. The following are the statutes which govern the Congress:—

(1) The VIII International Congress of Dermatology and Syphilology will be held on August 5th to 9th, 1930, in Copenhagen.

(2) Any member of the medical profession approved by the Committee of Organization may become a member of the Congress by registering with the Secretary-General before July 1st and by paying the fee for membership.

(3) The fee for membership shall be £2, \$10 (U. S. A.), 240 francs, or 40 Reichsmarks and shall entitle the member to one copy of the report of the Congress. Relatives of the members shall pay half the ordinary fee. Membership certificates shall be delivered at the office of the Congress on presentation of the receipt for subscription fee.

Application for attending the Congress shall be addressed to the Secretary-General.

(4) Members are requested to use the English, French, German or Italian language.

(5) The programme of the Proceedings shall be determined by the Committee of Organization, printed before the opening of the Congress and distributed to the members together with their certificates of membership.

(6) The subjects for discussion shall be of two classes: those selected in advance by the Committee, and those announced by the individual members of the Congress.

Each subject selected by the Committee shall be opened by two "rapporteurs" and a number of "co-rapporteurs," invited by the Committee. The reports shall be printed and distributed before the opening of the Congress. Papers on other subjects shall be announced to the Secretary-General before April 1st. Such papers must not have been published nor read before any scientific society.

(7) Thirty minutes will be allowed to each "rapporteur," 15 minutes for each "co-rapporteur" and for each reader of voluntary papers. Five minutes will be granted to any member for discussion of papers. The members are urgently requested not to exceed these time limits.

(8) Microscopes and projectors will be provided for the use of members.

(9) The typewritten text of the papers must be left in the office of the Secretary-General before the end of each meeting.

(10) The Committee of Organization shall decide as to the complete or partial publication of papers in the report of the Congress. The papers shall not exceed a maximum of 16 pages of 3,600 letters each for the "rapporteurs," and 6 pages for the "co-rapporteurs" and voluntary papers.

The Report of the Congress shall be published in the French language, the scientific papers in the English,

French, German or Italian language according to the desire of the authors.

(11) In connection with the Congress a scientific exhibition of casts, photos, drawings, anatomical and bacteriological preparations will be arranged, and also a technical exhibition of instruments, apparatus, medical preparations, etc.

The Secretary-General to the Congress is Dr. Svend Lombolt, Raadhushpladsen 45, Copenhagen, to whom applications for membership, for participation in the exhibition, and for permission to read papers should be addressed.

The special subjects selected for discussion in the 1930 Congress are: (i) the ætiology and pathogenesis of eczema; (ii) immunity, re-infection, and super-infection in syphilis; and (iii) tuberculosis of the skin and its treatment.

This international congress is now well recognised as a very important one, and there may be some of our readers who may be in a position to attend it, or to send in papers.

SPECIAL ARTICLE.

THE IMPORTANCE OF REFRACTOMETRY IN CLINICAL RESEARCH.

By DR. PAUL ROSTOCK,

University Clinic, Jena.

At the present day physico-chemical problems govern more than ever the method of working and the speculation of the scientist, and it is therefore not surprising that the medical research worker has made himself fully conversant with this method, in order to employ it in the most varied fields of investigation. Thus the determination of the optical reaction of the different human secretions and excretions has given us a deeper insight into what goes on in the body under healthy and diseased conditions. The polarimeter, the spectrograph and recently, the interferometer also, are used for clinical purposes; besides these, the refractometer has also for many years been looked upon as part of the equipment of a well-furnished laboratory.

With the aid of the last-named instrument the refractive index (also called coefficient, exponent or quotient) of a substance is determined. It is universally known that the velocity of light transmission varies in different substances. Rays of light passing from one medium to another alter their direction according to the laws of refraction at an oblique angle of incidence. For biological investigations the combination air against liquid; or, in the case of examinations made by means of instruments, liquid against glass, comes almost exclusively into consideration. On this assumption we understand therefore by "the refraction of light of a liquid" the refraction suffered by a ray of light which passes from the air into the liquid. The physical laws obtaining for this case may be summarised as follows. Under identical external conditions (such as temperature, pressure, etc.), the ratio of the angle of incidence

h to the angle of refraction b is the same with the same media.

$$\frac{\sin h}{\sin B} = n$$

Fig. 1.

By n we understand the index of refraction already mentioned above. In this connection it is not necessary to consider the definition of "specific refraction" and "molecular refraction"; on the other hand, the refraction of mixtures must be dealt with in detail. Careful investigations have shown that the refraction of mixtures in solution can be calculated from the refraction of the separate ingredients according to their proportion, provided no chemical changes have taken place when mixing.

As the refractive index alters according to the temperature during the investigation, the simplest and best plan is always to make the observations at the same temperature. If this is not possible, however, it is necessary to make a temperature correction of the value which has been read off.

First of all, we must acquaint ourselves with the apparatus available for determining the refractive index, and how it is manipulated. Numerous models of refractometers for the most varied ranges of appli-

Fig. 2.

cation are constructed by Messrs. Carl Zeiss, Jena, one of the leading manufacturers of

this type of instrument. It is impossible to describe them all here, but mention may be made of the Abbé refractometer, an instrument of great service for medical purposes, which is constructed with heatable and non-heatable prisms.

It is suitable for measuring the refractive index of all kinds of liquids and also of solid substances. For special examinations, especially in industry, the butter refractometer and the refractometer for the sugar and oil industries will be found of value; various models also serve for mineralogical investigations, amongst them being, in addition to complicated apparatus, a very compact and durable pocket refractometer for jewellers. Anyone desiring to be acquainted with the range of uses of this apparatus is referred to Loewe's excellent article (36) entitled "Refraktometer im Fabriklaboratorium."

In addition to this apparatus, which is primarily intended for practical use in factories, reference must be made to Pulfrich's instrument, the finest and most ideal of refractometers.

Fig. 3.

With this instrument all conceivable investigations can be carried out in the laboratory. These instruments are well suited to clinical research, but we have at our disposal an instrument which surpasses them considerably in simplicity of manipulation, without losing anything in regard to measuring accuracy for the purposes of the clinical physician. This instrument is the dipping refractometer made by Messrs. Carl Zeiss, Jena, of which some particulars follow as to its construction and manipulation.

It consists of a telescope-like instrument carrying on the one side an inclined prism and on the other an ocular.

The apparatus is extremely simple to manipulate. The prism is immersed in the liquid to be examined, which is contained in a glass beaker, and is illuminated from below by means of a mirror. A graduated scale is visible in the field of view. One half of this field of view is dark and the other bright,

the line of separation between the two being sharp. Should it have a fringe of colour, rotation of the knurled ring R (Fig. 5), which moves a compensator, will cause this to disappear. By means of the micrometer screw Z the scale can be so adjusted that a scale line coincides with the line of separation between bright and dark, and a value can then be read off on scale and micrometer screw, the index to the micrometer screw reading to tenths of an interval of the scale. The process of measurement is perfectly simple and unequivocal, and can be acquired in a very short time even by persons who previously were not familiar with optical measuring methods. With the aid of a set of tables, included with the apparatus and also reprinted on page 583 of this article, the true refractive index can then be easily calculated.

Fig. 4.

It frequently happens that the medical man has but very small quantities of liquid (for example, serum) available, and, when this is the case, the usual method of employing a small glass beaker and immersing the refractometer in the liquid would not do at all. However, in order that these small quantities may also be examined, a so-called auxiliary prism, suggested by Reiss, has been constructed.

The liquid (one drop is sufficient) is spread between the prism of the refractometer and the auxiliary prism, the latter being held firmly by a metal beaker with glass plate. The readings are taken as usual. The whole arrangement can be seen from the illustration (Fig. 5). If there is so little of the solution

that the drop does not completely fill up the space between the two prisms, the line of separation in the eyepiece field of view does not appear sharp, and, for the purpose of correcting this error, Pulfrich has designed an ocular stop as illustrated below.

Fig. 5.

Its manner of attachment to the refractometer and also its application can easily be

Fig. 6.

seen from the description which is included with the instrument.

A further important accessory to the dipping refractometer, which has not so far been commented upon, is the tempering bath. As

mentioned at the beginning, the refractive index of a solution changes with different temperatures, and it is therefore advisable always to make the investigations at the same temperature. For clinical investigations the use of an iron pan of about 2½ gallons capacity, with a jacket of felt (not shown in Fig. 7) and overflow joint, is recommended.

We will now turn our attention to the consideration of those fields of research in which refractometry has found favour, and which are of importance for both doctor and medical student. Here again only a brief sketch can be given; a detailed description, especially of the special technique, must be omitted.

Loewe's excellent account (37) gives a

Fig. 7.

This vessel is filled with ordinary tap water which has been brought to a temperature of 17.5°C. Almost all biological tables are calculated for this temperature which, as shown by experience, is retained for a long time. A revolving umbrella frame with 12 apertures for the insertion of glass beakers is suspended in the vessel. One is thus in a position to make uninterrupted readings without having to wait until the temperature of the water and the freshly inserted glass beaker are the same, because by the time the 11 samples already in the bath have been examined the freshly inserted beaker with its contents will have acquired the temperature of the surrounding water.

Complicated thermo-regulators with heating spirals and water pressure regulators are, as a rule, not necessary for the medical man's investigations.

Finally, it may be mentioned that a flow-through cell, designed by W. Goldbach, has been constructed, which renders it possible, with rotational examination of samples of a like nature, to employ the principle of flowing-through which has been adopted with success in other directions, i.e., to displace the sample just measured by simply filling in the next, without any cleaning being necessary.

general survey of the results achieved by means of refractometry in the branches of technical chemistry, the chemistry of food, and also biology. The same author (36) has also given an account of the range of application of the refractometer in the factory laboratory. Again, Hirsch (22) has given a brief survey of the importance of the refractive index in physical chemistry. This is the subject which interests the medical man above all and the following details will give some idea of what has so far been achieved in this field. At the same time, it must be emphasized that my description in no way claims to be complete. The space at my disposal precludes this and an outline only can be given. I have, however, endeavoured to include in the list of literature all the works which are of importance for workers in particular fields of refractometrical research. The purpose of this list is to provide the means whereby the reader can refer to the original works for details of the technique and special results of investigation.

In 1913 Reiss (52) wrote a comprehensive account of the refractometric examination of blood and, since then, this method has found favour in all branches of pathology and physiology, so that at the present day no clinical

laboratory is complete without a refractometer.

It is quite impossible within the compass of this paper to touch even briefly upon all the knowledge that we have gained from refractometric investigations for our medical reasoning and actions: this would fill a voluminous monograph. The following merely constitutes a general survey which should serve to stimulate interest in the making of further investigations. In the first place, we will consider the examination of blood serum.

A few words are necessary on the taking of a sample of blood for refractometric examination. A vein can, of course, be punctured, the blood allowed to deposit and then be examined. But if it is desired to examine frequently, for example the albumen content of the serum, the following method will be found preferable. Make a small incision in the lobe of the ear or the finger tip and collect the blood in a U-shaped glass tube about 12 cm. in length, having an inside width of 2-3 mm. and distended sides.

In five minutes' time centrifuge the little tube sharply. If a centrifuge is not available the blood can be allowed to coagulate; when this is done, however, the yield of serum is less.

For the purpose of investigation, both sides are lightly scratched with a glass-file on the border between serum and clot of blood. Remove the glass dust by wiping the tube, as otherwise it would scratch the prisms of the refractometer. Now take the U-shaped portion of the tube in the fingers of one hand and the two sides in the fingers of the other and break off both sides simultaneously. The serum is contained in these, and it can easily be examined in the refractometer with the auxiliary prism.

Reiss (52) has studied very exhaustively the connection between the refractive index of the blood-serum and its albumen content. He has classified his results in a set of tables, which are reprinted here, as they are of very great practical importance. In addition to

Fig. 8.

By capillary suction the little tube is filled with blood, the rapidity of the suction being regulated by sharply inclining the tube if necessary.

When one side of the tube is filled with blood, place the tube upright, so that the blood is uniformly distributed in both sides.

showing the percentage of albumen in the blood-serum, they include the percentage in transudation and exudation products, and, moreover, also render it possible immediately to convert the scale readings of the dipping refractometer into absolute refractive indices.

Reiss's Table for Converting the Readings of the Dipping Refractometer at 17.5°C. into Percentages of Albumen.

This table is in frequent demand in clinical laboratories, but as it is not readily accessible,* we produce it here with the author's kind permission in a somewhat expanded form.

Refractive Indices corresponding to scale divisions in same row.	BLOOD SERUM.			PRODUCTS OF EXAMINATION AND TRANSUDATION.		
	n_D for distilled water 1.33320 n_D for non-albuminous bodies 0.00277 Δn_D for 1 per cent. albumen 0.00172			n_D for distilled water .. 1.33320 n_D for non-albuminous bodies 0.00234 n_D for 1 per cent. albu- men 0.00184

43.6 " " = 4.73 "

* Verh. d. 76. Vers. deutscher Naturf. u. Ärzte, Breslau 1904, p. 36 ("Klinische Eiweißbestimmungen mit dem Refraktometer") and Chapter on "Refraktometrische Meßmethoden in der Biologie" by E. Reiss, in Abderhaldens "Biochem. Arbeitsmethoden," Vol. 8, pp. 84, et seq.

From them can be determined quite simply the percentage of albumen that corresponds to a refractive index reading on the dipping refractometer. It will be understood that the tables are only correct if it is assumed that the percentage of salts, etc., in the serum are practically constant, an assumption which entirely holds good in very many conditions of disease. The following table gives an idea of the disturbances which may be due to quantitative changes of the non-albuminoids in the serum. It gives the refraction of 1 per cent. substance in aqueous solutions calculated for the dipping refractometer:—

Sodium chloride	..	0.00175
Potassium chloride	..	0.00134
Disodium phosphate	..	0.0007
Urea	..	0.00145
Grape sugar	..	0.00142

Therefore, in conditions of disease which lead to a great increase of non-albuminoids in the blood (i.e., uræmia, diabetes, jaundice, etc.), the refractometric method of determining albumen is not to be employed, or else only by using a special method of correction.

Leendertz (33) has investigated the influence on refraction of the different kinds of coagulation. The relationship between refraction and viscosity of the serum has been studied by Rohrer (55), and, in carrying out his tests, he has verified the figures of Reiss (52). Herlitzka (21) has made very extensive investigations of the refractive index of protein solutions and recorded his results in numerous tables, to which reference only can be made here.

I must refrain from going into details as to the conclusions to be drawn by the doctor from the changing albumen content in the blood serum. In this connection the reader is referred to Reiss's comprehensive work (52), although it must be emphasized that since it was finished a large number of papers dealing with this branch of research have been published. Merely a few results of special interest may be mentioned briefly.

Pueddu (48) found the refractive index of the serum the same in healthy people of both sexes, young and old; menstruation, however, altered it. Normally, it lies between 1,348 and 1,351. Bergmann (7) states that the albumen content of the serum continually decreases in the second half of the period of pregnancy, more especially in the case of hydropic pregnant women, the decrease being as much as 10 per cent. In the case of protracted confinements, an increase of albumen in the plasma is observed. Masing and Denecke (39) ascertained by refractometric investigations that the serum from an anæmic region is about 6.5 per cent. thinner than that from capillaries, and the serum from clogged veins about 24 per cent. thicker. The values are constant in healthy persons.

Gansslen (16 and 17) has made very detailed investigations concerning the metabolism of minerals and other substances, in which he compared the refractive index of blood serum with that of the fluid of the tissues. This fluid he obtained by producing a "skin blister" by various artificial means, and his very interesting experiments merit extensive consideration. By means of refractometric investigations Zimmer (76) found that, when giving arsenical medication to human beings, there is to some extent a genuine deposit of substance; there is also, however, a spurious deposit owing to the retention of water in the blood and tissues. The condition of equilibrium between blood and tissue is very unstable. The influence of differences in nutrition on the albumen content of serum has been investigated by Mark (38) and recorded in several sets of curves. Different nutritive substances influence the albumen content very considerably; meat causes an increase in the absolute and relative quantity of albumen, and fat a decrease, whereas the administration of carbohydrates produces no change.

Meyer and Brühl (8 and 41) ascertained that, in the case of epileptics, the values taken during an attack differed from those taken at times when they were free from attack. In experimenting with serum in an anaphylactic condition in a rabbit Abderhalden and Wertheimer (2) ascertained a change in the refractive power when using the refractometer, whereas the rotary power, examined polarimetrically, was not altered. Roffo (54) found that by mixing the serum of cancer patients with that of horses the refractometric index is lowered and, by mixing horse serum with the serum of other patients, it becomes higher. It is important to observe that the index of horse serum does not differ very much from that of the serum of human beings. This process should have a diagnostic value. Considering the practical importance of the findings it is extremely desirable that these results be further investigated. From the results of refractometrical tests on serum-albumen, Wiechmann and Horsters (75) have been able to draw important conclusions in regard to the progress of experimental recurrent infection of rats.

From the Düsseldorf Surgical Clinic Achelis (3) reports that refractometric investigation of the blood serum gives important indications for the duration and extension of an intended surgical operation and for the extension of the narcosis.

Basilico (4 and 5) investigated the fluctuation of the refractometric value of serum under different experimental conditions. With the acidosis produced by the injection of sodium butyrate or sodium isobutyrate, the hydræmia that ensues continues for several hours. The same condition is observed after the administration of a ten days' scurvy

diet. Burger (9) investigated the behaviour of albumen in the serum before and after operations, thus enabling an opinion to be formed as to the capacity of regeneration or the capacity of resistance of the organism. After the extirpation of carcinoma it was noticed that those cases quickly relapsed, in which, after the 6th day, the albumen values of the serum continued to fall. By means of other investigations he ascertained that the post-operative decrease of the serum-albumen is not simply the result of a thinning of blood due to loss of blood, but must be interpreted as an expression of the regenerative power. Szenes (64) has given particulars of refractometric investigations of the serum in myositis ossificans and struma.

The following employment of refractometry in connection with the serum is also interesting. To establish death from drowning, Szulislawska and Tobiczky (65) compared in experiments the water-content of the body with that of the blood of the lungs, by investigating the contents of both ventricles of the heart with simultaneous determination of the freezing point; they obtained remarkable results. This method, however, failed in the case of decomposed corpses in water.

The methods employed for determining the combining-ratio of albumen and globulin in blood serum are interesting from the point of view of practice in clinical investigations and also when considered both theoretically and technically. Rohrer's method (55 to 57) is founded upon the determination of two physical values: refraction and viscosity. Wanner (73) has criticised this method and expressed doubt as to its reliability. Robertson (53) is the originator of another experimental method. In a serum test the following points are determined: (1) The refractive value of the non-albuminoids by heat coagulation, after acidification and separation of the coagulated albumen. (2) The refraction of the serum-albumin by combining the serum with a solution of sulphate of ammonia. (3) The refraction of the full serum. From these values is then calculated the percentage of globulin. Although this method of investigation is somewhat involved, values are nevertheless obtained which are extremely useful for practice. A micro method founded on the same principle has been devised by Berger and Petschacher (6), and the reader is referred to the original publication for an exact description of it. Schretter (71 and 72) has undertaken exhaustive experiments in connection with the specific refractive increase of serum-albumen, also serum-globulin, and his figures are important for the refractometric determination of these components in serum. The sources of error are fully taken into account in these investigations. Achelis (3) was able to obtain valuable hints for the indication and prognosis of surgical diseases by refractometric

determination of the proportion of albumin to globulin. From the serum of persons suffering from tuberculosis Gänsslen and Maier (18) ascertained that, in advancing stages of the disease, the refractive value of the serum decreased considerably as the disease grew worse, and, hand in hand with the progressive process in the lungs, there is an increase of the globulin. It follows, therefore, that a regular refractometric control of the blood-serum gives important indications in prognosis.

Refractometry has also been employed recently for the determination of fibrinogen. Kaufmann (27) has given particulars of this at the 37th Congress of the German Society for Internal Medicine. Hogler and Ubberrack (25) have investigated the relationships between the refractive index in capillary, venous, and arterial blood, as also its relationship to the fibrinogen content. The results are particularly interesting from a theoretical point of view. The original method of Winternitz (74) has been discarded at the present time as not being sufficiently accurate. Somogyi (63) has recently made comparative investigations concerning the different methods and he gives preference to the method of Leendertz and Gromelski (32-34). This is founded on the principle of determining by preliminary experiments the quantity of potassium chloride in the citrated plasma which will again produce coagulation. Then the refractive index of the mixture is determined before and after coagulation and, from the two values obtained and with the aid of a formula, the fibrinogen content calculated. Further particulars will be found in a brief account by Leendertz (32).

Starlinger and Hartl (66) are the authors of a very detailed critique of all methods for the determination of fibrinogen. By employing the interferometer instead of the refractometer they were able to obtain even greater accuracy of measurement.

It is also a comparatively easy matter to determine, with the aid of the refractometer, the quantity of blood in a living person. de Crinis (12) has published particulars of such experiments. The method is founded on the measurement of the albumen content, both before and after the intravenous injection of a definite quantity of physiological solution of sodium chloride, the refractive index of which has previously been ascertained. The serum undergoes dilution by the infusion and from this the total quantity of blood can be calculated. According to de Crinis (12) the infusion causes a difference of 7 per cent. in the albumen content. So far the method has been very little used. This may be concluded from the fact that it is not described in the latest edition of the well-known work on clinical laboratory technique by Brugsch and Schittenhelm. Having regard to the rapid elimination of the injected sodium chloride solution through the kidneys, it appears more

suitable to employ colloidal solutions (for example, dextrine, gum acacia, etc.), which in low concentration possess a high refractive value. This method has been disputed by McQuarrie and Davis (49).

Cobet and Ganter (11) have endeavoured by the same means of injecting liquids to determine the concentration of pleural exudations, a method which is probably of more interest theoretically than when considered from a practical medical standpoint.

In recent years refractometry has also been utilised as a means of determining the hæmoglobin in the blood. The methods may with advantage be described in detail, because up to the present they are not very well known and yet are exceedingly well thought out and of interest theoretically. There are two such methods which have been worked out by J. L. Stoddard and G. L. Adair (67). By means of careful preliminary investigations it was ascertained that 1 per cent. hæmoglobin corresponds to a refractive difference of 0.0019415. Thereupon two refractometric differential methods were formed for clinical practice: the one utilises the decrease in the refraction of light by coagulation of the hæmoglobin by heat, the other the increase in the refraction of light by hæmolysis of hæmoglobin. A short description of the technique may well be added.

The "long" method.—Two c.c. of blood is put into a centrifuge and, with 0.8 per cent. solution of sodium chloride, filled up to 15 c.c.; the glass is then closed with a rubber stopper and tilted over twice. The stopper is rinsed and the glass centrifuged with medium velocity for 5 minutes. The diluted plasma is removed by means of a pipette and the glass again filled up with sodium chloride solution, thoroughly shaken and centrifuged again. After removing the upper layer of liquid, add 1 mg. saponine, fill with distilled water up to 7 c.c. and mix well with a thin glass rod. The liquid is transferred to a measuring flask of 10 c.c., and care must be taken to see that none of the liquid adheres to the glass rod or centrifuge glass. The flask is then filled with distilled water to 10 c.c. After well mixing it is centrifuged and the refractive index of the solution measured (n_1). The hæmolysed blood is then poured into a test-glass, which is closed with a loosely fitting rubber stopper, and placed in boiling water for 3 minutes. The hæmoglobin then becomes separated. The cooled tube is tilted over and the contents filtered. The refractive index (n_2) of the filtrate is also measured: it is less than that previously measured. The hæmoglobin content is then shown by the following formula:—

$$\text{g Hæmoglobin dry substance in 100 c.c. blood} = \frac{(n_1 - n_2) \times 5}{194.2}$$

The method is more involved than those usually employed for determining the hæmoglobin, but, if loss of substance is avoided in the individual manipulations, extremely good results are obtained. It must also be mentioned that, owing to the heat coagulation, the salt content alters. The authors' investigations have proved that this constitutes an error of 0.06 to 0.05 per cent. only; this can, therefore, be practically disregarded.

The second "short" method is carried out in the following way: Take two test-glasses and put 1 c.c. of blood into each. Then put 5 c.c. of a 0.8 per cent. sodium chloride solution into the first glass, and into the second also 5 c.c. of a 0.8 per cent. sodium chloride

solution, but this contains 70 mg. of saponine per 100 c.c. Both solutions are then centrifuged and the refractive index (n_1 and n_2) determined. The refractive index of the salt solutions (n_3 and n_4) is also determined. The hæmoglobin content then amounts to:—

$$\text{Hgb} = \frac{(n_2 - \frac{(n_3 - n_4) 0.5}{5.6})}{194.2}$$

The formula appears extremely complicated; the measurements to be made are, however, very simple. The calculation is further simplified by the value

$$\frac{(n_3 - n_4) 0.5}{5.6}$$

being a constant which can be computed for the sodium chloride and sodium chloride saponine solutions, once they are mixed, and which then holds good for all investigations made with them.

Probably both methods appear more involved than those usually used in clinical laboratories, but the refractometric method of determining hæmoglobin has, above all others, the advantage of greater accuracy, although it is true that extensive experiments have not as yet been made with it. Only Gram (19) has given particulars of additional investigations. He ascertained that the values obtained by refractometric means agreed well with those found by colorimetric methods.

Pregl and de Crinis (47) have employed the refractometer for making investigations on Abderhalden defensive ferments, which, especially recently, again enjoy a wide theoretical and practical interest. Without going into details here of the basis of the reaction in itself (1) it may merely be said that the refractive index of the serum which is to be examined is first determined; it is then allowed to act upon a definite quantity of the particular organ of which the structure is to be tested, after which the refractive index is again determined. The organ powder which is manufactured in a special way does not in itself supply any soluble substance to the serum. Not until this splits up the organ-albumen do the disintegrated products dissolve and effect a change in the refraction. The difference in the refractive indices of the serum, before and after the action on the organ substances, accordingly expresses numerically the extent of the disintegration. Pregl's experiments were confirmed at the Abderhalden Institute by Hans Meyer (40). An exact description of the technical procedure of the reaction will not be given here, but it can be found in the latest edition of Abderhalden's works (1) or in Loewe's book (37) which has already been quoted on several occasions.

Schnupp (69) has successfully employed the refractometric method of Abderhalden's reaction in the diagnosis of pregnancy. Favourable results with cancer sera were also obtained by de Crinis and Mahnert (13). On the

other hand, it should be mentioned that the results of the investigations carried out by Serjski (62) and Kuppelwieser (30) question the value of the refractometric modification of the Abderhalden reaction, and so far no definite explanation is forthcoming to clear up the points raised. Also Höglér and Serio (24) considered (in 1923) that the refractometric modification of the Abderhalden reaction after Pregl was not yet suitable as a method for diagnostic purposes. Further research work has been carried out by Knipfer (28). He made investigations with the Pulfrich refractometer on sera of cancer patients, the sera being mixed, in the first place with deposits from cancerous cells and secondly with the same deposit after heat-coagulation. The figures gave a ratio of 1:2, which was exactly the opposite to the ratio obtained in the same way with normal sera. After x-ray treatment the ratio was altered in the serum of cancer cases. This showed an increase of the refractometric values on the whole, increased cytolytic power and increase of the defensive ferments. The ferment-increase was temporary and took its course approximately parallel to the reactions on proteids.

The disintegration which cancerous cells undergo in serum has been investigated by Nather and Orator (44) according to the method of Koritschoner and Morgenstern (29). They found that, beyond a certain age limit, the dissolving power of serum upon isolated cancerous cells disappears in a percentage of carcinoma-free cases, which, before this age limit, exhibited a typical power of solution in serum. Three out of every four people behaved, after their 45th year, like cancer patients, although they had no carcinoma. The authors believe that this supports the view that there is a specific disposition to cancer. It is exceedingly desirable that these interesting experiments be further extended and possibly confirmed.

The dissolving power of the serum of pregnant women with chloasma uterinum as compared with suprarenal glands has been studied with the refractometer by Fischl (15). It was found that there was a difference in the reaction of the pregnant serum according to whether chloasma contributed or not, in the sense that the addition produced an increased difference in the refractive value.

Apparently very few refractometric investigations have been made in the case of liquor cerebro-spinalis. The only work on the subject worth mentioning is that by Molnar (42), who, by determining the refractive index, has investigated the concentration of the liquor. The normal value lies in the neighbourhood of 1.33486 and 1.33517. In the case of organic diseases of the central nervous system it is higher; in the case of syphilis, the refractometric figure does not run parallel

with the extent of the globulin reaction. In Molnar's opinion refractometry is to be employed, in addition to the other qualitative tests, as a convenient and accurate test.

Endeavours to utilise refractometry for the examination of the physiology and pathology of the gastric juice secretions are not new. The experiments of Obermeyer and Pick (45), in the first place, may be mentioned here. These workers were able to prove that various ferments, among them pepsin (in contradistinction to trypsin), do not alter the power of refraction for sodium light of albuminous solutions. Hirsch (23) found that this was correct. Then Kuppelwieser and Rossler (31) studied first the connection between the effect of pepsin and the increase in refraction. The numerical results are interesting and are given in detail in Loewe's book (37). The first refractometric method of determining pepsin in gastric juice, which was of service in clinics, was worked out by Schorer (70) and somewhat improved by Reiss (50). Although somewhat involved, it has nevertheless proved to be of service. Details will be found in Loewe's book (37).

It is not necessary to give a detailed description of this method here because at the present time we have a simpler one at our disposal. This has been evolved by Rostock (58 to 59) and is based on the following lines of thought. If one allows a peptic solution, whose refractive index has been determined previously, to act upon a definite quantity of an insoluble albuminous preparation, parts of this albumen dissolve in the form of disintegrated products owing to the ferment action. They accordingly effect an increase in the refractive index. Therefore, the practical determination takes place in the following way: 10 mg. of Merck's dry and powdered blood-fibrin are put into a centrifuge glass, after having previously satisfied oneself by samples taken off hand and tested that it gives off no soluble substances in distilled water. To this is added 10 c.c. of the gastric juice to be examined, its refractive index being determined beforehand. The glass is tightly closed with a rubber stopper, inverted, and placed in a water bath at 42°C. for exactly one hour. At the end of this time the glass is centrifuged so as to throw the suspended particles to the bottom, and then again examined refractometrically. The difference in the scale readings shows the quantity of pepsin. In this way the troublesome conversion to the true refractive index is avoided. I have found this method answer extremely well in numerous practical experiments.

Rostock (60) has pointed out the fact that the peptic result of a gastric juice and the acid percentage do not represent corresponding values. On the strength of this announcement Orator and Knittel have likewise interested themselves in this question, and have

tested the method on a number of gastric patients. Details cannot be given here, but the concluding sentence of the recapitulation of the work may be quoted. "The separation of the findings into different groups of disease shows certain constitutional independencies of the pepsin values from the acidity values, which allow the value of the separate pepsin determination to be clearly seen." My own numerous investigations are still awaiting clinical tests, which will be proceeded with shortly. The results are published in Brun's *Beiträgen zur klinischen Chirurgie* ("Contributions to Clinical Surgery").

Fischer (14) also made investigations by means of the refractometric method concerning the peptic power of gastric juice. In carrying out such tests he has especially had in mind the ionic concentration, the power of the acid addition to draw water, and the presence of salts. He comes to the conclusion that it is, of course, possible to determine only the "momentary proteolytic effect and not the quantity of pepsin secreted by the stomach." This, in my opinion, is self-implied, because as long as a ferment is not proved to be pure, it is only possible to draw conclusions as to its quantity from the extent of its effect. Orator and Knittel (46) have repudiated Fischer's criticism and see no disadvantage to the Rostock method, in that it only allows the momentary proteolytic effect of the gastric juice to be determined and not the total quantity of the secreted pepsin. Kalk (26), too, has successfully used the refractometric method of determining pepsin in various pH concentrations and saline concentrations. The varying percentage of sodium chloride, in particular, exercises a considerable influence on the peptic power of gastric juice. Consequently, when determining the peptic power of gastric juice, it is essential to pay attention not only to the acidity but also to its percentage of neutral salts.

The method of investigation was also employed successfully by Rostock (61) for the purpose of ascertaining whether a peptic solution alters in its fermentative strength after being stored for a fairly long time.

Finally, we may mention the refractometric investigation of urine. Considering the promising early stage it has not by a long way attained the importance that is actually its due. Systematic research will surely reveal results of both practical and theoretical importance. Some time ago a refractometric method of determining the sugar in urine was devised by Grober (20). Equal quantities (about 75—100 c.c.) of filtered urine are put into two glass flasks. The one flask is closed tightly with a wad of cotton-wool, and the other, after the addition of cleansed yeast, covered with a watch-glass. Both are then

placed for 24 to 36 hours in an incubator. After having ascertained by the Nylander test the freedom from sugar of the fermented portion of urine, both samples are examined refractometrically. The difference in the readings, when divided by 2.9, gives the percentage of sugar.

So far as I know the method has not been used extensively. Priority claims have been asserted by Strubell (68), but his results are attacked in a controversial manner. Strubell himself arrives numerically at somewhat different results from Grober. Lemesic (35) has examined the effect of various diuretics on surviving kidneys, which have been artificially circulated with blood. Comparisons of the refractive index between the liquid which flows through and the secreted urine allow in any case of interesting deductions as to the mechanism of urine production. Detailed investigations have been made by Strubell (68) concerning the relationships between the density, lowering of the freezing-point, and the refractive index of urine. He was able to ascertain a parallel between these three values.

In the foregoing pages I have endeavoured to give a critical survey of what has been achieved by refractometrical methods of investigation for both doctor and medical student by way of valuable results. Much of this could only be given in outline, and insufficiently confirmed findings only briefly mentioned. The object of this classification is to arouse interest in the use of simple and accurate optical methods of investigation for the enrichment of our biological knowledge and the welfare of our patients.

Current Topics.

Sedatives in Labour, Particularly "Twilight Sleep."

By JOHN S. FAIRBAIRN, M.A., B.M. (Oxon.),
F.R.C.P., F.R.C.S.

(Abstracted from *Brit. Med. Journ.*,
April 27th, 1929, p. 753.)

A SEDATIVE may be indicated early in labour when the onset of the true rhythmic pains is delayed, and the woman is worried and fatigued by short, sharp pains that appear to do no good, or by a period, perhaps a day or more, of "niggling" pains, before the long, steady, and useful contractions are established. Also when the patient is tiring any time before the os is fully dilated and the head low in the pelvis. If she is left alone she may lose self-control, weep and throw herself about, and later become played out, and her uterus will not function properly. A hypodermic injection of morphine should be given when she is tiring, and before she is tired; the rest and comparative relief will enable her to regain her self-control, and uterine action will return with fresh strength after a period of rest. The relief to the patient also brings relief from the insistent pressure of distracted relatives that is so trying in domiciliary midwifery.

Another indication for the use of a sedative is what is called rigidity of the os. Commonly it is spasmodic, organic rigidity being very rare, and is most often met with in nervous, highly strung, but perfectly healthy primiparae. This rigidity is not to be considered as a specific condition of the cervix, for it is merely the expression of poor or erratic uterine action; with good contractions there will be good dilatation, with poor contractions poor dilatation. Rigidity frequently accompanies the cases already described in which the pains are

short and sharp and without rhythm, some times termed "colicky" action. The rigid os is to be regarded as a sign of disordered uterine action, and of the kind that yields to an opiate or other sedative.

Whenever there are signs of commencing fatigue, loss of control, and irregular uterine action, a liberal dose of some sedative should be given and repeated if need be. Practically all our emergency cases of delayed labour sent into hospital for immediate delivery—in many of which premature efforts at instrumental delivery have been made—are given morphine ($\frac{1}{2}$ or $\frac{3}{4}$ grain), and it is surprising how many of those without gross mechanical difficulties will deliver themselves after four or five hours' sleep—and sometimes catch us out by performing an unlooked-for "B.B.A." My experience of this type of case in hospital and of cases seen outside that take on a fresh aspect after a few hours' sleep has made me feel that enough use is not made of a sedative sufficient to secure for the patient a rest before resort is made to artificial delivery. If the head is near the outlet it is too late to secure rest, and simpler to try first an injection of pituitrin as a stimulant to uterine action, and if not successful in a quarter of an hour to deliver by the forceps. Also, morphine at this stage is liable to result in the foetus being born narcotized.

Twilight Sleep.

The morphine-hyoscine narcosis, or "twilight sleep" (Gauss), must be regarded neither as an anæsthetic nor an analgesic, for its aim is the production of amnesia of the events throughout labour. Its success is complete if the mother awakes from sleep or drowsiness following her delivery without any recollection of what she has been through, and if neither she nor her infant shows any ill effect from the narcosis. Dulling of pain to some degree is usually obtained, but the real objective is to abolish the memory of the recurrent pains, and thereby their psychological effects. The patient may groan during uterine contractions, wake up and perhaps raise her head and shoulders from the bed, exhibit the facial expressions of pain, and even complain bitterly and emphatically, but will sink back into a recumbent position and drowsy state when the contraction passes off, and no mental impression that can be recalled will remain. The successful induction of amnesic narcosis removes almost entirely the inhibitions of uterine action of emotional and psychological origin, greatly lessens fatigue, and increases the chances of rapid recovery without the nervous exhaustion that may follow a painful and trying experience in a sensitive subject.

It may be said that labour in such circumstances is not physiological, and it is true to the extent that dragging of a patient in this way diminishes the reflex response to those stimuli augmenting the strength of the contractions; but, on the other hand, it represents the attempt to remove those factors interfering with good expulsive power that the circumstances of our modern social life have brought about. Its use will be justified if the cases in which the narcosis is adopted are limited to those in which the avoidance of fatigue and the exclusion of inhibitory factors will give greater benefit than the disadvantages of lessening reflex response.

Method.

It is best to begin as soon as rhythmical labour pains are definitely established and cause distress. Some would have a degree of dilatation of the os to a size admitting one or two fingers, but examinations for the purpose of determining the amount of dilatation are not advisable. As will be explained later, it is, however, nearly always possible to begin induction after labour has been in progress some time by starting with light chloroform anæsthesia.

It is very important that the usual preliminaries preparatory to labour, particularly a thorough emptying of the bowels, should be got over before induction of the narcosis is begun, in order to lessen disturbance of the patient. Isolation and quietude for the patient are essential, to exclude so far as possible all external stimuli. She should be shaded from the light, her ears plugged with wool, and disturbed as little as close watching of her condition and the necessary attentions will allow.

The dosage is best described by taking a standard one and suggesting modification in one or other direction in certain conditions. The usual initial dose is $1\frac{1}{4}$ grain of morphine with $1\frac{1}{50}$ grain of hyoscine, followed at hourly intervals by $1\frac{1}{50}$ grain of hyoscine. The morphine is rarely increased beyond $1\frac{1}{4}$ grain, and is repeated only in special circumstances and in smaller quantity, but the hyoscine may be increased to $1\frac{1}{100}$ grain for the initial dose, or more often to $1\frac{1}{300}$ grain for the second dose if the response to the usual initial dose is insufficient. The general rules for determining the best dosage in the individual case may be stated thus. The standard dose should be increased in first labours and for big women of strong physique, and for imaginative, oversensitive, and nervous patients. Morphine $1\frac{1}{6}$ grain and hyoscine $1\frac{1}{50}$ grain will suffice for multiparæ, for women of a small or frail build, and for those of an easy-going unimagined type. If begun early in labour, and the patient is a big, strong primigravida intolerant of pain, the first dose should be morphine $1\frac{1}{4}$ grain and hyoscine $1\frac{1}{100}$ grain, the frequency of the injections and dosage of hyoscine afterwards being determined by the effect obtained. Idiosyncrasy to hyoscine must be watched for, and the subsequent injections lessened if need be.

The standard time for the subsequent injections of hyoscine is, roughly, at hourly intervals, but in practice the frequency is determined by the effect produced, the memory test being adopted as an index of the amnesic state. The time of the second injection may be anticipated if the response to the first is feeble, but, generally speaking, it is better to keep to the $1\frac{1}{50}$ grain at shortened intervals rather than increase the amount to $1\frac{1}{300}$ grain, unless very little effect has been obtained from the first dose.

The memory test is carried out by taking some fairly common object that will not greatly tax the patient's muddled intelligence to recognize, showing it to her, and asking what it is. An hour or so later she may be roused, and asked what she was shown. If she has no recollection of it, the object is produced and the question repeated. If the object presented to her brings back no glimmer of its previous presentation, amnesia is complete. The test is not reliable; often women are able, by an effort at the time, to remember objects previously shown, but are found to have lost all memory of the events in the labour after it is over. Also repeated rousing for this purpose is an interruption to the narcotic state. The test should not be begun till after the second or third injection, and, so far as possible, should be carried out when the patient is disturbed for some other reason—for example, for a drink, a hypodermic injection, to pass water, or have a catheter passed. Also, if any attention of this kind of a sufficiently distinctive character is repeated, the opportunity can be taken to see if the memory of the previous occasion remains.

With further experience the need for repeating the hyoscine injections can be largely determined by noticing whether the patient is fully under the influence of the drug and by watching for signs of overdosage. When fully narcotized she should be drowsy, dosing between pains, but wakened up by them, and relapsing at once into drowsiness again. Should she show no evidence of disturbance during the pains no further injections should be given until some effect becomes noticeable. Usually, after the second or third injection, an interval of two or more hours may be allowed before the next one, provided quietness and drowsiness continue.

Flushing of the face and dilatation of the pupils are usually present early and are not necessarily indications of overdosage. The pulse and respiration rate should be carefully observed, as any marked alteration either in the direction of slowing or quickening is an indication for ceasing administration for a time. With overdosage the pulse rate is increased and the respiration rate slowed, and therefore a watch should be kept on any disturbance of the ratio between the two. Usually there is at first some slowing of the pulse rate, probably from the previous excitement and subsequent quietude. When once the pulse rate has settled down, however, it should not alter greatly.

Unfortunately patients are very variable in their response to hyoscine; most of them conform to the type described—sleepy or drowsy between pains but roused by them. Some, however, may remain awake and yet be found afterwards to have complete amnesia, and others may become restless and troublesome. There is always considerable mental confusion, but unless it is associated with excitement and difficulty in controlling the patient, it is not an indication for interfering with the injections. Some degree of restlessness is usual in the early stage, before the complete effect of the drugs is obtained, but in occasional instances it may become very troublesome. It is an indication of overdosage with hyoscine, and may require further administration to be discontinued. A watch must be kept on the bladder, and if the patient is unable to empty it voluntarily the catheter must be passed. Thirst is always well marked and leads to frequent drinks being given. Food, usually liquid, must be given in all lengthy cases.

It will be clear from this general account of its administration that the amnesic narcosis calls for the continuous observation of the patient by a skilled nurse and constant attention by the practitioner in charge. The patient may appear quiet and yet wake up suddenly and in her mental confusion, get up and wander about and do strange things—for example, hide herself or try to escape. No bowls of poisonous lotion should be left within easy reach, for thirst may drive her to sample the first fluid that comes to hand. Also, to get good results calls for experience in the method.

There are sundry modifications that make its partial use easier to those with little experience of it. Its effects are most valuable in the first stage of labour. In the second stage when the stronger expulsive pains and the distension of the outlet are likely to rouse the patient, resulting in her reconstructing the whole labour and making the induction a failure, it is often easier to fall back on a light general anaesthesia, especially once the outlet begins to gape and birth is imminent. If that is done, it may not be "twilight sleep," but amnesia is secured. Also, if the injections have been discontinued or the patient is out of control, chloroform anaesthesia may be induced—just sufficient to allow of a full examination being made—and if the os is not fully dilated or the head not deep in the pelvic cavity, another injection of morphine—a small dose, say $1\frac{1}{8}$ grain—may be given which will take effect before the general anaesthesia is recovered from.

The great objection to the routine adoption of this form of narcosis in labour is, to my mind, its undoubted effect in lessening the expulsive contractions of the uterus and voluntary bearing-down efforts, and thereby increasing the number of low forceps operations. The effect on the child—which appears to be almost entirely due to morphine—is of minor moment, as, though born apnoeic and disinclined to breathe, if left alone respiration will be established in a short time. The injection of pituitrin $1\frac{1}{2}$ c.cm. (that is, up to 5 units) will reduce the number of forceps deliveries, but leave them still above the average, as we found when the method was tried out in a series of cases not specially selected as suitable. The effects on the third stage are not noticeable. Hence my view is that both a careful selection of cases should be made and strict adherence to Gauss's method left to those with long experience of it.

Selection of Cases.

It is valuable for all patients in whom a long and tedious labour may be anticipated, particularly cases of slight disproportion between the head and pelvis, when a long time for moulding is essential. Many of these cases would be of the kind designated as "trial" labours, and in them it is undoubtedly of great service in lessening fatigue; as soon as the head is well down further administration of hyoscine may be stopped, and, if the patient delivers herself, a little chloroform given during the birth of the head. If delivery by forceps is required, anaesthesia is necessary. It is also useful in cardiac cases that have been under ante-natal treatment for decompensation, by lessening fatigue and strain during labour.

Apart from cases in which there is a cause or clear reason for avoiding fatigue, this method is adopted occasionally for cases in which the temperament or excitable state of the patient, especially if associated with a slow and erratic onset of labour, suggests it. It is often asked for by women who have either had a trying experience in a previous labour or have a great dread of what is before them and are without confidence in their unaided powers of going through it. It is always advisable in a medical school to select cases of this type now and then for instructional purposes, so as to keep nurses and students acquainted with the method.

Ovarian Therapy.

(Abstracted from *The Prescriber*, Vol. XXIII.
May, 1929, p. 199.)

THERE are many ways in which ovarian therapy should be of use, and indeed empirical, or semirational, applications have proved this beyond question; for example the stimulation of puberty in the relatively common case of delayed menstruation, and of course, the mitigation of menopausal symptoms in natural or artificial menopause. A few cases of hypo-ovarianism probably result in sterility, and these might well benefit under the stimulating influence of ovarian therapy; such cases are widely reported. The indiscriminate exhibition of ovarian extracts in sterility could not be defended, however, as it is quite clear that the majority of these cases are due to inflammatory conditions and displacements. The interruption of pregnancy is another possibility pointed out by animal experiment, and if expectations are maintained, this should be a very useful method of induction in contracted pelvis. It is of course an easy matter to produce abortion in laboratory animals, and notoriously difficult to do so in woman; without putting any significance upon it, we may mention that a case was reported privately of a woman who induced abortion by taking oestrin by the mouth.

Novak (Baltimore) since 1922 has written much on this subject which has acted as a salutary break on undue enthusiasm, and in his last paper he maintains this sceptical attitude, perhaps, if we may say it with respect, rather too much so in the face of recent developments. In addition to the indications listed above, he mentions the following conditions which might benefit under ovarian medication: amenorrhœa, hypomenorrhœa, oligomenorrhœa, and premature menopause; possibly some cases of so-called primary dysmenorrhœa, genital hypoplasia, obesity, repeated abortion, and menstrual headaches. The condition of "hyperfunction" of the ovary, Novak points out, is a controversial one, and he can only find one scientifically substantiated pathological entity which can be ascribed to it, namely "functional uterine bleeding." This is due to persistence of the follicular phase, probably with an enhanced activity, and can be treated successfully with corpus luteum extracts when such are really potent. Uhlmann has of course purified a very active product containing the internal secretion of the luteal tissue, which was first separated by Seitz and Wintz.

Among recent reports of successful ootherapy is one by Elsner (Prague), in which 13 cases of amenorrhœa (various ages) were treated with "homovar," an extract of cattle ovary liquor folliculi prepared by electro-dialysis. Then Cohn emphasizes that the chief symptoms of ovarian deficiency are psychic, and such as are loosely termed "neurasthenia." Intravenous aqueous ovarian extracts, combined with diathermy to the ovaries, produced good results in fifty cases. Seguy had good results in treating ovarian insufficiency by means of preparations from the healthy human ovaries removed at operations for salpingitis or ectopic pregnancy. This work has been adversely criticized on ethical grounds. Yet another technique has been adopted in a few cases by Zwolinski (Warsaw) who used 5-6 c.c. of blood-serum from women in the last eight weeks of pregnancy, on the ground that it contains both the ovarian hormone and that of the anterior lobe of the pituitary. Nine cases of congenital or premature amenorrhœa were improved, but complications occurred in two. Two cases

of hyperemesis gravidarum are said to have been cured, but no significance can be attached to this.

In a cautious and critical paper Posch (Innsbruck) discusses the use of sistomensin, the oil-soluble oestrus-producing hormone, and agomensin, the water-soluble principle of the corpus luteum. He treated a variety of pathological states from insufficient menstruation to uterine hypoplasia and menorrhagia, metrorrhagia, etc. Sistomensin produced very good results in 13 cases, good results in 14, and no response in 13. This type of report is one which carries much more conviction than many of a more glowing nature. Similarly agomensin had excellent effects in 21 cases, definite results in 18, and no results in 12 cases; this preparation was most effective in hypoplasia and functional amenorrhœa. Sistomensin was most effective in the hæmorrhages of puberty.

Hirst (Philadelphia), in treating 17 cases of menstrual disorder and sterility, used "estrogen" and produced relief of "sexual frigidity," and after excluding all other possible causes of sterility had apparent success in patients with normal menstruation. Estrogen is a placental extract first described by Firestone, who treated twelve cases with it, and reports good results in six; the condition being nervous manifestations of ovarian deficiency. Yet another new preparation is "progonon," a water-soluble type of oestrin described by Streck (Wurzburg), which is active given by the mouth, and gave good results in amenorrhœa. Hannan (London) has also demonstrated that oestrin is active per os, although sixty times the dose is required. This is of course a very valuable discovery for the clinician. Haultain (Edinburgh) found, however, that cases of artificial menopause responded better to treatment both by injection and orally, than by the latter alone. King and Patterson (Baltimore) disagree with these results and state that corpus luteum, and whole ovary by mouth, and oestrin hypodermically, are probably useless in relief of menopausal symptoms.

Yet another method of treatment of menstrual disturbances is discussed by Drips and Ford (Rochester, Minn.) who adopted radiation, as has, of course, been much used both in England and on the Continent. They believe an essential hypo-ovarianism exists in cases of primary oligo- and amenorrhœa, and of menorrhagia and metrorrhagia. The evaluation of the method is difficult owing to the occurrence of spontaneous remissions; and in addition they combined their treatment with such measures as iron, vitamins, agomensin, sedatives, etc.

The main impression gained from this series of papers is that only small numbers of cases are reported, but the tone is decidedly hopeful. In addition there is much more caution expressed by most authorities than would be found in similar papers of eight or ten years ago. The indications are improving, but one is at present justified only in saying that ovarian therapy holds out good prospects of cure or amelioration in many conditions, if extracts from reputable firms are used and are chosen at least with some care. The blind use of "ovarian extract" in any gynecological complaint can never be defended.

The Treatment of Blackwater Fever by Oral Sodium Bicarbonate.

By C. C. CHESTERMAN, O.B.E., M.D., M.R.C.P. (Lond.)
(*The Lancet*, Vol. CCXVI, June 29th, 1929, p. 1355.)

IN view of the successful treatment of blackwater fever by intravenous sodium bicarbonate recently reported, the following case is of interest in that the patient's second attack of blackwater fever, and a relapse following it, both yielded within 24 hours to large oral doses of sodium bicarbonate, whereas his first attack 13 months previously, treated by other methods, was of a very serious and prolonged nature.

The patient, a man aged 23, was employed on a rubber and coffee plantation. In June 1927, he arrived in the Congo. He was very irregular in taking quinine and had occasional malarial fever. In February 1928, he had his first attack of blackwater fever, being admitted to

hospital on the second day with oliguria and exhaustion. Haemoglobinuria continued for a week and the treatment was by intravenous glucose, rectal salines, cupping to loins, hot baths, etc.

The present attack began on March 17th, 1929, when he was feverish and bilious and took two doses of 0.5 g. quinine hydrochloride in capsules. On the following day, in spite of fever, he went to work at dawn until he noticed that his urine was dark red. He was transported on an improvised stretcher to the river side and reached hospital in a steamer five hours later. On admission his temperature was 39.7°C. and his pulse-rate 68. He twice vomited brownish bile-stained gastric juice and had one dark liquid motion. The spleen was just palpable.

Treatment was confined to the administration of as much natural lemonade, Vichy water, and tea without milk, as could be taken, 1 to 3 g. of sodium bicarbonate and as much powdered glucose being added to most of the feeds.

The following points are of interest in this case:—
(1) Both in the initial attack and the relapse the disappearance of haemoglobin from the urine, which was formerly acid, followed a few hours after it showed an alkaline reaction. (2) This was effected solely by the oral administration of sodium bicarbonate (and the citrates of lemonade) in doses up to 21 g. in 24 hours. Bilious vomiting which caused rejection of the first few doses was controlled by frequent sips of this alkaline fluid. (3) The relapse on the tenth day followed a couple of 0.6 g. (10 grains) doses of quinine when the urine was acid, whereas 1.2 g. (20 grains) was taken with impunity ten days later when the urine was kept alkaline. (4) Sodium bicarbonate in large doses is easily detected in the urine by the effervescence of CO₂ caused by the addition of an acid. The haemoglobin in such urine gives a very slight cloudy precipitate on boiling, whether previously acidified with acetic acid or not, possibly on account of the formation of alkaline haematin. Nitric acid, however, throws down a heavy cloud.

Although in this case the illness was precipitated by quinine, it was definitely not a case of quinine haemoglobinuria, for the patient showed no sign of quinine idiosyncrasy before or after the attack. Moreover, its association with an enlarged spleen, bilious vomiting, and jaundice leaves no doubt that it was a case of true blackwater fever. The case can be written down as but of slight severity, only on the ground that it continued for so short a period, and it is suggested that the early treatment, within six hours of onset, definitely aborted what might have been an attack as serious as the first one.

Such simple treatment is available immediately for any sufferer, however far removed from medical attention. The pre-blackwater state should similarly be treated with small doses of quinine combined with generous doses of alkali taken some hour or so before. It is hoped that medical men practising in endemic areas will make known the possibility of such treatment of this dangerous and much dreaded disease, and will report in confirmation or failure as results occur, for any single practitioner has as a rule to wait some years in order to collect a series of cases.

Reviews.

A SURVEY OF MEDICAL MISSIONS IN INDIA. 128 Pp. with map. 1929. Poona: National Christian Council, 1, Staveley Road. Price, Re. 1.

This report is one which should be read by every earnest student of medical matters and policy in India to-day. It has been prepared by the committee on survey, efficiency and co-operation of the Christian Medical Association of India, in conjunction with the National Christian Council of India, Burma, and Ceylon—largely as the result of replies to a questionnaire. And it contains a mass of information which we do not believe to be accessible elsewhere. The committee have certainly done their work extremely well.

Medical missionary work is inspired by the highest of ideals; yet the isolated worker may become so immersed in his own task that he may tend to lose sight of the general and national problem. The report emphasises both the special value and the special difficulties of medical mission work. In the first place it discusses the place of medical missions in general missionary work; there is no need to make out a case for this; the value of medical missions is recognised throughout India, and many of them are famous for their record of pioneer work in ophthalmology, surgery, tuberculosis, leprosy, and other branches of medicine. The map attached to the report shows how widely scattered are medical mission hospitals all over India; if this map recorded the activities of a Government department it would be a fine record; recording, as it does, the activities of missionary, voluntary agencies, it is a splendid record. "It is our conviction" records the Christian Medical Association of India "that the ministry of healing is an essential part of the work of the Christian Church." And Tables I and II give a summary of the hospitals and dispensaries for medical relief in India—both Government run and those run by medical missions; a study of these tables should afford any critic of "Western" medicine occasion for reflection, for it shows how immense is the problem of medical relief in this sub-continent, and how well it has been met.

In chapter 2 of the report the general situation with regard to medical relief in India is further outlined. This is an essay, almost, with a much wider appeal to medical readers than to only medical missionaries; it deals with the prevalent diseases of India, birth and death rates, the economics of the population, and the thorny question of non-qualified practitioners. In connection with the last problem, it is of interest to note that the more the practitioner of the indigenous systems uses "Europe drugs," the better his practice; the chief difference between him and the qualified man being that the latter has been taught how to use such drugs, whilst the former has not. The number of doctors per 100,000 of the population in different provinces is given, and varies from 2.8 in the Central Provinces to 21 in Bombay.

Medical aid for women is next considered. In this special field medical mission work finds its greatest scope for valuable service, owing to the purdah custom. The general history of the development of medical missions in India is then briefly outlined. Special hospitals, such as the mission sanatoria for tuberculosis and the hospitals of the Indian Mission to Lepers are next considered. Other chapters deal with the relation of the Christian Church in India to medical missions, mission medical schools, literature for medical propaganda, organisation, and statements of policy by medical mission boards at Home.

Chapter 4—conclusions—is that which will interest the general medical reader most. In the first place it is realised that medical missions in India are not sufficiently closely in touch with the general body of the Christian Church in India. Secondly, efficiency—although admirable in many of the better equipped and well-known medical mission hospitals—must be increased. A high degree of efficiency is usually reached on the surgical side, whilst—as our readers well know—tuberculosis and leprosy are subjects which medical missions in India have made especially their own. But the standards of laboratory and x-ray work especially call for improvement. The medical missions in India are too scattered and too little organised, and here the Christian Medical Association of India and the bi-monthly *Journal of Christian Medical Missions in India* constitute the nucleus for an all-India organisation which would improve matters considerably. The chief needs are more medical missionaries and more and better equipment. Extension is possible in almost every field.

The training of doctors, nurses, compounders and laboratory assistants is one of the most important services that medical missions are to-day rendering in India. At present medical men and women trained in such schools are eligible only for the Licentiate and lower medical degrees, and the question of a Christian Medical College for India which would train for the university

M.B., B.S. standard has to be considered. The question of the safeguarding of Indian Christian women doctors and nurses after qualification is a difficult one, touched upon in the report. The demand for such skilled medical attendance is very great, yet naturally many medical missions hesitate to send out their graduates to places where they will be compelled to serve in male hospitals with no supervision or protection.

The chief problem of medical missions in India, perhaps, is the shortage of doctors and nursing sisters. In all too many places a single doctor has to bear the whole burden, not only of running a large hospital single handed without being able to take leave, but of also facing financial difficulties and the ever-present difficulty of making ends meet. And the splendid self-sacrifice shown by many and many a worker in field only too often leads to a complete break-down in health; it seems essential that every mission hospital should have two or more doctors and two or more nursing sisters. Constant transfers of staff is another difficulty, which has perhaps been hardly sufficiently realised by mission boards at Home; for in medical missionary work—more than in almost any other field—it is personality that tells, and the success of a hospital may come to depend almost entirely on the personality of its head.

At present only about one mission hospital in thirteen in India is self-supporting. It should be more widely realised in India that the fees charged by a mission hospital go to that hospital in all instances, not to the individual doctor concerned. Yet too often the necessity laid upon the medical missionary by his Home board of rendering his hospital self-supporting means an intolerable strain.

Finally comes information as to where special training is to be had in the medical missions in India; at Miraj in general surgery and eye work; at Arogyavaram in Madras in pulmonary tuberculosis; at many different centres in ophthalmology, general surgery, obstetrics, and leprosy. A collection of useful appendices, including an account of the constitution and bye-laws of the Christian Medical Association of India, complete the report.

We would urge the non-missionary medical reader, as well as the medical missionary, to study this report, for it is comprehensive and covers a very wide field—essentially that of the general provision of medical relief (and especially of medical relief to women) throughout rural India. That medical missions in India are doing splendid work our readers must be fully aware; that better organisation and co-operation are called for is the lesson of this interesting and well-written report.

R. K.

THE FACTS OF MODERN MEDICINE.—By Francis W. Palfrey, M.D. London: D. Appleton and Co. 1929. Pp. XVI plus 490. Price, 21s. net.

THIS work forms one of a series of health books for the layman published by Messrs. Appleton & Co. The intelligent layman is frequently to be found engaged in the study of popular works on natural science. Satisfactory popular works on medicine have, however, been extremely uncommon until lately. Medical men have no doubt hesitated before writing such works which may have the effect of rendering the lay public unduly introspective. We congratulate Dr. Palfrey on the successful way in which he has avoided this difficulty, and has presented the main facts of medicine in a non-dramatic manner and in extremely simple language. The book opens with a general account of elementary biology. This is followed by a description of the elements of human anatomy and physiology. The subsequent chapters are devoted to an account of the diseases of the various systems. Treatment is discussed in general terms only, and the author wisely avoids reference to the use of special drugs. The paths of infection are clearly indicated, and the mode of action of vaccines and sera are explained. The author is extremely happy in his advice to laymen as to the correct attitude to be adopted towards the science and art of medicine and its practitioners, viz., as to what the public may reasonably expect from a medical man. The author has secured a real

triumph in the exclusion of the less essential terms of medical terminology. We strongly recommend this work to the non-medical public.

R. B. L.

PERCUSSION OF THE CHEST.—By J. B. McDougall, M.D. (Glasg.), F.R.C.P. (Edin.), F.R.F.P.S. (Glasg.). London: H. K. Lewis and Co., Ltd. 1929. Pp. VIII plus 143 with 10 illustrations. Price, 6s. net.

PERCUSSION is one of the daily methods of physical diagnosis. It may lack the glamour of some of our present-day laboratory devices, but that is in itself no reason why its possibilities should not be further explored. The author is to be congratulated for bringing forward this little handy book containing all the necessary information about the subject—historical, the technique of thoracic percussion, the acoustic aspects and variations in note in certain diseases of the chest. This book is to be recommended to medical students as well as to medical practitioners.

S. P. B.

THE EXAMINATION OF PATIENTS.—By Nellis B. Foster, M.D. 2nd Edition. Revised. London and Philadelphia: W. B. Saunders Company, Ltd. 1928. Pp. 392 with 83 illustrations, some of them in colours. Price, 21s. net.

REFINEMENT of diagnosis compels the use of the trained senses of touch, sight and hearing. The development of laboratory methods has diverted attention from these fundamentals and the tendency now is to depend more on laboratory findings. Rarely can a laboratory test alone reveal the nature of disease. Usually it is a support to other evidence—a bit of data to be weighed in forming an opinion. While knowledge of any disease has been extended marvellously, yet the clinical features on which depend the differentiation of one disease from another are always relatively few in number. It is the ability to seize on those few relevant facts out of a mass of data that has always marked the true clinician. Diagnosis is a science and an art; a science in the method of using facts secured, an art largely in the mode of collecting the facts. This book is recommended as it presents in a clear and concise way the methods of determining the facts on which an accurate diagnosis is based.

S. P. B.

PRINCIPLES AND PRACTICE OF ELECTROCARDIOGRAPHY.—By C. J. Wiggers, M.D. St. Louis: The C. V. Mosby Company. 1929. Pp. 226 with 61 illustrations. Price, \$7.50 net.

THIS book deals with a method of investigating the actual physiological and pathological responses of the heart. The electrocardiograph is still an instrument for the specialist only, but to him it is a valuable instrument, and this work does it full justice. The letterpress is clear and concise, and amply furnished with helpful diagrams. It is suitably indexed, and altogether is a well got up production. Dr. Wiggers, who has been one of the pioneers in this subject, is to be congratulated on a very successful book.

C. G. R. M.

PROBLEMS IN SURGERY. UNIVERSITY OF WASHINGTON GRADUATE MEDICAL LECTURES, 1927.—By George W. Crile, M.D. Edited by Amy F. Rowland. London and Philadelphia: W. B. Saunders Company, Ltd. Pp. 171. Illustrated. Price, 18s. net.

THIS is a small volume consisting of six post-graduate lectures. The title is a little misleading. Several of the lectures deal not so much with discussions on problems of surgery, but with Dr. Crile's solutions of these problems. The first deals with the management of acute infections and its interest lies largely in what is prohibited. Crile regards the following prohibitions of outstanding importance in acute infections, stimulants, vaccines, intravenous antiseptics, intravenous infusions, diathermy and ultra-violet light.

His lecture on "pre-malignant and malignant conditions" is full of interest and is especially remarkable for his success in extensive operations for carcinoma

of the larynx. His experience in cancer of the stomach is very much the same as that of Mr. Walton, e.g., only about 3 per cent. of cases operated on survive a five-year period. The third lecture on "operations on bad risk patients" is worthy of study by all surgeons who have to deal with this type of case. The fourth lecture on "the mechanism of hyperthyroidism" deals largely with the operation of thyroidectomy. As his experience is based on 17,759 operations on the thyroid, there must be few surgeons who are in a position to question his procedure. His present mortality is 0.8 per cent., and 94 per cent. of cases are definitely and permanently cured.

The fifth lecture is entitled "diagnostic and operative clinic" and is really a post-graduate discussion of the surgery of the gall-bladder, the relationship of cancer and ulcer of the stomach, cancer of the breast, and duodenal ileus as a factor in the causation of migraine.

The sixth and last lecture is an interesting speculation and discussion of the evidence supporting his theory that man is a bipolar electric mechanism.

The book is well printed and the illustrations up to the usual high standard of American textbooks.

A. H. P.

GENERAL SURGERY. Edited by Evarts A. Graham, A.B., M.D. (Practical Medical Series), 1928. Chicago: The Year Book Publishers. Pp. 800. Price not stated.

GENERAL SURGERY published in the Practical Medicine Series gives a review of the advances in surgery that have been made during the previous year. Although it is published in America the work done in all other countries is given adequate recognition. We are pleased to find that reference is made to articles by Indian surgeons in several places.

The article on anaesthesia is of interest to surgeons in this country where in the great majority of hospitals chloroform still reigns supreme.

The anæsthetic preferences of American surgeons are set forth, based on 640 answers to a questionnaire.

Only one surgeon prefers chloroform and then only in average good risk laparotomies and cases of inguinal hernia.

Ether is by far the most popular anæsthetic, but a local anæsthetic is used in the majority of hernia operations and nitrous-oxide-ether in cases of poor risk laparotomies.

A very interesting article on "wound healing" includes the observations of L. H. Stocumb on the effects of chronic malarial infection during convalescence from operative procedures. The lighting up of the infection after operation, and the poor healing of the wound are described.

This has long been known to surgeons in India who take adequate precautions by means of quinine treatment. All recent advances and new opinions in surgery are discussed in the various sections.

The illustrations are good and there is a very complete index which in a book of this kind is invaluable. There is no doubt that every surgeon who wishes to keep abreast of the rapid advance in the methods and technique of his art should have this work in his possession.

H. H.

INJECTION TREATMENT OF INTERNAL HÆMORRHOIDS.—By M. C. Pruitt, M.D., L.R.C.P.S. (Edn.), F.R.C.S. (Edn.), F.A.C.S. (Edn.). St. Louis: The C. V. Mosby Company. 1929. Pp. 137. Illustrated. Price, \$3.00.

This little book gives a very good description of the modern method of treating internal hæmorrhoids by injection.

The author is an enthusiast and certainly produces very effective arguments in favour of the injection method.

He gives a brief description of the surgical anatomy of the anal canal. The pathology of hæmorrhoids is clearly discussed and a very useful classification from the clinical point of view is also given. The chapters on diagnosis and more particularly the diagnosis of those cases suitable for injection are very good. The operative technique which is simple is adequately described

and illustrated. The various solutions that have been used by different surgeons are enumerated.

A considerable part of the book is devoted to the history of the injection treatment. The change of opinion that has occurred since the method was first suggested is remarkable and now there can be no doubt that it is a popular and successful method of treatment in India, as in every other country, the presence of hæmorrhoids is a common complaint.

That this complaint can be cured in very many cases by injection without an anæsthetic must appeal to all surgeons. This book should prove invaluable to those who have to deal with this condition.

H. H.

SQUINT: ITS CAUSES, PATHOLOGY AND TREATMENT.—By Claude Worth, F.R.C.S. 6th Edition. London: Baillière, Tindall and Cox. 1929. Pp. 110 plus 246 with 42 figures in the text. Price, 10s. 6d. net.

THIS is the sixth edition of this valuable work which is a sufficient index of its popularity, and it is obvious that it has acquired a great reputation which needs a review.

The first edition of the book was published in 1903 and there have been no fundamental changes in subsequent editions.

It is largely due to the author that the great advances in the cause, pathology and treatment of squint have been made in the last thirty years. The only treatment carried out by the greater proportion of ophthalmologists consisted in prescribing glasses, followed perhaps by a tenotomy which was sometimes combined with a certain advancement. No effort was made to train the fusion sense or the prevention of amblyopia.

The book deals in great detail with the whole subject of squint. Chapters are devoted to binocular vision, convergent and divergent squint, amblyopia, the pathology of the fusion sense, the ætiology and investigation of squint, heterophorias and the treatment of squint.

For the operative treatment of squint the author is dogmatic in stating that advancement is the only satisfactory and safe operation. The operation of tenotomy of an ocular muscle should not be performed either alone or in combination with advancement of the antagonist muscle. Operations which aim at elongation of the muscle without severance of its continuity are condemned as the effect is that of a complete tenotomy. Simple shortening of a muscle by resection of a part and reattachment to the old insertion is fairly satisfactory where only a very small angular effect is required. The muscle, the contractile power of the muscle and the range of rotation of the eye are lessened.

Muscle tucking is also not satisfactory for a similar reason, and has the added disadvantage that an early excrecence is produced which may never quite disappear.

Ophthalmology owes much to this author by his teaching cases of unilateral squint in which treatment commenced early and carried out by the methods described in his textbook are nearly all perfectly cured, leaving good vision in each eye and good binocular vision.

The book is a most admirable one, well illustrated and written in a clear simple style. It will prove most valuable to ophthalmologists in India where squint with its inevitable sequelæ is also so common.

E. O'G. K.

MEDICO-LEGAL PROBLEMS.—By Lord Biddell. London: H. K. Lewis and Company Ltd. 1929. Pp. 100 plus VIII. Price, 5s. net.

In this book the author has brought together his writings on the subject, which have been published from time to time in the *Transactions of the Medical Society*.

The book is divided into four chapters. In the first the author has discussed from the ethical, legal, and medical standpoints the justifiability or otherwise of sterilisation as a prophylactic measure for individual reasons for the mentally unfit as a class, and questions relating to abortion and medical confidences.

1. 21st mo. 1929

In the matter of sterilization the author, after pointing out how the methods employed for this purpose may in certain circumstances amount to illegal maiming, goes on further to show how they may also stand irrevocably against the future wishes and welfare of the persons whose immediate purposes they are intended to serve. The medical practitioner should thoroughly familiarize himself with these aspects of the question before entering upon an undertaking of this nature.

In the section on abortion the legal and ethical positions with respect to termination of pregnancy, when it is not only justifiable but is also a duty, are clearly discussed and the section of the book should be of great help to the young practitioner.

In the chapter on medical confidences, the legal position with regard to such confidences has been clearly set out. Proper weight is given to professional secrecy, which the author describes as a grave moral duty resting on the medical practitioner and points out that any gratuitous breach in this respect would render him liable to a claim for redress in a court of law.

The author's style is simple, clear, attractive and free from dogma. The understanding of the problems involved and their solution is materially helped by the incorporation of illustrative cases.

This book will be read with interest and profit not only by the young medical practitioner but also by all medical men.

J. C. D.

THE KAHN TEST: A PRACTICAL GUIDE.—By R. L. Kahn, M.S., Sc.D. London: Baillière, Tindall and Cox. 1928. Pp. XII-plus 201 with 7 plates and 35 tables. Price, 18s. net.

THREE YEARS having elapsed since the publication of Dr. Kahn's previous work, *The Serum Diagnosis of Syphilis by Precipitation*, a considerable amount of data has been accumulated; and the author proposes to issue a second edition divided into three parts, of which the present publication forms the first part. The volume now published is an expanded account of the previous descriptions of the technical side of the test. It may be described as a laboratory manual of the Kahn test. The subject-matter, consisting almost entirely of detailed descriptions of technical processes, does not lend itself to a summary in a brief review. Dr. Kahn writes clearly, and his laboratory manual may be recommended to all engaged in the performance of his test.

R. B. I.

ARMY HEALTH IN INDIA, HYGIENE AND PATHOLOGY.—By Lieut.-Col. J. Mackenzie, M.A., M.B., Ch.B., D.P.H., R.A.M.C. Pp. 158 with several illustrations. London: John Bale, Sons & Danielsson, Ltd. 1929. Price, 10s. 6d.

THIS is a most admirable and important little book, which should be read by every officer in the military medical services in India. It deals with the bad old days, the present, and the future; whilst it will also be of considerable interest to the civilian practitioner. Practically speaking it is an essay on preventive medicine in the Army in India, and its most valuable feature is that the author has dug into the old records during his tenure as Director of Hygiene and Pathology at Army Headquarters, India, and gives his readers vivid accounts of the days of the East India Company and of the early days of the Army in India.

The consecutive chapters deal with the health of British troops in India, malaria, organization, research, cantonments, and conclusions. Sickness and mortality returns were first introduced into the British Army by Sir James McGrigor at the close of the Peninsular War in 1814, whilst in 1857 there was appointed a Royal Commission to investigate into the sanitary state of the troops in England. Army hygiene may be said to date from the time of appointment of this Commission. In 1859 a corresponding Royal Commission was appointed for India; this Commission, under the chairmanship of Lord Herbert, took four years over its labours, investigated almost every station in India, and drew up a voluminous and invaluable report. An amazing diagram constructed from this report shows the relative sickness and mortality

at that time for (i) the healthy Army in England, and (ii) the sickly European Army in India. The comparison is a most striking one. In 1860 the admission rate for the British Army in India was 2,000 per 1,000 of strength, and the death rate 32.5 per 1,000; Mian Mir in 1861 returned the astounding mortality rate of 353 per 1,000—largely due to cholera; Amritsar in the same year gave a return of 124 per 1,000—largely due to malaria. Figures such as these are a positive revelation of what conditions used to be in the past, and one of the most valuable features of the book is its wealth of similar information. The official *List of Diseases* in 1868 will cause the reader to smile; we wonder what "enthetic diseases" were? In 1887 the P. M. O. Bengal actually prides himself on an admission rate of only 1,404 per 1,000 per annum. On p. 18 is a most instructive diagram showing how the admission rate for British troops has fallen from nearly 2,000 per mille in 1856 to under 600 per mille in 1925; these are the solid results of Army hygiene; they depict graphically what the medical services have accomplished for the Army in India. The lowest figure of all was reached in 1911 (just over 500 per mille from the graph), but subsequent to this the effect of the war becomes noticeable, and had not been completely recovered from—even in 1925.

The second chapter deals with malaria in the Army in India. Malaria is the Moloch of the tropics; it attacks some 50 million persons a year in India, and causes 1½ to 2 million deaths a year; neither plague, cholera, nor war can put up so terrible a record. Malaria dominates the returns for the British Army throughout the world. In 1837 the admissions for "fever" were 776 per 1,000 troops in Bengal and the deaths 14.4. The author then outlines very briefly the old views that used to prevail about the miasmatic origin of malaria, and there is here much most interesting writing, and many abstracts from old time reports. In 1898 malaria accounted for an admission rate of 2,000 per 1,000 strength in Fort Lahore, but by 1911—the healthiest year ever recorded for the British Army in India—the general rate for all-India had fallen to 90 per 1,000. That, again, is something of a record. "Detention" for malaria is one of the worst crimes that a military medical officer can commit; the patient should be "admitted" and thoroughly treated. There appear to be two cardinal remedies for malaria in the Army in India—"cold storage," and mosquito proofing. The former means the sending of units from malarious stations to the hills during the malaria season; the latter—hitherto far too much neglected in India—pays over and over again in improved health.

Chapter 3 deals with organization; "the hygiene and pathology services of the Army in India owe their inception, not to the gradual appreciation of the advantages of a health organization, but to the compelling force of thousands of dead British soldiers—dead of enteric fever in the eighties and nineties, and with a death rate increasing year by year in rapid crescendo to its climax in 1898"—a year in which the admission rate reached the astounding figure of 2,375 per 1,000 troops, and the death rate was 654. Surgeon-Major Davies was then appointed to carry out bacteriological analysis of water supplies, and, from that tiny beginning, there sprang into being the hygiene and pathology department of the Army, which is to-day rendering invaluable service, and which contributed notably to the success of the British and Indian Armies during the Great War. Surgeon-Major Davies should have a monument erected to him, for his services proved so valuable as the first bacteriologist to the Army in India that they were continued as such year in year out. The author gives a good account of the re-organization of the department in 1925 after the war, and present-day conditions. Plans of different military laboratories are given which show how vastly improved are present-day facilities on conditions which used to prevail twenty years ago.

Chapter 4 deals with research work. The primary function of a hygiene and pathology department is not research, but the control of disease; yet it is amazing how much the Royal Army Medical Corps has contributed to medical research in India. The *Journal of the Royal Army Medical Corps* was founded in 1903, and

from that time to this there has been a continuous output of research papers of sterling merit.

Chapter 5 deals with cantonments, and here the early history of the growth of cantonments in India is outlined from 1711 onwards. Colonel Mackenzie's abstracts, which give a vivid account of camp life in the days of the East India Company and later, are intensely interesting reading. Between the years 1847 and 1856 100,000 men on the active list were reduced to 9,604; the effect of 20 years of service in India was to reduce 1,000 effectives to 96. A most instructive account follows as to the simply appalling state of military cantonments in the old days in India, with many quotations from ancient documents. It appears to have been a toss up whether one died of malaria, cholera, or dysentery; only the hardy survived.

To-day the average sick time per soldier is 7.6 days per annum in the British Army in England, and 11.7 days in the British Army in India. The difference is significant; but it is also significant of the immense reforms which have been brought about.

Chapter 6 records the author's summary and conclusions. Climate, *per se*, Colonel Mackenzie concludes, is not responsible for the morbidity and mortality of the Army in India. "Man, like every other form of life, perishes if his own waste products are not removed from his immediate vicinity. In England these waste products are removed; in India they are not." The health of British troops in India is on a lower level than that of the troops at Home owing to the prevalence of (i) certain tropical diseases, and (ii) venereal diseases. The so-called tropical diseases are largely insect-borne and can be prevented by the application of suitable measures. The excess of preventable disease in the Army in India, as compared with the Army in England, costs annually in hospital treatment a sum of approximately 57 lakhs of rupees (£400,000). Would it not be worth while to apply a fraction of this sum to the prevention of disease in the Army, rather than to its treatment? The greatest enemy which the British soldier has to face in times of peace is the biting insect which is transmitting tropical disease—malaria, sandfly fever, dengue; or even the non-biting fly which is transmitting bacillary or amœbic dysentery. That immense improvement has been effected in the past is no reason why still further marked improvements should not follow in the future.

We have tried to present an analysis of this most attractive and interesting book. Its historical value is great; also its appeal to the military medical officer. It is succinct, well written, and should be read through, not once, but twice; in the first instance to gather a general impression of its lessons; in the second, to study the tremendous amount of statistical and detailed information which it contains.

R. K.

Annual Report.

REPORT OF THE EUROPEAN MENTAL HOSPITAL, RANCHI, FOR THE YEAR 1928. BY LIEUT.-COL. O. A. R. BERKELEY-HILL, M.A., D.M., I.M.S. RANCHI, SUPD'T., GOVT. PRINTING, BIHAR AND ORISSA.

Colonel Berkeley-Hill's annual reports are always interesting documents, and the present one is no exception to the rule.

The available accommodation for the year was for 102 males and 96 females, a total of 198. The most notable change during the year was the discontinuance of the policy of strict segregation of the sexes. The "male" and "female" sections have accordingly been re-named "north" and "south" sections respectively, and wards in the north section re-named Maudsley, Conolly, Kraepelin, and Juan wards. In the south section also the wards have been re-named. The "borderline cottages" have now become simply the "cottages." Instead of different sections accommodating the two sexes, wards

for males are now interspersed with wards for females in the same section.

There were 88 admissions during the year, including 19 re-admissions. The number of voluntary boarders was 31. Criminal insanes under treatment numbered 7. The patients come from every province in India—149 out of 280 of them from Bengal, and only 20 from Bihar and Orissa. The ratio of cures during the year was 14.83 per cent, whilst 19.44 per cent. are recorded as improved. The majority of cases cured are cured by short courses of treatment. The death-rate for the year was 4.6 per cent. Two misadventures occurred during the year, a case of suicide of a female patient—the second case only of suicide which has occurred since the hospital was first opened in 1918; and a fire in Conolly ward, due to a patient having set his bed alight. The general health was good.

During the year a vigorous campaign of propaganda in respect to mental hygiene and prophylaxis was pursued; also the Bengal Council of Women continued to inspect and report on the home conditions of discharged patients and to give them the very necessary advice and help.

No sort of seclusion or restraint is placed on the patients, with the exception of such measures necessary for the administration of hydrotherapy.

The chief types of mental disorder are in order of frequency secondary or terminal dementia, dementia præcox, imbecility, circular insanity, paranoia, confusional insanity, and others. An innovation during the year was the introduction of special "habit formation charts." In these the nature of the bad habit is recorded in the left hand column, and the measures most likely to cure it in the next column. In the last column the ward sister enters up the effect, if any, which the measures instituted have had on the bad habit. The occupational therapist also enters his remarks on the chart, and in this way several members of the staff are, so to speak, enrolled for an attack on a bad habit. The results so far have been very good.

Results with hydrotherapy continue to be most satisfactory. Two cases treated by psycho-analysis were discharged cured during the year; also two treated by prolonged sleep induced by Somnifen. The band continued to play its important rôle in providing musical treatment, musical drill, and choral and community singing. The cinema Colonel Berkeley-Hill considers to be of great therapeutic value. A travelling circus gave a performance, which most of the patients were permitted to attend. Evening promenade concerts were introduced on Mondays; at these the band plays and light refreshments are served. On May 17th, the tenth anniversary of the opening of the hospital, the patients and staff were "At Home" to visitors. Nearly 20 per cent. of the inmates take part in games, chiefly football, hockey, cricket, tennis, swimming and boating. Fourteen picnics were also held.

The occupational therapy building was completed and occupied during the year, thus supplying a much needed improvement. The garden was much improved during the year, and gives an excellent supply of fresh vegetables.

Receipts from all sources during the year amounted to Rs. 4,94,640, and expenditure to Rs. 4,28,711. The average cost per resident patient per annum works out at Rs. 2,193. Sister Marie Le Balche, the senior nursing sister on the staff, unfortunately contracted pneumonia, followed by a relapse after sea bathing at Puri, and was in a critical condition at the time when the report was written. One of the ward boys died of carbon monoxide poisoning from sleeping in a closed up room with a blazing charcoal brazier; whilst a second had a temporary attack of insanity. Otherwise the health of the staff was good. Lectures were given to the staff, who were also invited to write "research essays"; there is a regular weekly conference of the staff at which various matters are discussed. Visitors to the hospital during the year included Colonel Graham, I.M.S., Public Health Commissioner with the Government of India; also the delegation of the League of Nations. In this latter connection Dr. Yves Biraud, in a letter of thanks to the Medical Superintendent writes: "It was an education to us to see the methods which you use for the treatment of mental cases. Your occupational training and the absence of

any physical restraint on your patients were considered by us to be of particular interest in view of the successes which you obtain thereby." M. and Mme. Genis, the Consul-General for Belgium and his wife, visited the hospital in September. On their arrival the band played the Brabazon, and the Belgian flag was broken at the flagstaff.

In every respect an interesting and stimulating annual report.

Correspondence.

BLOOD PRESSURE IN INDIANS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Will you, or some of your readers, kindly inform me through the medium of your journal, as to the formula for finding the normal systolic blood pressure in Indians? According to European authorities, the normal systolic blood pressure is roughly 100 plus age in years, but Dr. A. C. Mozumdar of Calcutta in his book *Bedside Diagnosis* gives 90 plus half the age in years for Indians to be roughly the normal systolic blood pressure in Indians. Has any extensive series of observations been made on Indians; and on what experimental basis does Dr. Mozumdar's formula rest? Does it apply only to Bengalis, or does it hold good for residents in the United Provinces and Punjab also?—Yours, etc.,

N. K. MUKERJEE, L.M.F.

223, REKABGUNJ, FYZABAD,
3rd August, 1929.

UNDESCENDED TESTIS AS A CAUSE OF PHYSICAL REJECTION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I should be much obliged if any of your readers could give me advice as to whether a candidate for employment in the Police Department should, or should not, be rejected, on account of an undescended testis on one side.

Particulars of the case are as follows:—A Hindu male, aged 21, appeared before me for examination for admission to the Police Training School, Moradabad, on the 12th July, 1929. He was a well built youth, quite normal in other respects, but entirely devoid of a testis on the right side. The scrotum looked unilocular. No empty sac or space was felt in the right side of the scrotum. The left testis was normal, and did not appear to be over-developed. There was no impulse on coughing at the right external abdominal ring, which was of the same size as the ring on the left side. There was no swelling, pain, or tenderness in the right inguinal canal up to the internal ring, or in the right iliac region. The boy and his father both stated that the subject had had only one testicle since birth, and that this had caused him no trouble, though he had led an active life at school for several years.

I disqualified the candidate, as I did not like the risk of a possible strangulated hernia. He also had somewhat defective vision in the right eye.

What are the risks in such a condition, and should it be made a cause for rejection on physical grounds or not?—Yours, etc.,

RAMESHWAR SINGH, L.M.S.,
Officiating Civil Surgeon.

MURTRA,
16th July, 1929.

KHAKI DRILL AND SKIN IRRITATION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The following facts may possibly be of interest to your readers and of use in cases similar to my own.

For several years I suffered from an irritating skin disease which, without pathological examination of scrapings, was diagnosed variously as "tinea" or "lichen." Various doctors prescribed various ointments

—chrysarobin, benzoic, resorcin, salicylic, etc., etc., and iodine liniment, all of which were ineffectual. I had also a good deal of X-ray treatment, which was perhaps successful in certain parts, certainly unsuccessful in others. Early in the course of the affliction I noticed a close connection between it and sweating—it often recrudesced after violent exercise, especially in damp hot weather. Recently I noticed a recurrence after wearing khaki drill or twill clothing when I had been sweating very little or not at all, and I have accordingly made experiments which to my satisfaction establish the fact that the rash was caused by khaki not by sweating, for I have sweated profusely wearing other material than khaki, both rough and smooth, without a recurrence of the rash. My original belief that the sweating caused the rash is due to the fact that I generally wear khaki (as most people do in the East) when shooting or hill climbing or riding.

I shall be glad to answer any question you may care to put to me if my doing so would be of any use.—Yours, etc.,

H. WILKINSON, C.I.E., I.C.S.,
British Envoy at the Court of Nepal.

THE BRITISH LEGATION,
NEPAL,
22nd July, 1929.

(Note.—We are glad that Mr. Wilkinson has raised this point in our columns, for our own experience during the war was that khaki drill may be extremely irritant to some persons, though not to others. New-comers to India are frequently told to wear a cholera belt, and always to have flannel next to the skin. Anyone who has lived for several years in a hot and humid climate knows that such advice is nonsense. One should wear the lightest possible texture of clothing next to the skin; a very light cellular vest, perhaps, and a light twill shirt. We have shown Mr. Wilkinson's letter to Lieut.-Col. H. W. Acton, L.M.S., who is in charge of the Skin Clinic at the Calcutta School of Tropical Medicine. He remarks that there are two factors concerned in such cases: (i) the condition of the skin with regard to irritability, some persons being far more sensitive than others; and (ii) the texture of the cloth next to the skin. Many persons are quite unable to stand rough twills in contact with the skin.—EDITOR, I. M. G.)

VOMITING OF "BEES."

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The following case history is perhaps sufficiently peculiar to warrant publication:—

A Brahmin female, aged about 18 years, had a severe attack of "hysteria," which subsided about the sixth day. A month later she complained of a feeling of "something in her throat" and vomited after her next meal. To the intense amazement of the onlookers the vomited material contained 15 or 16 "bees," which, after moving about sluggishly for some time, flew away. The next day she vomited charcoal; the day afterwards hair. On the fourth day some thirty identical insects were vomited. The insects are about half an inch in length, of a black colour, and are similar to those often found in cow-dung. It is clear that this patient is in the habit of swallowing earth, but the incident is so unique that I should be glad if any of your readers could throw any light on it.

I have kept some of the vomited material and the insects for examination.—Yours, etc.,

TINCORI SIRCAR, L.M.P.

DHAMDHA,
PURNEA DISTRICT,
12th June, 1929.

(Note.—In reply to our request, Dr. Sircar was good enough to post to us the material which he had preserved, and this was submitted to Mr. M. O. T. Iyengar, Entomologist to the Public Health Department, Bengal. Mr. Iyengar reports that the insects are beetles belonging to the family *Tenebrionida*. Presumably they were swallowed in the larval state by the patient in earth containing them; not necessarily at the time of the attack.

Oct., 1929.]

of hysteria, but later; possibly on two or more occasions.
 Editor, I. M. G.)

A SUGGESTED MEASURE IN THE CONTROL OF PLAGUE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—Plague is a disease which involves three hosts; man, the rat, and the rat flea. At present our attempts at control of the disease are directed towards exterminating rats, removing man from the infected areas, and inoculating him against the disease. The proposal to house large populations in rat-proof houses is impracticable, whilst one cannot inoculate every person exposed to infection. The rat is an almost domesticated animal, and its numbers depend on the food supply.

Now Rowland's experimental studies have shown that rats which recover from plague have a certain degree of immunity which lasts for some months. Inoculation with anti-plague vaccine confers an immunity in man which lasts for about six months; the same measure also protects rats for several months.

Our anti-rat measures during an epidemic may destroy many immunised rats. Would it not be possible, instead, to introduce into infected areas large numbers of rats (preferably males only) immunised against plague by anti-plague vaccine? One would suggest that three rats per head of population be used in the infected area, and also that such immunised rats be introduced into the villages surrounding the infected area. These would pick up the rat fleas that have left infected rats, and the antibodies in the blood of the immunised rats might even reduce the multiplication of plague bacilli in the infected fleas.

This suggested measure might at least be tried out experimentally on a small scale. If infected fleas, feeding on immune rats, gradually become free of their infection, such a measure might become a most important one in the eradication of plague.—Yours, etc.,

ACCACIO DA GAMA, D.P.H.,
 Assistant Director of Public Health,
 C. R. D., Sind.

KARACHI,
 25th July, 1929.

(Note.—We have only published an abstract of Dr. da Gama's letter, as the original is rather too long for publication. We believe that a considerable volume of observations was accumulated on this subject by the Plague Commission. But is the suggestion to introduce very large numbers of inoculated rats into an infected area a practicable one?—EDITOR, I. M. G.)

Service Notes.

APPOINTMENTS AND TRANSFERS.

LIEUTENANT-COLONEL W. M. Houston, I.M.S., Port Health Officer, Bombay, is appointed Inspector-General of Civil Hospitals, Bihar and Orissa, with effect from the afternoon of 6th August, 1929.

On return from leave Lieutenant-Colonel D. P. Goil, I.M.S., has been appointed as Civil Surgeon, Howrah, with effect from the 3rd August, 1929.

The services of Major W. J. Webster, M.C., I.M.S., an officer of the Medical Research Department, are placed temporarily at the disposal of the Government of Bombay for employment as Officiating Assistant Director, Haffkine Institute, Bombay, with effect from the 1st August, 1929, or subsequent date on which he assumes charge of the duties of the appointment.

The services of Major J. B. Vaidya, I.M.S., are placed temporarily at the disposal of the Government of Assam, with effect from the date on which he assumed charge of his civil duties in that province.

Major J. L. Sen, M.C., M.I. Assam, is appointed to act as Institute, Dehra-Dun, vice granted leave, with effect from the 5th August, 1929, and until further orders.

The services of Major E. C. A. Smith, I.M.S., are placed permanently at the disposal of the Government of Bombay for employment as an alienist.

The services of Major H. C. Alexander, I.M.S., are placed at the disposal of the Government of Bihar and Orissa, with effect from the 1st July, 1929.

PROMOTIONS.

Majors to be Lieutenant-Colonels.

R. F. D. MacGregor, M.C., M.B. Dated 29th July, 1929.
 A. L. Sheppard, M.B., F.R.C.S.E. Dated 29th July, 1929.
 P. K. Gilroy, M.C., M.D., F.R.C.S. Dated 29th July, 1929.
 J. A. A. Kunahan. Dated 29th July, 1929.
 M. L. C. Irvine, M.D. Dated 29th July, 1929.
 E. W. O'G. Kirwan, M.B., F.R.C.S.I. Dated 29th July, 1929.
 G. L. Duncan, M.B. Dated 29th July, 1929.

Captains to be Majors.

S. L. Patney, M.B. Dated 2nd August, 1929.
 D. N. Bhaduri. Dated 4th August, 1929.
 R. G. Dani, M.B. Dated 4th August, 1929.
 P. F. A. Grant, O.B.E., M.B. Dated 9th August, 1929.
 C. S. V. Ramanan. Dated 19th August, 1929.
 K. R. K. Iyengar, M.D. Dated 5th July, 1929.
 M. Prasad, M.B. Dated 5th July, 1929.
 G. C. Maitra. Dated 14th July, 1929.
 J. J. Rooney, M.B. Dated 22nd July, 1929.
 Bodh Raj Chaudhri. Dated 22nd March, 1929.
 The provisional promotion of the undermentioned officers to the rank of Captain as previously notified by the Army Department, is confirmed, subject to His Majesty's approval:—
 G. S. Chawla, M.B.
 T. A. Malone.
 W. Scott, M.B.
 B. S. Nat, M.B., F.R.C.S.
 V. A. Edge.

LEAVE.

Lieutenant-Colonel E. C. Hepper, I.M.S., Civil Surgeon, Bareilly, is granted leave for 12 months, with effect from 1st May, 1929, or date of availing.

Major S. M. Hepworth, M.B., I.M.S., Acting Superintendent, X-Ray Institute, Dehra-Dun, is granted, preparatory to retirement, leave on average pay for 1 month and 2 days combined with furlough on private affairs for 1 year under military rules, with effect from the 5th August, 1929.

Major S. S. Sokhey, M.D., D.T.M. & H., I.M.S., Officiating Director, Haffkine Institute, Bombay, is granted leave for 4 months out of India, with effect from the 3rd August, 1929.

Major Jetal M. Shah, M.B.E., I.M.S., is granted, with effect from 3rd October, 1929, or subsequent date of availing combined leave for 16 months.

NOTES.

"BOOTS, CASH CHEMISTS."

"BOOTS, CASH CHEMISTS" is a household word in the United Kingdom, and it will interest our readers to know that this very well-known firm—Messrs. Boots' Pure Drug Co. of Nottingham—have recently opened their own depot at Mercantile Buildings, 10, Lall Bazar, Calcutta. Such special preparations as their Stabilaran, gonococcal vaccines, liver extract and insulin are here kept in cold storage under ideal conditions. The resident

representative is Mr. Ralph Paxton, at the above address, from whom information and literature may be obtained.

BRITISH MEDICAL ASSOCIATION MEETING AT MANCHESTER, 1929.

As a means of collating a quantity of information and presenting it in an attractive form and in a limited space, it would perhaps be hard to improve upon the system adopted by Burroughs Wellcome & Co.

A most striking feature of this firm's exhibit was the revolving illuminated structure adopted to display the sources of eight typical medicaments of vegetable origin used in the production of notable "Tabloid" and associated products. These hand-paintings possess an intrinsic beauty of their own and would claim attention on this score, apart from any professional interest. To the practitioner, however, the display must also bring back memories of his youthful interest in botany and remind him of the many processes—some tedious, some interesting, some extremely difficult—to which the raw material harvested from woodlands and fields or from cultivated herb gardens must be submitted before reaching his patient.

The Ephedra hand-painting proved of particular interest, partly because natural ephedrine is the medicament of the moment in the treatment of asthma, hay-fever, and other engorged conditions of the naso-pharynx, and partly because the plant itself is not at all familiar even to students of botany. There is, indeed, reason to believe that the illuminated reproduction of *Ephedra sinica* on the Burroughs Wellcome & Co. exhibit afforded to many visitors their first opportunity of studying this interesting plant at close quarters.

In a similar illuminated octagonal exhibit, the sources of eight typical medicinal substances of animal origin were shown in association with "Tabloid" products prepared from them. This original yet simple method of presenting a coherent view of the essentials of modern organo-therapy aroused considerable interest and provided many already acquainted with the subject from the clinical standpoint with much condensed information of a practical sort.

The causative organisms of certain specific diseases were shown as illuminated coloured photo-micrographs. Associated with these were products used in the diagnosis, prophylaxis and treatment of the diseases concerned.

Some indication of the part played by "Tabloid" medical equipments in exploration, travel, warfare and aviation was obtained from the display of the actual "Tabloid" outfits distinguished by association with famous explorers. The equipments used by Stanley, Peary, Scott and the Mount Everest Expedition were shown and also many standard cases which, though not destined to be so severely tried, seemed to hold the same promise of utility in emergencies. Dioramic displays of the critical events in the story of the expeditions were shown and provided striking evidence of the exacting conditions successfully encountered by the "Tabloid" Medical Equipments.

An illuminated chart demonstrated the relative values of different brands of malt extract. It showed the result of an independent examination by the Inland Revenue Department, Ottawa, Canada, of 152 specimens of malt extract. Only 10 of the 152 samples proved satisfactory malt extracts in every respect. Of these ten, no fewer than seven were "Kepler" Malt Extract, and all the specimens of this extract examined by the Government Analyst were approved by him.

APPARATUS FOR RADIOLOGY.

We have recently received from Messrs. Newton & Wright, Ltd., 471-473, Hornsey Road, London, N. 19, a copy of their brochure No. A[29], which gives a list of their high tension transformer units, which will be of

considerable interest to radiologists in India. The Simplex Unit, depending upon the self-rectification of a hot cathode tube, and restricted to an output of 30 milliamperes as a maximum, is the simplest apparatus listed. It is adapted to either direct or alternating current. Their Snook machines, both the junior model and the standard model, are very well known; the former suitable for private practice, the latter for heavy work in a large hospital. The super-tension Snook model is intended for those radiologists who require an apparatus for therapy up to a fairly high tension, as well as for radiography.

The development of the thermionic valve has altered radiographical work of recent years, and in this connection the Mono-Valve and Tetra-Valve outfits manufactured by the firm are of interest.

The different equipments issued by the firm comply, as far as possible, with the recommendations laid down by the X-ray and Radium Protection Committee; and all apparatus is tested before despatch and is accompanied by a twelve months' guarantee.

"INFECTED WOUND THERAPY."

UNDER the above title, the Denver Chemical Manufacturing Co., 163, Varick Street, New York, have issued a brochure dealing with the use of their well-known product "Antiphlogistine" in such conditions. Recent investigations show that glycerine is not only an ideal antiseptic, but also a germicide, capable of penetrating the tissues, of stimulating local leucocytosis and tissue repair. Antiphlogistine is stated to contain 45 per cent. of glycerine on analysis, and combines the virtues of glycerine, plus sustained heat and moisture and the mechanical protection afforded by the aluminium silicate base of the preparation. It is both powerfully hygroscopic and bacteriostatic, and also quite non-irritant. Any medical man who has had much experience of the preparation will not hesitate to vouch for its vastly better results than with the old-fashioned fomentation.

A copy of the brochure will be sent to any medical man upon application to the Denver Chemical Manufacturing Co.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers, relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India, Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name; as any such action would constitute a breach of professional etiquette.

Original Articles.

"KATAPHYLAXIA," A PHENOMENON SEEN CLINICALLY IN FILARIASIS.

By H. W. ACTON,

LIEUTENANT-COLONEL, I.M.S.,

Director and Professor of Pathology and Bacteriology,
and

S. SUNDAR RAO, L.M.P.,

Darbhanga Research Scholar, Filariasis Enquiry,
Calcutta School of Tropical Medicine and Hygiene.

Introduction.

THE term anaphylaxia or allergy is used for a phenomenon characterised by generalised hypersensitiveness of certain mesoblastic cells, and is produced by a leakage of certain protein poisons into the circulation. On the other hand, the term kataphylaxia is employed when there is only a localised failure of the tissue-defence mechanism, without involvement of the similar tissues in other parts of the body. In 1911-1912 the senior author had the privilege of seeing Sir David Semple's original experiments, which demonstrated the existence of this latter phenomenon. Semple first injected washed spores of the tetanus bacillus into the muscles of rabbits and guinea-pigs, and then, some days or weeks later, gave quinine subcutaneously, but at a different site. The animals developed tetanus and died as a result of the quinine injections. Semple (1911) explained these results as follows; washed tetanus spores, free from toxin, do not produce tetanus, and leucocytes normally remove such injected spores by degrees from the site of injection; the injection of quinine, however, produces a localised area of necrosis at the site of injection, the leucocytes carry the spores to this area, and—as the tissues are dead and therefore deprived of oxygen—this dead tissue forms a suitable nidus in which the spores develop into bacilli; these bacilli multiply rapidly, produce toxins, and therefore cause tetanus.

Gye and Cramer (1929) have shown that the same phenomenon holds good in their experiments on the *Vibrio septique*, and for the closely allied organism of gas gangrene. They first injected washed spores of these organisms into the tissues, and six months later injected calcium salts into the tissues; this produced gas gangrene. Gye and Kettle (1922) found that mice became more susceptible to infections with the bacillus of tuberculosis after injections of solutions of silicic and ortho-silicic acid; this susceptibility was both localised as well as generalised in these animals. During the course of some research work on tuberculosis in Indian cattle with Taylor (1917) Acton noted that, although the incidence of tuberculosis in Indian cattle is rare—only some 4 per cent.—yet the infection was always localised to the bronchial glands, and occurred particularly in those glands which had been irritated by fine particles of flint, etc. Many of these animals had enlarged glands which were not tuberculous, but which when sectioned showed numerous endothelial cells

replacing the lymphoid tissue; and amongst these cells were particles of flint that had been inhaled by the animal whilst feeding, and had found their way into the glands—a condition of silicosis of the lymphatic glands. The tuberculous nodules with acid-fast bacilli in them were almost invariably found in these enlarged silicosed glands. Cramer (1924), and in the same year Cramer and Kingsbury (1924) showed that in animals fed on a diet deficient in vitamins the mucus secreting cells of the intestine lose their protective power and allow bacteria to invade the deeper tissues. Acton and Chopra (1925) showed that in epidemic dropsy the same phenomenon was present, as intestinal bacteria were found to invade the tissues. They showed that various faecal streptococci and bacilli of intestinal origin could be obtained from the urine by catheterisation in such cases. Dr. K. P. Banerjee (1927), Assistant Professor of Pathology at the Calcutta School of Tropical Medicine, worked out an improved technique for the cultivation of such organisms in the urine. This method has given us much valuable information in studying the phenomenon of kataphylaxia in filariasis, and in allied problems. Acton and Chopra considered that epidemic dropsy was caused by certain toxins produced as the result of decomposition set up in damp rice during the monsoon months, and that it is not due to avitaminosis. This toxin acts on the mucous membrane of the bowel as is shown by the diarrhoea associated with the disease, and this breaks down the local defence-mechanism of the columnar epithelium of the intestine, allowing intestinal bacteria to invade the tissues and produce fever. The recovery of such intestinal organisms from the urine is evidence that they have invaded the body system from the gut. The work of Besredka (1925) on bilivaccin has shown that the local defence-mechanism of the intestinal mucosa can be stimulated against such pathogenic bacteria as typhoid and dysentery bacilli.

The phenomenon of kataphylaxia is worthy of much more study than has at present been given to it. It is a much less dramatic phenomenon than anaphylaxia, but it is more important. An investigation into the causes of this failure of the local defence-mechanism shows that it is more widespread and more subtle than is the phenomenon of anaphylaxia, since it involves all the tissues derived from the epiblast, hypoblast, and mesoblast. The epiblast and hypoblast are concerned with the protection of the mesoblast from surface invasion by bacilli from the skin or the gut. As far as we are aware, only two of these tissues have been studied, the mesoblast and hypoblast.

(i) *Epiblastic Kataphylaxia*.—The senior author of this paper hopes to deal with this subject in a later memoir. Here, however, we may make a few remarks to make our description of this condition clearer. The surface layers of the epidermis of the foetus *in utero* do not undergo keratinisation, but contain certain waxy substances which form a waterproof coating, and

protect the foetus from maceration in the liquor amnii. After birth this layer is cast off as the vernix caseosa, and the superficial cells gradually undergo keratinisation. This is the age when infants are most commonly attacked by seborrhoea, impetigo, etc. In the adult the epidermis varies in texture in different parts of the body, areas in which the skin is especially fine and thin being such as those between the fingers and toes. The epidermis consists of two layers; a few layers of horny cells and a basal layer. The skin in the areas where it is thin is commonly attacked by scabies, *Tinea cruris*, and other septic and ringworm infections, and these are also the areas where the horny layer of cells is first lost, as in trade and jute dermatitis. Weeping eczemas are also usually confined to those areas which are the sites of ringworm, seborrhoea, or pityriasis rubra, as the protective action of these horny cells is impaired and the lymph channels opened up to communicate with the surface, so that plasma exudes and forms a very favourable medium for the growth of streptococci and staphylococci.

(ii) *Mesoblastic Kataphylaxia*.—We have already seen that any substance which destroys the tissues locally favours the local development of spore-bearing organisms; e.g., tetanus and malignant oedema—the necrosed area forming an anaerobic nidus for the growth of these anaerobic bacilli. The liability to tuberculosis amongst those who suffer from pneumoconiosis, due to the irritation of the lung tissue by foreign particles of coal, dust, silica, etc., is a further example of mesoblastic kataphylaxia. The prevalence of bronchitis and broncho-pneumonia amongst persons heavily infected with *Ascaris* or *Anchylostoma* infections is still another example; this is well known and is due to damage caused to the lung tissue by the passage of the larvæ from the lung capillaries to the bronchioles on their way to the trachea. Acton and Sundar Rao (1929) have pointed out that most of the acute inflammatory lesions in filariasis associated with high fever are due to various cocci, streptococci and staphylococci, coming to the local damaged area from some external or internal septic focus. Such liberation of septic organisms from a local focus into the blood stream is a well known phenomenon; they may settle down in different localities, such as the joints with symptoms of arthritis; in the nerves, with symptoms of neuritis; and in the muscles, with symptoms of myositis. The reasons why such organisms will from time to time settle down in different localities requires further explanation.

With regard to filariasis, we shall show (i) that a toxin is liberated by the adult *Filaria bancrofti*, whilst laying her embryos; (ii) this toxin causes certain local irritative lesions in the glands and lymphatics, which break down the local defence-mechanism of these tissues; (iii) in certain individuals this toxin gives rise to a condition of widespread allergy in all the tissues of the body; whilst (iv) septic organisms, coming from some

septic nidus, via the blood stream, settle down and multiply in these damaged glands and lymphatic vessels, where local kataphylaxia has occurred, unaccompanied by generalised allergic phenomena.

(iii) *Hypoblastic Kataphylaxia*.—We are of opinion that most of the protection of the surface epithelium of the large and small intestine is due to protection afforded by the secretion of viscid mucin—the viscosity of mucin preventing bacteria from invading the deeper tissues. Resredka considers that the columnar cells of the intestine can establish a local immunity when subjected to the action of certain toxins in the presence of bile salts. We have already seen that in certain conditions of the alimentary canal—in avitaminosis (Gye and Cramer), in epidemic dropsy (Acton and Chopra), and also in intestinal ulcerations such as dysentery and diarrhoea—the local defence-mechanism may be broken down, and thus permit bacteria of intestinal origin to invade the blood stream. Most of such invading bacteria are either destroyed in the tissues or eliminated in the urine or bile. The urine, as Banerjee (1927) has shown, forms an excellent culture medium for these organisms, when it is withdrawn by catheter and incubated without the addition of any culture medium. Streptococci and staphylococci in such cultures give rise to puff-balls or powdery masses, and these must form excellent nuclei for the production of calculi. Fujimaki (1926) and McCarrison (1927) have both described the formation of such calculi in rats fed on a vitamine-deficient diet. Panja and Banerjee (1927), at the suggestion of the senior author, have shown that most cases of bacillary cystitis have their origin in bacteria coming from the intestinal tract and finding the urine in the bladder at body temperature a suitable culture medium.

The phenomenon of kataphylaxia is more important than that of anaphylaxia, since the latter only involves certain cells of the mesoblast and the defence mechanism in the endocrine glands, whereas the former may affect any of the tissues of the body.

Some of such kataphylactic effects are purely mechanical, such as the protective action of the horny layer of the epidermis; the destruction or irritation of the mesoblast by poisons or foreign particles; the loss of mucin secretion by the intestinal mucosa, of hypoblastic origin. There is also an inherent property of these surface cells to withstand attack by organisms on the skin or in the gut. In mesoblastic tissue we have the development of the phenomenon of immunity which is developed by these cells against certain bacteria. Whenever we have this local resistance lowered or destroyed, we may see the development of the phenomenon of kataphylaxia. Illustrative examples are the impetigo of young children under 7 years of age, where the protective layer of the skin has not fully developed, the development of ecthyma which occurs only in such individuals whose mesoblast resistance has

been lowered, and the weeping eczemas secondary to ringworm infection.

The Toxin of Filaria bancrofti.

Hamilton Fairley and Glen Liston (1924) have shown that a toxin is produced by the adult female of *Filaria medinensis*, and that its effects can be seen as soon as the female worm approaches the surface to lay her embryos. This toxin is responsible for the eosinophile granulation tissue reaction which occurs around the worm, and for the formation of the vesicle. If the worm is broken whilst it is still in the tissues, or if the milky uterine fluid containing embryos is injected under the skin, an urticarial rash develops on the body. Unfortunately we have not been able to obtain direct proof of the existence of a similar toxin in *Filaria bancrofti*, as this worm is very much smaller and extremely difficult to find in the tissues. We were fortunate enough once to find one adult

F. bancrofti. These microfilariae have to penetrate first through the superficial and then the deeper lymphatic channels and glands to reach the large lymphatics at the back of the thorax and abdomen. They may be arrested as they are developing in transit through the lymphatic channels at different levels of this chain. Should they penetrate to the big lymphatic channels and attain maturity and give rise to embryos, the female, when laying embryos, will pour forth her toxin and this will give rise to a reactionary eosinophilia in the blood stream. On the other hand, should semi-developed filariae be arrested in the lymph channels and glands on their way to the large lymphatic channels, they cannot mature; they are incapable of proceeding to sexual maturity; do not produce larvæ; and hence no microfilariae are found in the blood of such patients. In brief, the immature filariae have been caught up and arrested in the lymphatic channels, where they cause obstruction, and microfilariae are not produced.

TABLE I.
Eosinophilia in Filariasis.

Percentage.	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	49	55	Total.

In cases with filarial diseases without microfilariae in the peripheral blood.	3	11	26	17	12	19	3	2	1	1	1	3	0	1	0	0	0	0	0	0	0	0	100

female and two adult males in an abscess. Most of the developed filariae that we have seen have been discovered by sectioning such tissues as filarial varices, glands, etc., and not by dissection. We will therefore have to rely mainly on such indirect or circumstantial evidence as we can bring forward in support of our view that *Filaria bancrofti* produces a toxin.

Increase in the number of eosinophile leucocytes in the blood is usually regarded as a sign of helminthic infection, and is also found in such conditions of allergy as asthma, urticaria, and others. Now in filariasis, due to *F. bancrofti*, microfilariae are usually present in the peripheral blood at night. Only in such persons as have no obstruction of the lymphatic channels, either complete or incomplete, i.e., in cases of filarial hydrocele and chyluria, are microfilariae seen in the peripheral blood at night. In persons who are developing elephantiasis, and in whom the lymphatic obstruction is complete, microfilariae are usually not found in the night blood, only some 2 to 6 per cent. of such cases showing microfilariae. The etiology of such conditions may be explained as follows. In a hyperendemic area a patient will be repeatedly bitten by *Culex* mosquitoes conveying the microfilariae of

Table I shows the difference in the count of eosinophile leucocytes in 100 patients with microfilariae in their blood and 100 patients in whom no microfilariae could be found, but who were suffering from such types of filarial infection as filarial lymphangitis, or lymphatic obstruction. We see that in individuals in whom microfilariae are present in the peripheral blood stream, the mean eosinophile percentage works out at 8.969; whilst in those where no microfilariae can be found in the peripheral blood stream, owing to local obstruction of the filariae in the lymphatics, the mean eosinophile percentage works out at 4.62. The senior author of the present memoir regards a high percentage of eosinophile leucocytes as indicative of leakage of some foreign protein of animal origin into the general circulation; just as a polymorphonuclear leucocytosis is regarded as indicative of some acute septic process present in the body. Thus we find that in case of filariasis when toxins from the adult female worm are entering the body, the eosinophile count is high; whereas in cases where the immigrant worms are held up and obstructed in the lymphatic channels and glands—and thereby giving rise to obstruction, and perhaps local inflammation—the eosinophile count is low.

The occurrence of allergic or toxic symptoms and signs in filariasis. We have very rarely seen such signs and symptoms in persons suffering from filariasis with complete lymphatic obstruction, in whom no microfilariae could be found in the peripheral blood. But in persons in whom such microfilariae have been found we have frequently observed signs of intoxication, or allergy. Thus attacks of urticaria are quite common among them; the rash may persist for a few weeks or months, occurring nightly; or it may be periodic, seen only once a week or every ten days, or occurring with lunar periodicity every fourth week or so. Such patients always show microfilariae in their peripheral blood at nights, and their eosinophile leucocyte count is usually over 6 per cent. They do not react to the ordinary food sensitiveness tests, nor respond to the methods usually employed in the treatment of urticaria by endocrine therapy. Arsenical compounds, such as soamin, or polyvalent vaccines made from the various strains of streptococci or staphylococci or both together, give the best result in the treatment of such filarial urticarias. In such treatment what is carried out is probably either a general increase of body resistance, or a diminution of the general sensitiveness of the body tissues, but one cannot predict whether soamin or autogenous vaccines will be the more successful. Sometimes we have observed periodic attacks of non-suppurative lymphangitis in the breast, arms, or legs around aberrant migrating filariae, when they are near the skin surface. Although such cases occur, they are not very common, since the worm is not usually near the skin surface. At such times these filarial carriers may suffer from periodic headaches or migraine, or a slight rise of temperature, which Forman and Pitale (1928) consider are due to the action of the toxin.

We shall discuss in greater detail later on the lesions produced in the tissues by the filariae; it will be seen that they are very similar to those produced by *Filaria medinensis*, except that *Filaria bancrofti* always lives in the lymphatics, whereas *Filaria medinensis* can burrow her way through the tissues. The irritation of the tissues is seen from the earliest stage onwards of invasion of the subcutaneous tissue by the embryos injected by the mosquito. In an experimental infection we found that the skin in the region where the developing filariae had penetrated became thickened and red, and this condition persisted for some days. Three months later a transient patch of lymphangitis appeared on the outer surface of the arm, and so far no microfilariae have been found in the blood at night.

The lymphatic vessels and glands all show signs of irritation, due to the action of some toxin in the worm, and they respond by hypertrophy of the endothelial cells of the vessel walls or of the gland tissue to produce a granulation tissue which contains a large number of eosinophile cells. When obstruction has taken place in the lymphatic glands or vessels, aberrant

migration of the filariae may occur, so that when they approach the skin surface patches of hyperaemia or oedema (peri-lymphangitis) are seen, similar to those observed in cases of guinea-worm infection as the adult worms are coming to the surface.

This evidence strongly suggests that *Filaria bancrofti* produces a toxin which enters the blood stream and causes an eosinophile response from the bone marrow, similar to that produced by the toxins of other animal proteins.

The nature of the lesions caused by the toxin.

In filariasis there are two kinds of toxins—helminthic and bacterial—that act on the tissues, producing lesions which merge into one another, but which can usually be differentiated from one another. The filarial lesions can be distinguished by two points, first the chronicity of the lesions, and secondly, the nature of the cellular response made by the tissues against this toxin. The endothelial cells of the lymphatics or the reticulo-endothelial tissue of the lymph glands hypertrophies and eosinophile cells migrate into this area. This eosinophile granulation tissue is the response of the tissues against the filarial toxin. On the other hand, there are more acute and more diffuse lesions, when the tissues respond to the bacterial infection. The vessels in the neighbourhood dilate, lymph is poured out into the tissues (inflammatory oedema), and numerous polymorphonuclear leucocytes invade the area. These inflammatory lesions are caused by staphylococci or streptococci; in the case of the former organisms the infection may go on to suppuration (filarial abscess), and in the case of the latter organisms a typical inflammatory lymphangitis or cellulitis is seen clinically. A study of the microscopical sections of these lesions readily gives us the information as to whether the helminthic or the bacterial toxin has played the predominant rôle in the production of a particular lymphatic obstruction.

For the present, we will not discuss the effect of the bacterial toxins, but will only consider the effects produced on the tissues by the filarial toxin. The immature filariae in the proboscis of the mosquito are deposited on the skin surface, burrow their way through the epidermis and reach the superficial villous lymphatic terminals in the papillae. In their passage upwards along the lymphatics they are compelled to pass through the main intercepting lymphatic glands that are placed along the course of these vessels. Many of these immature filariae are caught in the reticulo-endothelial tissue of these glands and there destroyed; this is illustrated in Plate II, fig. 4. The filariae that succeed in passing through these glands reach the main lymphatic trunks of the arm, leg, or abdomen. When they reach maturity and the female commences to lay her embryos the microfilariae find their way into the blood stream, via the thoracic duct.

PLATE I.

Fig. 1.—Section of lymphatic gland showing females with coiled embryos in the uteri and desquamated endothelial cells around the worms.

Fig. 2.—Same as Fig. 1. Showing a plug of cells at the head end of the worm.

Fig. 3.—Lymphatic gland with immature filariæ.

Fig. 4.—Immature filaria being absorbed in a small dilated vessel in the hilum of a lymphatic gland.

Fig. 5.—Section showing the dilated lymphatics at the hilum of a lymphatic gland due to obstruction of the efferent vessels going to the gland above.

Fig. 6.—Section showing granulomatous masses which project into the lumen like papillomatous growth.

PLATE II.

Fig. 1.—Hæmatoma of the spermatic cord.

Fig. 2.—Section of a gland showing the tail ends of four worms. Note the amount of irritation is much less here compared with Plate I, fig. 1.

Fig. 3.—Irritation of the reticulo-endothelial tissue of lymphatic gland.

Fig. 4.—Section of a lymphatic gland. *F. bancrofti* being destroyed by giant cells. Fibrous tissue.

Fig. 5.—Formation of a scar in the substance of a gland as a result of destruction of the worm.

Fig. 6.—Lymphoid tissue gradually replaced by fibrous tissue.

We will therefore first consider the action of the filarial toxin on the main lymphatic trunks. This effect is best seen at the site where mature females are found and where they are obviously laying their embryos. Plate I, fig. 1 shows sections of two adult females; the uterus of each is full of coiled embryos and the lumen of the lymphatic contains a large number of desquamated endothelial cells derived from its endothelial lining. As the vulval orifice of the worm is situated close to its head end, the main action of the toxin which is expelled at the time when the embryos are shed is on the wall of the vessel, and is seen to be most marked near the head end of the filaria. Thus in Plate II, fig. 2, which is a section near the tail ends of four worms the same amount of irritation is not seen in the lymphatic as in the case of Plate I, fig. 1. At the head end of the worm a plug of cells is usually formed (Plate I, fig. 2) consisting of cells derived from the vessel wall as the result of desquamation of the endothelial lining. In this way an obstruction is formed against the centripetal flow of the lymph and the pressure rises in the obstructed lymph channels. The gravid female probably lays the embryos intermittently for a few days in each month, and this is the most likely explanation of the lunar periodicity of febrile attacks and other symptoms, which patients are so emphatic about when explaining their case. When the gravid female has ceased to lay embryos, toxins are no longer excreted to the same extent as during fecundation, and for the time being the inflammation subsides. This intermittent rise in the lymph pressure is the first factor in the mechanical production of the lymph-varices which are of filarial origin. These repeated attacks of inflammation weaken the wall of the lymphatic, and with the rise in lymphatic pressure the vessel wall dilates; thus Plate I, fig. 5 shows the dilated lymphatic channels at the hilum of a lymphatic gland due to obstruction of the efferent vessels going to the gland above.

The intermittent rises in pressure, associated with weakening of the vessel wall—particularly in those lymphatics supported by loose tissue—cause them to dilate and become tortuous like varicose veins, the condition known as lymphatic-varix. Clinically such varices are seen most frequently in the spermatic cord, around the superficial inguinal glands, on the inner aspect of the arm, etc. The repeated entrance of more mature or adult filariae into these dilated, tortuous lymphatics keeps up the irritation of the vessel wall, so that the endothelial cells hypertrophy and come to form a granulomatous mass which projects into the lumen like a papillomatous growth (Plate I, fig. 6). The slightest traumatic injury to these granulomatous growths ruptures them and bleeding occurs into the lymph vessel, and clotting of the blood does not take place unless the hæmorrhage is severe, as in the case in hæmato-chyluria, or if the rise in pressure is great enough to control the bleeding, as in hæmatoma of the spermatic cord. Plate II, fig. 1 shows such a

hæmatoma of the spermatic cord, and Plate I, fig. 6 shows the condition of lymphatic varix outside the area of the hæmatoma.

As long as the lymphatic obstruction is only partial or intermittent, microfilariae will be found in the blood stream at night. Hence it is the rule that in cases of *chyluria* and *lymphatic varix of the cord* microfilariae are practically always found in the blood. On the other hand, the lymphatic obstruction may become permanent, and if the lymphatics are sufficiently large in calibre, filariae will come into them, mature, and commence to lay embryos. Each time that embryos are ejected the toxin ejected at the same time will cause desquamation and hypertrophy of the endothelium, and after recovery the endothelial cells will form fibrils which will thicken the wall of the vessels until the lymphatic vessel looks more like a vein than a lymphatic, and the lumen is gradually diminished in size. Plate I, fig. 3 shows such a lymphatic containing three immature filariae. Sometimes the obstruction above is so marked that many of the main lymphatics are thickened and sclerosed, so that the immature filariae are unable to find lymphatic channels sufficiently large in diameter to allow them to pass through and reach maturity, and are forced to remain in the smaller lymphatics. Here they die and are absorbed *in situ*, partly as the result of phagocytosis by the giant cells, partly by the effect of cytolytins produced by the endothelial cells. Plate I, fig. 4 shows such an immature filaria being absorbed in a small dilated vessel in the hilum of a lymphatic gland. The fact that many filariae die in the small vessels and thus never reach maturity provides a second reason to explain why microfilariae are so rarely found in the peripheral blood when obstruction is complete.

The next point to investigate is the reason why the adult female filaria selects certain main lymphatic vessels of the body in preference to others in order to reach maturity and lay embryos. Adult filariae have been found in the main lymphatics of the abdomen near the thoracic duct, in the pelvis of the kidney, in the enlarged varicose vessels of the spermatic cord, near the glands draining the limbs, and in filarial abscesses. The main object of the immature filariae, as soon as they have penetrated the skin of the arm, leg, etc., is to travel centripetally towards the main large lymphatic channels in which they mature and lay their embryos; the embryos finally finding their way into the blood stream, and so into the *Culex* mosquitoes. The commonest site in which we have found mature filariae has been the large lymphatic vessels, either at the hilum of a gland, or in a varicose lymphatic channel; (Plate I, fig. 1; Plate II, fig. 2).

Immature filariae are found in the smaller lymphatics, or where the lumen has been diminished by fibrosis (Plate I, figs. 3 and 4). This fact shows that, as soon as the afferent vessels to the gland above are blocked, the filariae cannot pass any further forward, and have to

migrate in some other direction (*aberrant migration*) in order to reach a dilated lymphatic channel sufficiently large in size to allow them to develop and attain maturity. The main cause of aberrant migration is therefore lymphatic obstruction above. The filariæ coming from the leg have to traverse three sets of glands in the course of their journey up towards the thoracic duct, *viz.*, the inguinal, pelvic, and abdominal glands; whilst those from the arm area have to traverse two sets of glands, the epitrochlear and axillary. Blockage may occur at any of these sites.

When the adult filaria is in the abdominal group of glands the obstruction is rarely complete; microfilariae are generally found in the peripheral blood, and such aberrant migration as occurs generally takes place along the lymphatic channels of the spermatic cord, kidney, etc. In the pelvic group of glands the obstruction is usually complete as regards the passage of adult filariæ towards the abdominal lymphatic vessels; consequently microfilariae are not usually found in the blood, and aberrant migration commonly occurs towards the external and internal iliac regions. When the superficial inguinal glands are involved the obstruction is usually more marked in one limb than in the other; the filariæ have to migrate back into the dilated lymph channels of the limb, causing recurrent attacks of inflammation, with or without abscess formation, conditions so commonly observed in this group of patients. Discussion of this subject in detail would be out of place in this paper, but we hope to deal with it more fully in a subsequent publication. Here we may briefly state our findings in the matter, as follows:—

(i) In places in India where the infective season is of short duration; the microfilariae rate moderate or low, e.g., below 10 per cent., and the age incidence of clinical symptoms of filariasis from 20 years upwards, the filariæ usually reach the main abdominal lymphatic trunks, and microfilariae can usually be found in the peripheral blood. Obstruction is only partial and results in chyluria, lymphatic-varix of the cord, etc., whilst elephantiasis is but rarely seen.

(ii) In places where the infective season is longer in duration; the microfilaria rate higher, between 10 and 20 per cent.; and the chief age incidence from 12 to 15 years, the filariæ may or may not reach the main abdominal lymphatic trunks. If they do so the obstruction is partial, microfilariae being found in the blood, and the symptoms being as in (i). If the obstruction is complete, as shown by cedema of the legs, arms, scrotum, etc., microfilariae are only rarely seen in the blood.

(iii) In places where the infective season extends almost throughout the year; the microfilaria rate is high, over 20 per cent.; and the age incidence 10 years and upwards, the filariæ very rarely reach maturity in the main abdominal lymphatics, so that hydrocele, chylocele, and chyluria are not usually observed, as the

obstruction of the lymphatics occurs very early in life. The superficial lymphatics are first involved and here elephantoid conditions of the legs, arms, breasts, etc., are seen as the most common clinical manifestations of filariasis.

These different clinical manifestations of filariasis have been noted to be characteristic of different countries, and of different areas within the same country, and have puzzled many workers on filariasis. Some, indeed, have attributed them to different species of filariæ. We now put forward the view that these different symptoms are one and all due to the same species of filaria, *Filaria bancrofti*, but that the clinical variations are due to differences in the intensity and duration of the infection at different sites in the lymphatic system of the body. In places where a few filariæ injected by mosquitoes at long intervals gain access to the limbs, these pass through the afferent lymphatic channels and glands without causing much irritation or obstruction. On the other hand, in places where large numbers of immature filariæ are being injected month by month by infected mosquitoes into the same persons, immature filariæ penetrate through the skin, irritate the lymphatic glands in sequence as they enter them, and give rise first to inflammation, and then obstruction. The site of obstruction is dependent on how quickly, and where, the lymphatic glands are first destroyed by the passage of the worms through them.

Changes in the Lymphatic Glands.

We may next consider the changes that occur in the lymphatic glands. As the immature worm, injected by the mosquito, travels along the afferent lymphatic and enters the lymphatic gland, it has to work its way along the lymph space between the trabeculae and the lymphoid nodules of the cortex to reach the medulla. In this situation the passage of the worm is rendered difficult as it has to traverse the dense reticular tissue of the medulla. Sometimes the worm is held up; the tissues react against it; endothelial cells proliferate, and eosinophile cells are seen scattered throughout the area. Plate II, fig. 3 shows such an area through which a worm has passed, leaving eosinophile granulation tissue to mark its course. At other times the immature worm is strangled by the granulation tissue and dies; and giant cells are formed near the dead worms. Plate II, fig. 4 shows an immature male being destroyed by giant cells. When the worm is thus destroyed (Plate II, fig. 5) the granulation tissue becomes vascularised by the formation of new blood vessels and is by degrees converted into fibrous tissue, so that a scar results in the medulla of the gland.

Now one of two changes may occur in such invaded lymphatic glands.

(i) When numerous immature filariæ are constantly passing through the gland, the whole gland becomes increased in size and in the course of a short time is converted into a mass of eosinophile granulation tissue, and no longer contains any lymphoid tissue. As the lymph channels are

obstructed by this granulation tissue, lymph can no longer percolate through the gland, and filariæ also cannot possibly pass through it. The afferent vessels are blocked; the lymphatic pressure rises, and the lymphatics below dilate, particularly those situated in the hilum of the next and more distal lymphatic gland. The worms cannot pass forward and are forced to migrate backwards, and mature in the dilated vessels in the hilum of the distal glands (*vide* Plate I, fig. 1 and Plate II, fig. 2). The enlarged gland can no longer be irritated by the passage of worms through it; the granulation tissue becomes further vascularised; scar tissues result, and the gland becomes small in size, hard, fibrous and atrophied (*vide* Plate III, fig. 1). These changes may occur in the abdominal, common iliac, external and internal iliac, and superficial inguinal glands, and are dependent upon the number of injected filariæ that are passing through these glands. In heavily infected places such as Cochin, where the patient is bitten again and again by infected mosquitoes, enlargements of the superficial inguinal, and epitrochlear glands are common, the filariæ being so numerous that blockage occurs towards the distal end of the lymphatic system; on the other hand, in such places as Allahabad, where only light infections occur, and the percentage of infected mosquitoes is very small, involvement of these superficial glands is not seen.

(ii) When only few filariæ are passing through the superficial glands for short periods of the year, they leave only microscopic scars in these glands. They penetrate to the deeper lymphatics and the cumulative effect of their toxin is seen at the sites where the mature females are laying their embryos; i.e., near the right and left juxta-aortic glands, causing partial obstruction of the area drained by these glands, and thus giving rise to such conditions as chyluria, chylocele, etc.

Changes in the Skin.

Finally, we have to consider the effect of the immigrant filariæ on the finer lymphatic capillaries of the skin. In persons living in moderately or heavily infected areas the tissues of the limbs, breast, scrotum, or vulva become enlarged and oedematous, and later on both the epidermis and the deeper tissues hypertrophy to produce the enormous pendulous masses or swellings so characteristic of filarial elephantiasis. What happens in such cases is as follows:—Owing to the adenitis produced, the afferent vessels to the gland are obstructed, and the lymph cannot flow freely towards the central lymph system; the tissues below therefore become oedematous and swell. The lymph pressure increases; at first the deeper lymphatic vessels dilate; then those of the subcutaneous tissues; finally those going to the skin; so that more and more plasma is poured out into the tissues, and the part becomes more and more swollen. Plate III, fig. 3 shows this dilatation of the surface lymphatics and the separation of the

white fibrils and dartos muscle by exudation of lymph into the tissues. This tissue is known as "blubbery tissue" because when one cuts into it the lymph pours out and the tissue collapses. At this stage there is more or less complete obstruction and hence microfilariae are not found in the peripheral blood of such patients.

Now let us consider what happens when immature filariæ continue to be injected into such persons by infected *Culex* mosquitoes. The immature filariæ can no longer reach the abdominal lymphatics and the blood stream; they penetrate to the blocked lymphatic glands and no further. They may be caught and destroyed in their immature stage at this site, as shown in Plate I, figs. 3 and 4, and Plate II, figs. 4 and 5; either in thickened lymphatics or in the gland substance. More often they migrate downwards or laterally into areas where the lymphatics are enlarged, and where they can develop and attain maturity. Plate I, fig. 1 shows mature females with embryos *in utero in situ*, and Plate II, fig. 2 mature males and females in the enlarged lymphatics at the hilum of the superficial inguinal glands.

When the internal group of the superficial inguinal glands are obstructed, the worms migrate back through the dilated lymphatics of the scrotum, where they mature and commence to lay embryos. This aberrant migration of the maturing filariæ is due to their endeavours to reach lymphatics of a sufficiently large calibre to allow of their maturing and attaining full development, and this condition explains the many fugitive swellings, abscesses, etc., that are so often characteristic of filariasis. That is to say, when obstruction is complete above, many of the filariæ do not reach maturity, but die in the lymphatics and are absorbed, whilst others which are able to gain access to a suitably large lymphatic channel develop to maturity, copulate, and commence to lay embryos. These embryos, however, cannot gain access to the blood stream, but are compelled to remain in these obstructed lymphatics. Now blood is probably very necessary to the life of the embryos; it probably provides them with certain diffusible foodstuffs, such as sugar. Whether this is so, or not, the microfilariae from such worms ultimately die in the obstructed lymph stream, and are carried down by gravity or by back pressure to the finer lymph vessels of the skin. They irritate these finer lymph vessels all along their course, as is seen by the presence of endothelial hyperplasia. Thus Plate III, fig. 6 shows irritation round the lymphatics draining the sweat glands. In this way the fine villus-like lymphatics in the papillae undergo dilatation (Plate III, fig. 5), and, as the lymph flow is obstructed from the surface, the papillae hypertrophy. At the same time the surface horny layer does not keratinise properly, and therefore there is a loss of surface protection against the invasion of the skin by bacteria. Often a group of these surface villus-like lymphatics are obstructed, and the skin over them hypertrophies;

and becomes raised—forming lymphatic cysts (Plate III, fig. 2). When these cysts are pricked lymph, which may or may not contain micro-filariae, oozes out of them.

After many years of such chronic filarial irritation of the tissues, or sometimes in a few years' time, when subacute or acute bacterial inflammatory attacks occur in the skin, the fibroblasts in the blubbery skin multiply and form new fibrous tissue, which makes the skin dense and hard—the typical elephantoid skin (*vide* Plate III, fig. 4). The fibrous induration extends deep down into the tissues as far as the sweat glands, and, interfering with the lymphatics in this region, first produces oedema around the sweat glands, (*vide* Plate III, fig. 6). Fibrosis follows, and eventually the glands are destroyed, so that the skin in elephantiasis is always harsh and dry. In the meanwhile the surface hypertrophy of the epidermis has become more and more marked (Plate III, figs. 3, 4, and 5); fissures occur in the ill-developed horny layer, allowing micro-organisms to invade the corium. In these very large warty elephantoid limbs repeated attacks of inflammation due to infection coming from the surface are extremely common, and increase the oedema and exhaust the patient.

Kataphylaxia in Filariasis.

In a previous article (Acton and Sundar Rao, 1929), we have shown that most of the serious lymphatic obstruction that is produced in the lesion known as elephantiasis is not due to the *Filaria bancrofti* itself, but is caused by such invading pyogenic cocci as staphylococci and streptococci. The former organisms produce localised areas of inflammation around the dead worms, which may or may not go on to suppuration (filarial abscess). The latter may produce acute attacks of lymphangitis, cellulitis, or periadenitis which may in itself cause a lymphatic obstruction with a condition comparable to the elephantiasis nostra of Europe. This condition is not due to the *Filaria bancrofti* itself, and the lesion resembles "white leg." In our former paper we pointed out that these cocci might be derived from either external or internal foci, and in many instances we were able to show conclusively that this is so by isolating the same type of organism from some septic focus as well as in the local inflammatory area. Such micro-organisms gain access to the blood stream from the source of focal sepsis, and settle down in the area involved in the acute filarial inflammatory process in preference to any other in the body. The staphylococcus produces localised areas of inflammation, associated with a low grade of fever, 99°F. to 101°F., and with moderate leucocytosis, 10,000 to 14,000 per c.mm. The lesions may be suppurative or non-suppurative. In the latter case the clinical manifestations are periadenitis around the superficial inguinal glands, e.g., the inguinals, saphenous, and epitrochlear; orchitis; or inflammation around aberrant migrated filariae in the limbs, breasts, or spermatic

cord. Suppuration may take place around the filariae in the lymphatic glands in any of these situations. Clinically identical lesions may be produced either by the filariae alone or by them in conjunction with staphylococci. In the case of staphylococcal superinfections we get pus cells in the exudate and on culture the *Staphylococcus aureus* or *mollis*; in the purely filarial cases the inflammatory tissue consists of an eosinophile granulation tissue which may undergo caseation and softening. The pus is sterile, and there is only slight fever and moderate leucocytosis. Plate I, fig. 1 shows a mixed filarial and bacterial infection of the gland.

On the other hand, more virulent infections occur as the result of streptococcal invasion of the tissues. These can never be mistaken for purely filarial manifestations. The symptoms and signs are those of a profound and sudden toxæmia, with high fever, 103°F. to 105°F., a rapid pulse, and more marked leucocytosis, 12,000 to 16,000 per c.mm. The clinical syndromes known as filarial colic (i.e., infection of the retro-peritoneal tissues and lymphatics), endemic funiculitis (i.e., infection of the lymphatics of the spermatic cord), filarial cellulitis of the tissues of the limbs or breast, and acute filarial lymphangitis around the vessels coming from some external septic focus are of this origin. In filarial colic death is usually due to an acute septicæmia and toxæmia; in endemic funiculitis to a generalised streptococcal peritonitis. In cellulitis and perilymphangitis the attack commences with a rigor and high fever; as a rule suppuration does not occur, and the inflammation subsides in a few days. A few sharp attacks of these streptococcal infections of the limbs or breast produce in a very short time a lymphatic obstruction which it would take some years for filarial obstruction alone to have produced. Microscopically such streptococcal infection can easily be recognised by the inflammatory oedema around the lymphatic vessels (*vide* Plate IV, fig. 2), the fluid containing relatively few polymorphonuclear leucocytes.

We will next explain the reason why the combination of filarial lymphatic obstruction and the sharp attacks of streptococcal or staphylococcal infection in this devitalised and oedematous tissue gives rise in a very short time to the enormous elephantoid condition of the legs, arms, breasts, scrotum, vulva, etc., in certain individuals, the inflammation recurring time after time in the same area. This condition is brought about by kataphylaxia, a condition in which a break-down occurs in the local defence-mechanism of the tissues. The filariae have been shown to irritate the mesoblastic tissues in three ways:—

(i). The filariae cause a localised irritation of the reticulo-endothelial cells of the lymphatic glands, which lowers their resistance and renders them more vulnerable to attack by various pyogenic cocci. Colour-Plate IV, fig. 1 illustrates this point very clearly. We are indebted to Dr. J. M. Henderson, Research Worker under

PLATE IV.

the British Empire Leprosy Relief Association, Calcutta School of Tropical Medicine, for the absolutely unique specimen illustrated in this plate. During the course of his researches on leprosy Dr. Henderson was removing suspiciously enlarged lymphatic glands in the vicinity of leprosy lesions and examining sections of them to see if they were invaded by the *lepra bacillus*. At that time we were inclined to believe that filarial obstruction only affected the large and main lymphatic glands, and had not realised the importance of the more superficial and smaller glands. The obstructed glands are found to consist of a mass of granulation or fibrous tissue, and the density of the inflammatory tissue makes it impossible for any filariae to travel through the glands. Plate IV, fig. 1 has been drawn from Dr. Henderson's specimen and was shown to the members of the Far Eastern Association of Tropical Medicine at the Seventh Congress in Calcutta in 1927. (The sections are rather thick; photographs alone would give only a very poor idea of the general structure, hence we have resorted to a colour plate rather than a photograph. Plate II, fig. 4, however, shows the same condition photographically.) In this specimen the worm, an immature male, has been caught and entangled in the reticulo-endothelial tissue of the medulla of the lymphatic gland, and an eosinophile granulomatous reaction has occurred around it. At the site of maximum irritation giant cells are seen on the outer side of the worm. Five different sections of the coiled worm are seen, four of them cut transversely and one obliquely. The centre of the field, stained a deeper red, consists of endothelial cells undergoing necrosis. The lighter area around this consists of the endothelial granulation tissue with giant cells, and the darker blue area is the normal lymphoid tissue of the gland. This affected area would in time have been vascularised by the formation of new blood vessels; when micro-organisms in the blood stream reach such a devitalised area they multiply in it and give rise to repeated attacks of local inflammation—such attacks being far more often due to concomitant bacterial infection than to purely filarial irritation alone; periadenitis follows, and the gland finally becomes hard and fibrotic (Plate III, fig. 1).

(ii) In Plate IV, fig. 2 the section shows dilated lymphatics in the hilum of a gland containing adult female filariae. Around these lymphatic vessels oedema of the tissues with leucocyte immigration of polymorphonuclear cells is seen. The endothelial lining of the vessels cannot be made out in the section, owing to its desquamation. This inflammation is most probably due to a secondary streptococcal infection. The filarial toxin has caused desquamation of the walls of the lymphatic channels and dilatation of the vessels in the neighbourhood. The increased vascularity in this devitalised tissue has allowed the secondary streptococci to produce their characteristic inflammatory reaction. Such secondary bacterial inflammatory attacks inside

the gland may give rise to fibrosis, fibrosis tissue gradually replacing the lymphoid tissue (*vide* Plate II, fig. 6).

(iii) When oedema occurs in the limbs, scrotum, etc. (as shown in Plate III, figs. 3, 4, and 5), not only does the stagnant lymph form a suitable nidus for the growth of pyogenic cocci, but its presence causes devitalisation of the cellular resistance, and makes the tissues more vulnerable to attack by these bacteria.

Finally, the defence mechanism of the surface layer or epidermis is gradually being impaired as the elephantiasis of the part is increasing in size. As the lymph cannot be properly drained away from the surface areas owing to the blockage of the terminal villous lymphatics in the papillae, and owing to inflammatory changes in the junctional vessels in the region of the sub-papillary plexus, it accumulates and percolates upwards to the prickle cell layer, producing hypertrophy of the papillae (*vide* Plate III, figs. 4 and 5). At the same time the keratinisation of the horny layer is interfered with, so that the mechanical protection afforded by this layer is partially or completely lost. On the upper aspect of the foot and instep, and in the scrotal skin, groups of these terminal lymphatics may be involved in this obstructive inflammatory lymphangitis, so that the epidermis is thrown into large papillomatous growths (*vide* Plate III, figs. 2 and 4), and dilated terminal lymphatics are seen giving rise to the so-called lymphatic cysts of the skin. Deep fissures form in the papillomatous area, owing to movements of the limb and the rigidity of the tissues of the corium, and the tissues are very prone to attack by secondary septic infections from the surface. Secondary streptococcal infections under such conditions more usually come from foci situated on the skin, whereas staphylococcal infections are more commonly derived from internal septic foci.

SUMMARY AND CONCLUSIONS.

1. The distinction between anaphylaxia or allergy, where there is a generalised hypersensitiveness of certain mesoblastic cells due to leakage of certain protein poisons into the circulation, and kataphylaxia—the localised break-down of cell defence-mechanism—is clearly brought out.

2. Earlier researches on the correlation of these manifestations with certain diseases are briefly reviewed.

3. It is shown that in kataphylaxia (which is the more important of the two conditions mentioned) tissues derived from the epiblast, hypoblast and mesoblast respectively may be involved; and are discussed in this paper.

4. In filariasis two types of kataphylaxia occur; i.e., a lowering of the mesoblastic tissue-defence owing to irritation by the filaria, or oedema and an epiblastic type seen in elephantiasis, when the surface protection of the epidermis is impaired by hypertrophy.

5. A large number of filarial cases have been studied with special reference to the presence of a toxin in this nematode, and the evidence for kataphylaxia. Though the presence of a toxin cannot be proved experimentally in the case of *Filaria bancrofti*, as has been done in the case of *Filaria medinensis*, circumstantial evidence, such as the onset of an eosinophile reaction, suggests the presence of a toxin. In persons with microfilariæ in their blood there is a higher percentage of eosinophile count than in those without them.

6. Additional proof of the existence of a toxin is obtained from the irritation and subsequent changes in the tissues brought about by the worm, similar to the effects produced by the guinea-worm.

7. It is suggested that these toxins produce allergic symptoms such as urticaria, periodic headaches, migraine, slight rises of temperature, etc.

8. The nature of the lesions caused by the filarial infection is discussed and it is shown that they are of two kinds—helminthic and bacterial. In the case of the former, the lesions are of a chronic type with a distinct eosinophile reaction, and in the latter an acute inflammatory type with a polymorphonuclear leucocyte exudate.

9. The action of the toxin on the lymphatics, leading to the formation of the different types of filarial diseases, is discussed in detail. Greater reaction of the lymphatic wall near the head (vulval) end of the worm points to a localisation of the toxin at this end. From a detailed study of a large number of glands and lymphatics from cases of filarial infection, it is concluded that this toxin sets up partial or complete obstruction by gradually bringing about desquamation and hypertrophy of the endothelial cells of the lining of the lymphatics, and thickening of the vessel walls. The progressive changes in the structure of the gland by the passage of the immature worms through it, or through the death of the immature worm during its passage, are reviewed.

10. The reason for the absence of microfilariæ in advanced cases of filarial disease, and aberrant migration of the adult worm leading to the aggravation of the pathological condition, are briefly indicated.

11. The changes taking place in the skin in cases of elephantiasis as a result of pathological changes in the tissue due to causes acting both from within and from without—in the latter case as a result of secondary infection—are described in detail.

12. The evidence of kataphylactic state is obtained from (i) a localised irritation of the reticulo-endothelial tissue of the lymphatic glands which lowers their defence and renders them more vulnerable to attack by the various pyogenic cocci: (ii) the production of œdema of the tissues with leucocytic migration of the polymorphonuclear cells and desquamation of the endothelial lining of the vessels: (iii) lymph stasis in the extremities and scrotum, lowering the cellular resistance and favouring the growth of pyogenic

cocci: (iv) the gradual changes in the epidermis with the production of hypertrophy of the papillæ, papillomatous growths and lymphatic cysts of the skin, with secondary bacterial infection from external foci.

A CASE OF HUMAN INFECTION WITH A GNATHOSTOME IN INDIA.

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.M.
(From the Hookworm Research Laboratory, Financed by the Indian Jute Mills Association.)
Calcutta School of Tropical Medicine and Hygiene.

SINCE "creeping eruption" was first described by Lée (1874) in England, it has been recorded from almost every country in the world, but although its manifestations in different countries are similar, it is now known to be caused by a variety of parasites.

Broadly speaking, creeping eruption of temperate climates is due to invasion of the subcutaneous tissue by larvæ of various species of the family *Cestridæ*, and creeping eruption of the tropics and sub-tropics is caused by immature nematodes.

The frequency of creeping eruption was first noted in Florida and the Southern United States

by Kirby-Smith (1925), and subsequently Kirby-Smith, Dove and White (1926), White and Dove (1927 and 1928), Shelmire (1928), and Kirby-Smith (1929) have clearly proved that in this locality the disease is due to larvæ of *Ancylostoma brasiliense*. In Australia, Heydon (1929) found that the same species of larvæ is the causal factor, and he is also inclined to incriminate the larvæ of *A. caninum*. Cawston (1928) is of the opinion, on clinical and epidemiological grounds, that creeping eruption or "sandworm disease" as it is known in Natal, is due to the same cause. Thus in the course of about four years, since its first recognition, this form of creeping eruption has been identified in three widely separated countries, so it is probable that it will soon be found in other places as well. At the same time, frequency of infection of dogs and cats with *A. caninum*, and *A. brasiliense* does not necessarily mean that creeping eruption will be common among human beings, for although practically all the dogs and cats of Calcutta harbour one or both of these parasites, the writer has been informed by Lieut.-Col. Acton, I.M.S., that no case of this condition has been seen at the skin clinic of the Calcutta School of Tropical Medicine, where many thousands of cases have been treated annually for the past seven years.

The third type of creeping eruption is caused by an immature Gnathostome, and is much less common, and as far as is yet known it is much more limited in distribution. The first case of human Gnathostome infection was reported by Levinson (1889) who identified a worm removed from an abscess of the breast of a Siamese woman by a Dr. Deutzer. This observer said he had seen two similar cases but he did not find the parasite. Levinson named the worm *Cheiracanthus siamense*.

The second case of this disease also came from Siam, the parasite being removed from the skin by a Dr. Kerr, who sent it to Prof. Leiper for identification. Leiper (1909) described this worm, and considered it to be identical with Levinson's specimen, the name of which he corrected to *Gnathostoma siamense* (Levinson, 1889). Following the examination of the type specimens of *Cheiracanthus robustus* Diesing, (1838) in Vienna, Leiper (1911) expressed the opinion that *C. robustus* Diesing, 1838, and *Gnathostoma spinigerum* Owen, 1836, were probably identical, and that *G. siamense* was also the same species. Therefore the correct name of the two Gnathostomes recovered from human beings was *Gnathostoma spinigerum* Owen, 1836.

The third case was reported from the Malay States by Samy (1918), who obtained his specimen from an abscess on the thenar eminence of a Chinaman, who had never been in Siam. This worm was identified as *G. spinigerum*.

The fourth case was that of a Japanese woman who had lived for a long time in China. She developed an abscess of the breast and the

parasite was found on opening it. Tamura (1921) gave a full account of this case and a careful description of the parasite, which leaves little doubt that it was an immature male of *G. spinigerum*.

Robert (1922) reported three cases in Siam. The first patient was seized suddenly with a spasmodic cough, which lasted for about a day, and which resulted in the expulsion of a Gnathostome. The second began with swelling of the right hand which subsided and was followed by swelling of the right arm; a similar condition occurred later in the right foot, to be followed by patches of oedema on the abdomen, from the last of which the parasite was expressed. From the first onset to the expulsion of the parasite a period of eight months elapsed. The third case exhibited hæmaturia and hæmatemesis, which was succeeded by a localised oedema on the abdominal wall from which a worm was obtained. Robert does not say that the hæmorrhages were due to the parasite, they may have been merely coincident.

The eighth case, reported by Morishita (1923, 1924), was from the thenar eminence of an adult male Japanese who had lived for a long time in Tokyo. This case is consequently regarded as indigenous to Japan. Although it was somewhat damaged, Morishita was able to identify the worm with certainty as a specimen of *G. hispidum* Fedtschenko, 1872.

Two other cases, which have been reported, are those of Morishita and Faust (1924). Both of these worms were obtained from male Japanese who were resident in China; one specimen was from a serpiginous eruption on the left shoulder, the site of the other is not stated. Both worms were very immature and one of them had no body spines nor transverse striations, but in other respects it was so much like the second example, that they consider it justifiable to identify both specimens as specimens of *Gnathostoma* species, and possibly *G. spinigerum*.

The present case, which came to the writer's notice, is the first record of the condition in India. The patient was a Mahomedan male *act.* twenty-six years, and a clerk by occupation. He has been resident in Jalpaiguri for many years, and he has never been out of Bengal. He first noticed a swelling between the thumb and first finger of the right hand, which gradually extended, involving first the dorsum and then the palm of the hand, in the course of three or four days. There was no pain nor tenderness, but the epitrochlear gland was enlarged. The swelling then spread to the right middle finger, which was somewhat red and painful, and in about two days time the patient noticed a small whitish point near the tip of the finger. He opened this with a needle, and the worm escaped from the puncture, accompanied by a serious discharge. All signs of inflammation rapidly subsided after the worm was removed. Previous to the present attack the patient had a

similar swelling of the right hand, which first appeared about seven years ago, and which lasted for about ten days. Ever since that time he has had attacks of the same nature at intervals of a year or more, this has been diagnosed as of filarial origin, but microfilariae have never been found in the blood in spite of repeated examinations.

The Parasite.

The worm is only slightly shrunken and is about 3.56 mm. in length, by 0.42 mm. in greatest diameter. The head bulb is 0.34 mm. in breadth and 0.20 mm. in length. There are two lateral crescentic lips each bearing two papillae. The

Fig. 1.
A. Whole worm.
B. Body spines.
C. Head bulb spines.

external surface of the lips is smooth, but internally three lobes are visible, indicating that when the worm is more fully developed the lips would probably be three-lobed structures, typical of the genus *Gnathostoma*. The head bulb is

Fig. 2.—Photomicrograph of anterior portion of worm showing broad roots of spines on head bulb, and raised transverse striations.

armed with four rows of spines numbering about forty in each row. These spines have only a short sharp point projecting backwards through the cuticle, but beneath the cuticle they are seen to have broad roots of slightly varying shape. Usually there are two rounded or occasionally pointed processes running backwards beneath the skin, one on each side of the projecting spine; in some cases these lateral processes almost pierce the cuticle. The spines, including the roots, measure 12 to 16 μ in length, and 9 to 14 μ in breadth. The cuticle of the body is furnished with raised transverse ridges about 12 μ apart, and rows of spines project posteriorly from these ridges. They have simple sharp points, and beneath the skin the roots appear as simple oval structures. The length of these spines from root to tip is about 7 to 8 μ , and near the anterior end of the worm they are about 6 μ apart; they extend to the extreme posterior end of the worm, but they gradually become more widely separated in successive rows from before backwards, so that near the posterior end of the worm they are 15 to 20 μ apart in each row. Very little internal structure could be made out, probably on account of imperfect fixation, but towards the anterior end there is a suggestion of ballonets, and behind these there is a broad clear oesophagus, which is followed by a dark intestine. The intestine follows a slightly wavy course to terminate in an anus near the tip of the tail. No genitalia are present, probably because the worm is too young.

Discussion.

Most of the worms described by other workers have been much more fully developed than is the writer's specimen, and consequently they have been specifically identified, but the two specimens from Morishita and Faust's cases are of approximately the same size as the writer's, and it is interesting to note that all three of these specimens have only four rows of spines on the head bulb. But the similarity ends here, for in Morishita and Faust's specimens the spines are only 10 μ in length by 5 μ in breadth, and they are described as simple structures, whereas the writer's specimen bears head spines which are much larger and which have broad complex roots. It is conceivable, that on fuller development these head spines might have three points projecting from the cuticle, as there is already an indication of these extra points beneath the skin. Another interesting fact is the presence of rows of simple spines throughout the length of the worm; these of course might give place to multi-pointed spines on fuller development, but it is not likely that the spines on the posterior part of the body would disappear completely. Therefore it seems unlikely that the writer's specimen is an immature example of *G. spinigerum* because the spines do not extend to the posterior extremity in this species; nor is it likely to be an immature

example of *G. hispidum*, because, although the body spines of this species extend throughout the length of the worm, the head spines of *G. hispidum* are simple structures. It therefore seems possible that this specimen may be a young worm of a species not yet recognised.

The finding of this immature worm with a suggestion of three-pointed spines on the head bulb raises the question whether *G. spinigerum* Owen, 1836, and *G. robustum* (Diesing, 1838) are really identical, for Owen (1836) in his original description stated that the spines on the head bulb had three points, similar to those on the body of the worm. As far as can be ascertained, Owen's original material has not been re-examined, but Leiper (1909) says that *G. robustum* of Diesing is most probably a synonym of *G. spinigerum* Owen. Leiper (1911) examined Diesing's original material of *G. robustum* in Vienna and he says it "..... is acceptedly the same as *Gnathostoma spinigerum* Owen, of the tiger." This view is now generally accepted, for Baylis and Lane (1920) in their exhaustive revision of the family *Gnathostomidae* go even further and define the genus *Gnathostoma* as having simple spines on the head bulb. The fact that Owen described triple-pointed spines on the head bulb seems to have been ignored without comment, and his species has been made to include specimens which have single spines on the head bulb. Under the circumstances it would seem preferable to leave Owen's species intact until it is definitely known whether *Gnathostome* species do or do not exist with complex head spines, and at the same time to re-erect *G. robustum* (Diesing, 1838), as a distinct species, and to place in it all those specimens which Leiper's researches have shown to be identical with Diesing's type material.

Although a search of the literature has only produced ten cases of human infection with a *Gnathostome*, in which the parasite has been recovered, it is obvious, from the excellent paper of Robert (1922), that this condition is a common and definitely recognised clinical entity in Siam, which is the most important endemic centre of the disease. Robert says the disease is always characterised by transient and migrating oedema, and apparently the serpiginous raised line regarded as characteristic is only exceptionally present, when the worm is burrowing just beneath the skin. More often the parasite is situated deeper in the tissues, when all that is manifest on the skin is an oedema which moves from place to place as the parasite proceeds through the tissues. Many cases in Siam undergo spontaneous cure without the parasite being found; Robert considers this may occur in one of two ways. Either the worm dies *in situ*, or else it may be spontaneously evacuated through an internal mucous surface. In support of the latter method of cure being common there is Robert's first case in which the worm was coughed up, and the same author quotes the case of an intelligent and reliable Siamese lady, who described to him

the escape of a worm from the side of her tongue.

Nothing is yet known of the etiology of the disease, for the life history of the causative parasite is only most imperfectly understood. Robert says that after most careful inquiries lasting over a period of twenty-five years he has only been able to hear of one case in a male; he is therefore inclined to consider that infection is probably acquired during some typically female domestic work such as the preparation of food. Against this observation of Robert, that it is essentially a disease of females, is the fact that out of the six cases reported in this paper, which have come from outside Siam, only one was in a female. It has been suggested that infection may occur by the accidental ingestion of an insect intermediate host of the worm, or that the young worms have a free-living stage during which they have the power of penetrating the skin. In support of the latter view is the fact that of the eleven cases reported above at least four have occurred in the hand.

The behaviour of the worm in the human being probably represents the wanderings of a parasite in an unsuitable host, in which it is not able to reach full development, but it should be borne in mind that although the larvæ of *A. braziliense* behave in a similar manner in certain individuals, in others they are able to reach the small intestine and to undergo full development. It is therefore possible that in the course of time, exceptional cases of *Gnathostome* infection in human beings will be encountered in which the worm has reached the stomach and undergone full development, as it does in its normal hosts. Fulleborn (1927) has produced a similar condition to the eruption caused by *A. braziliense*, by the application of the larvæ of *Uncinaria stenocephala* to his own skin, so it seems probable that many other larval nematodes eventually will be found to produce allied skin lesions when they gain entrance to man, he not being the suitable host.

The discovery of the worm described above, in a man who has never been out of Bengal extends the distribution of human *Gnathostomiasis* to the Westward of its hitherto known distribution, because, since its first recognition in Siam the only other countries in which it has been found are once in the Malay States, once in Japan, twice in China, and once in a Japanese recently returned from China.

The writer is indebted to Captain K. M. Basu, I.M.S., of Jalpaiguri, first for sending the specimen, and later for supplying notes of the case.

(Note.—It would probably add greatly to our knowledge of the rarer parasitic worms if readers of the *Indian Medical Gazette* were to forward parasites, either from men or animals, which they do not recognise. The writer of the above article would always be pleased to receive and identify such material and to render due acknowledgment for it. If parasites are first washed by shaking in normal saline and then dropped into hot 70 per cent. alcohol, and forwarded in the latter fluid, they would almost certainly arrive in a state fit for identification.—EDITOR, I. M. G.)

NOTES ON THE DETECTION IN THE URINE OF SOME DRUGS USED FOR THE TREATMENT OF MALARIA.

By RICHARD GREEN, M.B., B.S.

(From the Institute for Medical Research, Kuala Lumpur, F. M. S.).

A. THE DETECTION OF SOME OF THE ALKALOIDS OF CINCHONA IN THE URINE.

SOME little time ago an enquiry was received by this Institute concerning the absorption from the bowel and the excretion in the urine of

quinine-ethyl-carbonate (euquinine). On this occasion a child had been given treatment for malaria; "tasteless" euquinine had been employed and in view of its comparative insolubility the medical adviser wished to know whether the drug was being absorbed. In reply it was suggested that the child's urine be tested with Mayer's reagent, but it was not known how soon after administration the euquinine could be demonstrated in the urine by the reagent, the period of maximum excretion, or when the drug would cease to be demonstrable; nor was it possible to indicate the degree of variation to be expected among individuals in absorbing and excreting euquinine or any of the other derivatives of cinchona used for the treatment of malaria.

An endeavour was made, therefore, to gain some information on the points mentioned above, the conditions of the enquiry being briefly as follows:—

(i) The drugs chosen for investigation were quinine alkaloid, quinine sulphate, quinine hydrochloride, quinine-ethyl-carbonate (euquinine) and cinchonine; all of which have been shown by Fletcher (1923) to be effective against malarial plasmodia. These various cinchona derivatives were obtained from the British Drug Houses, London.

(ii) Where possible the drugs were given on each occasion to the same three cases; healthy persons of different nationalities. Case 1 was a European weighing 150 lbs., Case 2 a Chinese (128 lbs.), and Case 3 a Tamil (105 lbs.). On one occasion when quinine sulphate was investigated, Case 1-A, a Malay weighing 113 lbs., was substituted for Case 1.

(iii) The drugs on each occasion were given in powder form to the cases already mentioned and their administration was followed by drinking about half a pint of water. The drugs were swallowed between 8.30 and 9 a.m.; from one hour to one-and-a-half after the morning meal.

(iv) Following the administration of the drugs, urine was passed at intervals of twenty minutes during the first hour and subsequently every hour until retirement to sleep. The urine passed the following morning was also obtained for testing.

(v) It is well known that when Mayer's reagent* is added to urine containing alkaloids, a whitish opalescent cloud forms (which if due to alkaloids, disappears on heating and reappears on cooling) the density of which is generally in proportion to the amount of alkaloid present in solution. Accordingly, each specimen of urine obtained was filtered, 10 c.c. was reserved as a control and to another 10 c.c. was added fifteen drops of Mayer's reagent. If a precipitate was observed this was tabulated in accordance with its quality as dense, medium or faint, the standard of this tabulation remaining the same throughout the experiments.

* Mayer's reagent = Mercuric Chloride 6.8 gm.
Potassium Iodide 24.9 gm.
Water 500 c.c.

(vi) This method of testing for the presence of cinchona alkaloids was adopted, as although the employment of finer methods of detection, such as those used by Ramsden, Lipkin and Whitley (1918), were considered, it was thought that simpler tests, convenient to the clinician, would be more desirable and would satisfy more closely the terms of the original enquiry concerning the use of Mayer's reagent.

Results.

The results observed by using Mayer's reagent are shown in the following chart:—

Comments on Results Observed.

(a) The time when the alkaloids first became detectable.

With reference to quinine, euquinine and cinchonine, no reaction with Mayer's reagent was obtained until two hours after the drugs had been given. After quinine sulphate had been swallowed, it was demonstrable in the urine forty minutes, one hour, and two hours later. Quinine hydrochloride appeared to be absorbed and excreted more quickly, and in one case it was detected in the urine twenty minutes after the

CHART.

usual five-grain dose has been given, while in the other two cases it appeared forty minutes afterwards.

(b) *The period of maximum excretion as estimated from the density of the precipitate.*

As with the results observed under (a) there was considerable variation not only as regards the drugs given, but also among cases given the same drug. With quinine alkaloid, the maximum excretion appeared to take place between the third and eight hours—with quinine sulphate, between the third and the ninth hour—quinine hydrochloride, between the second and fifth hour—euquinine, between the second and fifth hour—and with cinchonine, between the second and seventh hour.

(c) *The time when detection of the alkaloids was no longer possible.*

The drugs ceased to be demonstrable in the urine between nine and thirteen hours after administration. The excretion of quinine hydrochloride seemed to be completed more rapidly than that of the other drugs, while traces of quinine and cinchonine were still found between eleven and thirteen hours after administration of the doses specified.

(d) *General.*

Ramsden, Lipkin and Whitley (1918) have pointed out that, of quinine given by mouth or by intravenous or intramuscular injection, only a fraction, varying with different patients from 23 to 66 per cent., reappears in the urine; also that the healthy human kidney excretes quinine at much higher concentration than that at which it is present in the contemporaneous blood.

The observations of Nierenstein (1920) were that about half the quinine administered to the human subject is excreted as such in the urine. The remainder is metabolized and two disintegration products, quinidine and hæmoquinic acid, appear in the urine.

Among the cases referred to in the present investigation, certain variations in excretion occurred with each drug used. It is thought probable, however, that greater variations may occur among healthy individuals than those already shown on the chart; further, that even greater modifications in the absorption and excretion of cinchona alkaloids may take place in diseased conditions, particularly of the alimentary canal and of the kidney.

In Malayan hospitals, other diseases frequently accompany malaria, and treatment of the malaria with quinine is given along with treatment for the accompanying disease. Whether the therapeutic action of the quinine is affected to any great extent in these cases by alterations in absorption and metabolism caused by the accompanying disease is a difficult matter to determine, but it appears to be of sufficient importance to warrant further investigation.

Finally, where it is desired that the administration of cinchona derivatives used for the treatment of malaria be checked by the use of Mayer's

reagent, it is hoped that the details in the chart above may afford some indication of the results to be expected and of the variations occurring among healthy individuals.

B. THE DETECTION OF PLASMOQUINE IN THE URINE.

The detection of plasmoquine in urine by the use of chloranil (tetrachloroquinone, $C_6Cl_4O_2$) has been described by Schulemann, Schönhöfer and Wiegler (1927). The test depends on the formation of a blue dye when plasmoquine reacts with chloranil; and is carried out as follows:—

(i) Two or three hundred c.c. of urine are mixed with 20 c.c. of 50 per cent. caustic potash solution. This sets free plasmoquine base, if present.

(ii) The plasmoquine base is then extracted from the treated urine by agitation with ether three times, using 30 c.c. on each occasion.

(iii) The total ethereal extract (90 c.c.) is filtered rapidly and washed twice with 10 c.c. of water containing two drops of normal soda solution.

(iv) The plasmoquine is then extracted from the ether by thorough agitation with 6 c.c. of two per cent. acetic acid solution.

(v) The acetic acid solution is next separated from the ether, warmed on a water bath to remove dissolved ether and is ready for the colour reaction to be performed.

(vi) Three c.c. of acetic acid is added and about 0.05 gm. of chloranil. The mixture contained in a test tube of 1.6 cm. diameter is then heated for about ninety seconds in a free flame. If more than one part of plasmoquine in 50,000 is present a blue or blue-green coloration develops.

(vii) The solution is then cooled, left for some minutes to allow excess of chloranil to crystallize out, filtered, and to the filtrate 1 to 1.5 c.c. of ether is added.

(viii) The ether remains in solution until the acetic acid is partly neutralized by the addition of a few drops of 50 per cent. caustic potash solution, when, if plasmoquine is present, it separates as a deep blue upper layer.

It is said that, applied in this fashion, 100 c.c. of urine containing 1 in 2,000,000 of plasmoquine, gives an ethereal layer of bluish green colour and that the presence of quinine in the urine does not interfere with the test.

Results Observed in using the Chloranil Test.

At first it was thought that, if applied to the cases used for the previous experiments, this test for plasmoquine might be used to indicate the period of absorption, maximum excretion, etc., of plasmoquine; also that it might afford some information concerning those cases which do not tolerate plasmoquine. Accordingly 0.03 gm. of plasmoquine was given to Case No. 1 and the test for plasmoquine was made with each specimen of urine passed, as previously, at frequent intervals. The quantity of plasmoquine, however, in these small samples of urine was not sufficient to yield positive tests and the experiments were repeated, giving 0.03 grms. plasmoquine to Cases 1, 2 and 3, but on these occasions the total amount of urine subsequently passed during eight-hour periods was tested.

The following table shows the results observed :—

Case No.	Details.	PERIODS DURING WHICH URINE WAS COLLECTED AND TESTED.		
		1st 8 hours	2nd 8 hours.	3rd 8 hours.
1	Quantity of urine passed Result of Chloranil Test	410 c.c. Positive	215 c.c. Negative	285 c.c. Negative
2	Quantity of urine passed Result of Chloranil Test	360 c.c. Positive	260 c.c. Negative	160 c.c. Negative
3	Quantity of urine passed Result of Chloranil Test	430 c.c. Positive	200 c.c. Negative	315 c.c. Negative

Comments.

(a) Difficulties in carrying out the chloranil test.

During the application of the test, the separation of the ether layer formed after the urine had been shaken up with the caustic potash and then with ether, was found to be incomplete and delayed. The first extraction seemed to be the most difficult, as an intermediate layer of emulsion was formed between the urine and the ether, this emulsion containing a fair proportion of the ether which was to be recovered for the next stage of the test. On the suggestion of a colleague, however, four or five drops of alcohol were added and this hastened considerably and rendered more complete the separation of the ether from the intermediate layer. More complete separation was also effected by carrying out the extracting and separating processes at a low temperature, accordingly each specimen of urine to be tested was given a preliminary chilling in an ice-chest.

At the final stage of the test (*viii*), the heat resulting when the acetic acid was partly neutralized with caustic soda, tended to drive off the ether layer which separated during the neutralizing process. It was found convenient to carry out this stage by surrounding the test tube with ice. There were no reasons to regard these slight modifications as interfering with the delicacy of the test.

(b) Interpretation of Results.

The dose of plasmoquine given to each of the three cases was 0.03 grm. and the average quantity of urine passed was 875 c.c. during the 24 hours following administration. If none of the plasmoquine given had been metabolized and all of it excreted evenly over a period of 24 hours, the highest concentration of the plasmoquine in the urine would have been about one in 29,000. Again if, in common with quinine, about half the plasmoquine had been excreted as such in the urine, the dilution of plasmoquine would have been about one in 58,000.

The test is said to be effective when the amount of urine used is 100 c.c. and the dilution is as high as 1 : 2,000,000, so that, in connection

contained plasmoquine in quantities of more than 1 : 2,000,000; but that subsequently the urine contained less than that amount or none at all. It did not seem likely, however, that all the plasmoquine given was excreted during the first eight-hour period.

On the other hand, of stated quantities of plasmoquine given by mouth to the human subject, it does not appear to be known how much is excreted and how much is metabolized. In this connection Achundow (1928), whose results have become available since the above tests were performed, found that, in a few of his cases, absorption and excretion of plasmoquine (as estimated by the chloranil test applied to the urine) did not appear to take place; and with regard to these cases, it has been suggested that the drug had undergone some change in the body which prevented the usual reaction to the chloranil test.

At the present moment it may thus be said that our knowledge of what happens to plasmoquine when ingested by the human subject is in an unsatisfactory state. The symptoms of intolerance or idiosyncrasy that have been noted in patients treated with plasmoquine may well depend on abnormalities in metabolizing and excreting the drug.

The effective dosage of plasmoquine is small and its detection in the urine is, as yet, a difficult matter, while Henry (1929) considers that possibly an even more delicate test than that of Schulemann and his colleagues is required to ensure detection of plasmoquine in urine. This test, however, as it stands, demonstrates the presence of plasmoquine in high dilution and seems to offer some prospect of advancement in ascertaining the fate of plasmoquine in the human body.

Acknowledgments.

I am indebted to Dr. A. Neave Kingsbury, Director, Institute for Medical Research, Federated Malay States, for permission to publish this paper and to Mr. J. Shelton, F.R.C., for his suggestions in connection with the performance of the chloranil test.

THE VALUE OF PREVENTIVE INOCULATION AGAINST CHOLERA.

SOME FIGURES FROM BURMA.

By G. JOLLY, C.I.E.,

LIEUTENANT-COLONEL, I.M.S.,

Officiating Director of Public Health, Burma,

J. J. G. DA COSTA, L.M.S.,

District Health Officer, Meiktila,

and

AH. SHOUNG, M.M.F.,

Assistant District Health Officer, Meiktila.

A SEVERE epidemic of cholera broke out in the Meiktila district of Burma during the year 1928. Its special interest lies in the fact that a very large proportion of the inhabitants of the infected villages were inoculated, and secondly in the fact that careful records were kept.

The epidemic began in the latter half of May and was over by about the middle of November.

The disease originated in the Mahlaing Township of the district and spread thence to all the other townships and to the municipal town of Meiktila. In the district there occurred 992 attacks and 30 in the town. The rural figures are the more interesting of the two and are of much greater importance statistically than the town figures.

The total population of Meiktila district at the last census was 281,029. In this population there were 992 attacks, giving an attack rate of 3.53, and 744 deaths, giving a death rate of 2.65.

Out of this total population, 50,096 persons were inoculated against cholera during the course of the epidemic, by single doses of one c.c. of cholera vaccine obtained from Kasauli. The 230,933 remaining persons in the district were not inoculated. The comparative figures of attacks and deaths among the non-inoculated and the inoculated persons are shown in Tables 1 and 2 below:—

TABLE I.

Non-inoculated population in the district, 230,933
Cholera attacks in above, 954. Attack rate, 4.13
Cholera deaths in above, 706. Death rate, 3.06

TABLE II.

Inoculated population in the district .. 50,096
Cholera attacks in above, 38. Attack rate, 0.76
Cholera deaths in above, 38. Death rate, 0.76

It will be observed that the attack rate among the non-inoculated population in the district is 5.43 times greater than the attack rate among the inoculated population, while the death rate among the non-inoculated is 4.03 times that among the inoculated.

Out of a total of 1,030 villages in the district of Meiktila, 152 were infected during the epidemic, containing a population of 55,011 persons out of a total population of 281,029 contained in the district. This therefore was the population exposed to infection and among whom infection did actually occur, and it is interesting therefore to note in detail the statistics of the attacks and deaths among this population, comparing the figures for the non-inoculated with those for the inoculated.

Among this population of 55,011, there were 992 attacks of cholera, giving an attack rate of 18.03 and 744 deaths, giving a death rate of 13.52.

Of the 55,011 persons living in the infected villages, considerably more than half, namely 32,450, were inoculated, being a percentage of 58.99. Tables 3 and 4 below give the attacks and deaths with their rates among the non-inoculated population and among the inoculated:—

TABLE III.

Infected villages.

Non-inoculated population ..	22,561
Cholera attacks in above 954. Attack rate,	42.29
Cholera deaths in above, 706. Death rate,	31.29

TABLE IV.

Infected villages.

Inoculated population ..	32,450
Cholera attacks in above 38. Attack rate,	1.17
Cholera deaths in above 38. Death rate,	1.17

It will be observed that the attack rate in the non-inoculated population of the infected villages is 36.15 times greater than the attack rate in the inoculated population of these villages. It will also be noted that the death rate among the non-inoculated population is 26.74 greater than that among the inoculated.

The fact that the ratio of the attack rate among the non-inoculated to that among the inoculated is greater than the corresponding ratio of deaths is due to the circumstance that out of 38 attacks which occurred among the inoculated population of the infected villages all proved fatal. This point is illustrated in Tables V and VI which show the percentage of deaths to attacks of 74 among the non-inoculated compared with 100 per cent. among the inoculated.

TABLE V.

Infected villages.

Non-inoculated population ..	22,561
Cholera attacks in above ..	954
Cholera deaths in above ..	706
Percentage of deaths to attacks ..	74.00

TABLE VI.

Infected villages.

Inoculated population	32,450
Cholera attacks in above	38
Cholera deaths in above	38
Percentage of deaths to attacks	100.00

Both in the case of the non-inoculated and in that of the inoculated, the percentage of deaths to attacks is very high, and, as will be shown later, is much higher than the similar figures in the town of Meiktila. This high percentage of deaths to attacks may be due to the fact that the great majority of these cases occurred in remote villages, and that in few instances were the services of a trained medical man available for treatment during the attack.

The 100 per cent. mortality among the 38 cases occurring in the inoculated population of the infected villages would, however, appear to indicate something more than mere lack of skilled medical aid, because, although the figures are small and therefore relatively insignificant statistically, it is nevertheless unusual to find even among so small a group of cases of cholera a cent. per cent. mortality. There is, however, another possible explanation. When we analyse these 38 deaths among the inoculated population, we find that in each case the attack of cholera began before the end of the fifth day following preventive inoculation. In no instance during the whole epidemic was any person who had been inoculated attacked by cholera later than the fifth day following inoculation. The actual figures are given in Table VII below:—

TABLE VII.

Inoculated population in infected villages	..	32,450
Cholera attacks on 1st day of inoculation	..	10
" " " 2nd " "	..	7
" " " 3rd " "	..	5
" " " 4th " "	..	4
" " " 5th " "	..	12
" " after 5th " "	..	nil
Total cholera attacks in above population	..	38

A possible explanation for the 100 per cent. mortality among these 38 cases is the negative phase which follows upon an injection of vaccine. The figures suggest that the positive phase does not become established until after the 5th day following inoculation. On the other hand, some mild cases following inoculation may have been missed.

In Meiktila town, with a population of 7,231 (excluding the Cantonment) there were during the epidemic period 30 attacks of cholera giving an attack rate of 4.15, and 12 deaths giving a death rate of 1.66. Tables VIII and IX show the attacks and deaths with their rates among the non-inoculated population and the inoculated population respectively:—

TABLE VIII.

Non-inoculated population	..	2,369
Cholera attacks in above, 30.	Attack rate,	12.71
Cholera deaths in above, 12.	Death rate,	5.08

TABLE IX.

Inoculated population	4,871
Cholera attacks in above	nil
Cholera deaths in above	nil

In comparison with the rural figure (Table V) in Meiktila town the percentage of deaths to attacks among non-inoculated was 40. The relatively lower death rate in the town was unquestionably due to the existence of a district hospital and the presence of skilled medical attendance.

EPIDEMIC JAUNDICE (WEIL'S DISEASE) OR MALARIA IN KANDI SUBDIVISION OF MURSHIDABAD DISTRICT IN 1928.

By S. N. SUR, M.B., D.P.H., D.T.M.,
Assistant Director of Public Health, Malaria Research,
Bengal,

and
HARIPADA SARKAR, L.M.S., D.P.H.,
Assistant to the Assistant Director of Public Health,
Malaria Research, Bengal.

IN October 1928, Mr. S. C. Singha of Panchthupi village of Kandi Subdivision stated in a letter addressed to the senior writer that "in the subdivision of Kandi a new malady has been in evidence; it is like epidemic jaundice." On asking particulars from him as to the place of occurrence of such cases he informed me that the medical officer of the local S. S. Charitable Dispensary cured all the three cases which had come under his treatment. "Several other cases were treated by various other medical practitioners of the locality. The largest number of cases, some of which proved fatal, occurred at and about Kandi. Malaria is less in evidence this year owing, I think, to the excess in rainfall. The cases of jaundice have cropped up during the break which has continued since the middle of August."

The junior author of this paper was deputed to investigate the matter in the same month. He called on the Assistant Surgeon-in-charge of the Kandi Charitable Dispensary and three other private medical practitioners of the town. No acute cases of jaundice were available at the time and most of the cases that had suffered from jaundice had got over the trouble, while only one old woman had died. The history of the attack was taken of the three cases who still showed signs of jaundice, e.g., slight yellow tinged conjunctivæ, etc. The attack started with slight fever and pain all over the body in general, about three weeks before the visit, and there was no history of epistaxis or hæmoptysis or purpura. One of the patients only had a tender and enlarged liver, while all of them had enlarged spleen and one only had slightly injected conjunctivæ. Both urine and blood films were examined in all the three cases.

Their condition at the time of investigation is shown below in the table:—

Malignant tertian parasites were found in 6, benign tertian parasites in 2, and quartan in 1.

Cases.	Caste.	Age.	Sex.	Conjunctivæ injected.	Hæmoptysis.	Epistaxis.	Limb pains.	Enlarged liver.	Enlarged spleen.	Jaundice.	Albumen.	Epithelial cells and casts.	Acetic Acid Test*.	Phosphates.	Blood for malarial parasite.	Type of malarial parasite.
1-K	Muhammadan	20	M	—	—	—	+	—	+	+	—	—	—	+	—	B. T. (all stages). Do.
2-0	Hindu	38	M	—	—	—	+	+	+	+	—	—	—	+	++	
3-8	Hindu	16	M	—	—	—	+	—	+	+	—	—	—	+	++	

* "Acetic Acid Test"—"The urine of a case of Weil's disease from the 5th to 8th day is said to give an intense green reaction when one or two drops of acetic acid are added to about one inch of the urine in a test tube."—(Manson-Bahr).

The "acetic acid test" as noted above in all the cases gave negative results. In addition to the ordinary chemical tests of the three samples of urine, bacteriological examination was also made in the following manner. They were centrifuged and the deposit injected intraperitoneally into three guinea-pigs. The guinea-pigs did not develop any symptoms and continued to be quite healthy for over one month, and their blood did not show any *Leptospira icterohæmorrhagica* (the causative organism of Weil's disease) under dark-ground illumination.

Blood films of all three cases that suffered from jaundice were examined. Two of them showed heavy infection with benign tertian malarial parasites, while one was negative (*vide* table above). The person whose blood was negative for malaria parasites had been taking quinine during the visit. From the above results it seems clear that all the cases of jaundice were possibly of malarial origin and not due to Weil's disease. Castellani and Chalmers mention a type of "a typical subtertian malaria" which simulates "yellow fever" and "Weil's disease" (*vide* Castellani and Chalmers, 3rd Edition, page 1172). These authors mention malarial jaundice being caused by malignant tertian infection. But at Kandi this type of jaundice was apparently excited by benign tertian infection also, as both the positive cases showed benign tertian parasites in all stages of development.

That this area is a hyperendemic area is shown by random sampling of blood films from the inhabitants of that village. Altogether 11 films were examined, of which 8 were positive for malaria parasites as shown in the table below:—

Malignant tertian was therefore the most prevalent species during the month of October at Kandi.

There is thus little doubt that the reported cases of jaundice were due to the heavy infection with malarial parasites. There was no evidence of spirochaetosis. The writers are therefore of opinion that the epidemic jaundice referred to by Mr. Singha was of malarial origin and not due to Weil's disease.

THE INFECTIOUSNESS OF LEPROSY.*

By E. MUIR, M.D., F.R.C.S. (Edin.),

School of Tropical Medicine and Hygiene, Calcutta.

FROM ancient times leprosy was held to be infectious. The best known proof of this is the stringent rules imposed in the Mosaic Law for the isolation of lepers. Yet the disease described in the Bible was probably not only leprosy as we know it to-day but also included a multiplicity of scaly skin diseases such as various forms of tinea and possibly syphilis and yaws.

The laws imposed in the middle ages in England and throughout Europe show the common belief that leprosy is spread from the infected to the healthy by contact, and it was largely due to this belief that the incidence of leprosy diminished and the disease had almost died out of England by the end of the 16th century.

In the 17th century unfamiliarity with leprosy and new teaching with regard to heredity swayed

* Being a paper read at the meeting of the Calcutta branch of the British Medical Association on Friday, 9th August, 1929.

public and medical opinion to the ideas that leprosy is hereditary, and this belief was largely held in Europe till near the end of the 19th century. In 1862 a report of the Royal College of Physicians of London, prepared by a special committee, supported this theory; and even in the beginning of the 20th century so great an authority as Jonathan Hutchinson opposed the teaching that leprosy is spread by contagion. But since the discovery of Hansen's bacillus in 1872 the belief has gradually grown stronger that the disease is caused by this organism and that *contact* is the chief factor controlling its spread. The discovery that malaria, yellow fever and filariasis are carried by mosquitoes, that plague is carried by fleas and that other diseases are spread by other insects, lead to the question whether leprosy was not also spread in this way. Lebouf by means of his own experiments and by summarizing the literature on the subject has shown that, though house-flies may carry lepra bacilli in their gut after feeding on infectious ulcers and deposit the same on the mucous surface of the nose or on the raw wounds of healthy persons, yet evidence is lacking that biting insects are at all an important factor in carrying the disease.

The return of the swing of the pendulum in favour of contagion led to renewed energy in the direction of isolating lepers in asylums and colonies, and large numbers of these institutions were founded in the end of the 19th and the beginning of the 20th centuries. The public subscribed to these and Government expended money on them, largely under the impression that by isolating lepers the spread of the infection would be limited. But little endeavour was made to ascertain whether the cases isolated were the most infectious and dangerous ones or not.

The questions now to be considered are:—

(1) Is leprosy infectious or contagious, and if so to what extent?

(2) In what stages, types and phases is it most infectious?

(3) What are the best means to be taken in a country like India to prevent the spread of infection?

(1) There is abundant evidence to show that leprosy is spread from the infected to the healthy by direct contagion and that children are more liable to infection than adults. While children removed from infectious parents at birth practically never develop the disease, those brought up by a highly infectious mother seldom escape infection, a whole family of 5 or 6 children acquiring the disease from a parent or elder brother or sister: 40 to 50 per cent. of children are said to acquire the disease if not removed from leprosy parents. If this is so probably 100 per cent. are infected in some instances, i.e., when parents are highly infectious; as a certain proportion of the parents are not infectious at all, and this number has to be deducted. On the other hand, conjugal infection (the husband infecting the wife and the wife the husband) is

comparatively uncommon, being given variously as 2 to 5 per cent.

The factors which determine the chance of infection are:—

(a) The closeness of contact. Progressively dangerous we have: village infection, house infection, room infection, bed infection. The closer the contact the more likely is the disease to be transmitted.

(b) The length of contact: the longer the contact the more likely is leprosy to be acquired.

(c) The infectiousness of the leper: in certain types, stages and phases of the disease leprosy is much more infectious than in others.

(d) The general resistance of the person in contact. This is a very important factor that has not been sufficiently realized in the past. Condemned criminals have been inoculated with suspensions of human tissues containing large numbers of Hansen's bacilli and some of these have failed to develop leprosy. It has been argued from this that leprosy is not spread by direct inoculation. The probable explanation is either that the particular bacilli inoculated were dead or, what is more likely, that the resistance of those inoculated was sufficient to prevent the development of the disease.

The resistance of the patient may be lowered by various factors:—

(a) Various diseases have this effect. The most common predisposing diseases in India are syphilis, malaria, helminthic infections, streptococcal infections, dysenteries and kala-azar; but in fact almost any disease may have this effect. There are various slight and exceedingly chronic infections of various kinds which cause little or no signs and would probably not be detected in the usual course, but which are detected when special examinations are made of leprosy patients. These inconspicuous infections are able to act as important predisposing causes and their removal often results in the rapid improvement of leprosy lesions. Thus serological examination shows the presence of syphilis in many cases where this disease was unsuspected. Chronic dysenteric infections and pyorrhoea are often brought to light only when examined for as possible causes of lowered resistance in leprosy.

(b) Besides these various diseases there are many other factors which lower the resistance of the body. These have been brought out clearly by the work of the leprosy survey party of the British Empire Leprosy Relief Association in several of the provinces and states of India. It has been found that generally speaking leprosy is most common among semi-aboriginal, low caste Hindus. The aboriginal such as the Sonthal, living a healthy life in the jungle, mixing only with members of his own or similar tribes and his life regulated by simple but wise tribal rules, escapes the disease. When he begins to leave his primitive life and mix with other castes he becomes subject to leprosy in proportion to the

degree of mixing that takes place and the consequent abandonment of his old tribal customs. Thus the survey party divide villages into three types: those where there is only one caste; those in which there is more than one caste but the castes live in separate quarters of the village; and those in which the various castes are mixed and not separated into quarters. In the first, leprosy is invariably most scarce, in the second more common, and in the third most common of all. The reason for this is that special tribal or caste rules are more lax where more mixing takes place; and promiscuity—sexual, sartorial and social—become common, resulting in venereal and other diseases; and as there is closer contact there is more chance of spreading the disease. Low caste servants are often employed in Brahmins' houses and convey leprosy to the high caste children that they tend.

Another important factor is the precariousness of food supplies in regions where famine is frequent, due to meteorological and geographical conditions; famine generally being the result of a failure of the monsoon. The Bankura district is a conspicuous instance of this and the famine also frequently drives the inhabitants to seek work and substance in more fertile regions; in this way they carry leprosy to non-endemic areas. Leprosy is being spread at the present time owing to such causes in the Maldah, Rajshahi and many other districts of Bengal.

(2) In what stages, types and phases is leprosy most infectious?

Another very important point to be considered is the relative infectiousness of the various types, stages and phases of leprosy. Without going into details of the pathology of leprosy it is sufficient to give a brief sketch of the course of the disease.

Leprosy can generally be diagnosed with certainty from clinical signs long before it is possible to find Hansen's bacilli in smears or sections. The lesions first noticed are chiefly skin patches which vary from a quarter inch to several inches in diameter when first noticed and may be depigmented and whitish or erythematous. They generally show keratosis, stunting or destruction of hair, and anhydrosis. They show various changes in sensation such as deep analgesia, loss of heat and cold sensation, paræsthesia and loss of epicritic sensation or superficial anæsthesia. The more marked the last symptom is, the greater is the thickening of the sensory nerve branches supplying the area and the less chance is there of finding Hansen's bacilli in the lesion.

Occasionally the first early sign of leprosy is thickening of nerve trunks without any apparent corresponding skin lesions.

In the second stage in a typical case of leprosy (B 2 or B 3) bacilli can be found in ever increasing numbers, until a smear taken from any skin lesion or from the mucous membrane of the nose

contains millions of acid-fast bacilli in every field of the slide.

In the third stage (A 2) the bacilli begin to diminish again, leaving deformities of the hands, feet and face.

In some types in which the resistance is fairly high, a small anæsthetic skin lesion (A 1) may persist for years without increasing in size. Sections of such an area fail to show Hansen's bacillus and yet, if that patient's resistance is lowered by any intercurrent disease or other cause, the edge of the patch may begin to extend, becoming at the same time slightly raised, and later a few bacilli may be found in the margin. On the other hand, if the patient's resistance is not lowered and treatment is given, the patch may be expected to disappear entirely. Whether a patient should be considered a danger to the community if he has a patch which is undoubtedly leprosy, but in which sections examined by an expert fail to show Hansen's bacillus, and whether he should lose his employment on that account are the main questions under consideration in this paper. There are no bacilli circulating in the body and being excreted in the sputum, fæces, urine or nasal secretion; all these are negative in such a case. The bacilli are confined to the skin lesion and possibly to the branches of the neighbouring cutaneous nerves. They are so few in number that search with infinite care fails to show them, and those that actually exist are separated from the surface by the epithelial covering of the skin. In order that such a patient should infect anyone else one or more of the infinitesimal number of bacilli has to find its way out of the skin through the epithelium, find its way into another person through his skin or mucous membrane and there meet with a suitable soil in which to grow. The chances of such an occurrence are not one in a billion, and the danger is absolutely negligible.

Even when a few bacilli can be found after much search in such a lesion the danger of infection is practically nil, and yet it is well that (erring if at all on the safe side) such a patient leave his work until the bacteriological examination becomes negative.

(3) What are the best means to be taken in a country like India to prevent the spread of infection?

My experience leads me to recommend as perfectly safe the rule that the line of isolation be drawn not between the clinically positive and the clinically negative cases, but between the bacteriologically positive and bacteriologically negative cases.

This means that all cases which are in the stage which though clinically positive is bacteriologically negative, a stage of the disease which may last for months and even years, should be allowed to continue their work, mixing freely with others. This, however, should be allowed only provided that they continue under efficient,

regular treatment until all active clinical signs have been absent for some considerable time, and remain under medical observation for two years after treatment is stopped.

The importance of adopting this attitude, instead of ostracizing bacteriologically negative though clinically positive cases by removing them from their work is that, patients will be attracted to take treatment in the early stage and to stick to the treatment regularly and conscientiously, instead of doing their utmost to hide the disease until it has passed on to the second stage which is more difficult to treat and in which they are a danger to their families and neighbours. It is obvious that the former instance is much less likely to spread the disease than the latter.

Yet so strong is the prejudice against leprosy that there are still some employers who will cast out their employees when they hear that they have leprosy, although they are advised that they are in the early, non-infectious stage and that they are not a danger to others. On the other hand, there are numbers of clerks, peons and other employees to-day in Calcutta who were formerly under our treatment for leprosy and whose recovery is largely due to the fact that their employers took our advice and continued to employ them, thus providing a means of maintaining themselves during the prolonged period of treatment.

The early diagnosis and treatment of leprosy is undoubtedly the most hopeful method of dealing with the disease, but it is impossible to carry this out to any large extent unless clinically positive but bacteriologically negative cases are counted as non-infectious.

With regard to bacteriologically positive cases we find them in all stages of infectivity. It is those of them who discharge Hansen's bacilli from the nose that must be looked upon as specially dangerous to the public, also those with ulcerating nodules—as opposed to trophic ulcers which are not as a rule infectious. Examination of the surface of the epithelium when it is not ulcerating seldom shows Hansen's bacillus. Speaking generally a patient's infectivity may be judged by the number of bacilli which are discharged from the nose, seeing that almost all patients who have skin lesions in which there are many bacilli and who are at all likely to spread infection, have at the same time a marked lesion of the nasal mucosa. When such a case is healing up under treatment we generally find that by the time the nose becomes bacteriologically negative there are very few bacilli to be found in the skin. In fact I believe that if we could eliminate the infection caused by patients with nasal infection, we should practically have eliminated all infection; but though this may be true I believe in leaving a considerable margin of safety and, except in employments in which the patient does not come in contact with others or touch things which have later to be touched by others, I recommend that employment be stopped

until the patient becomes bacteriologically negative.

From the point of view of employment we can therefore divide patients into three groups:—

(1) *Those who, though clinically positive, are bacteriologically negative.* They should be allowed to continue their work provided they place themselves under regular, efficient treatment, reports of their progress being asked for and sent to their employers by the doctor from time to time, so as to ensure that they do not neglect treatment and that they are continuing to make satisfactory improvement.

(2) *Patients whose skin is bacteriologically positive to a slight degree, only a few acid-fast bacilli being found with difficulty, and the nose bacteriologically negative.* Such patients should, if possible, be allowed to go on leave, still drawing their pay. In many cases six months' treatment will render them bacteriologically negative, when they can be allowed to return to work still carrying on treatment as long as is necessary. The same periodical reports should be asked for and sent to the employer.

(3) *Patients in whose skin there are larger numbers of acid-fast bacilli and especially those whose nasal mucosa is bacteriologically positive.* If such patients have earned a considerable amount of leave, say one or two years, it may be possible in some cases for them to be rendered non-infective before the leave expires; but in many cases this will not be possible. The extent to which employers can be held liable for maintenance of such patients during their term of treatment is a matter for consideration. Some employers we have found very generous, others the reverse.

If some such classification as the above were generally accepted and acted upon it would tend to have three effects:—

(1) Employers would be more likely to insist on medical examinations of their employees with a view to finding out if leprosy is present or not.

(2) Employees would come forward more readily for diagnosis and treatment and not try to hide their lesions as long as possible for fear of losing their employment. Thereby they would ensure their own recovery, being treated in the early, highly remediable stage; and the danger of the spread of infection to their fellow workers would be lessened.

(3) The knowledge that there was danger of losing their employment would act as an incentive to the patients to do their utmost to get better quickly—a very important factor in speeding up improvement.

The present indiscriminating ostracism of all cases of leprosy which still holds good in some quarters has the opposite effects, patients doing their utmost to remain concealed. Such concealed lepers are often, it is easily understood, the most dangerous of all infection-carriers.

OBSERVATIONS ON A SERIES OF BACTERIOLOGICAL EXAMINATIONS OF TUBE WELL WATER IN RANGOON.

By MILITARY ASSISTANT SURGEON G. MACKEY,

D.T.M., I.M.D.,

*Assistant Director, The Harcourt Butler Institute of
Public Health, Rangoon,*

and

G. G. JOLLY, C.I.E., M.B., Ch.B., D.P.H., D.T.M. & H.,
LIEUTENANT-COLONEL, I.M.S.,

Director of Public Health, Burma.

THE general opinion of tube well water when judging its quality from a bacteriological point of view is that it is usually very pure and above suspicion.

Support is given to this opinion by the facts that:—

(1) A physical examination shows the water to possess the qualities required of a good water in so far as appearance, taste, smell, etc., are concerned.

(2) The source of the water lies far below the surface and is therefore, one would imagine, beyond the limits of penetration of organisms associated with soil and surface supplies.

From results obtained from examinations of tube well water carried out at the Harcourt Butler Institute at different periods of the year, it was found that the quality varies and does not always come up to the high standard of purity which it is supposed to possess. With a view to determining to what extent this is the case, a series of examinations, extending over a period of 10 months and covering 6 months of the wet and 4 months of the dry season, were carried out.

Rangoon with its numerous tube wells, which are used to supplement the Hlawga Lake supply, lends itself admirably to a piece of work of this nature, and the bulk of the samples examined were collected from two tube wells, possessing a high reputation for the excellent quality of their water, and which have been in daily use for a number of years.

The results of examinations of samples of water collected during the period 1st November 1927 to 28th February 1928, both in this and previous work, showed that tube well water certainly does during the dry months of the year uphold its reputation for purity; in fact one may go a step further and describe it as practically sterile, if absence of lactose-fermenting organisms in 100 c.c. of water and a negligible total count may be regarded as significant of this.

Owing to this dry season sterility it will be clear that a study of the bacterial flora of tube well water in Rangoon, can only be made during the wet months of the year, i.e., 15th May to 31st October, when the presence of lactose-fermenting organisms has on occasions been detected in 1 c.c. of water.

These observations were commenced on the 1st May 1927, about a fortnight before the rains broke, and it was intended in the first instance to record the results of a daily examination of

water from the tube well supplying the Central Jail in so far as the presence or absence of lactose-fermenting organisms and the total count in 1 c.c. on agar were concerned. This water was examined daily from the 1st May 1927 to the 28th February 1928 with a break of 2½ weeks from 17th June to 3rd July 1927.

In the period from August 1st to 31st October, water from the Jail tube well and from the tube wells of the Rangoon Foundry and Windermere Park, as well as from some others, was examined. The observations during this period were further extended to determine the ability or otherwise of the lactose-fermenting organisms present to utilise citrate, and in the latter case further tests with a view to identification were carried out.

From 1st November 1927 to 28th February 1928 the results recorded showed an entire absence of lactose-fermenting organisms in 100 c.c. of water with a total count of less than 10 organisms per c.c.

The observations therefore fall naturally into three periods:—

(1) The period from 1st May to 31st July 1927, during which 74 examinations of the Jail supply were made; the presence or the absence of lactose-fermenting organisms and the total count in 1 c.c. on agar only being recorded.

(2) The period from 1st August to 31st October 1927, during which 119 examinations of samples of water from the jail supply and additional sources were carried out, the following determinations being made.

(a) The presence or absence of lactose-fermenting organisms.

(b) Their capability when present of utilising citrate or otherwise.

(c) Their identification when non-citrate utilisers.

(d) The total count in 1 c.c. on agar.

(3) The period from 1st November 1927 to 28th February 1928, during which 85 samples were examined. The results of these examinations consistently showed lactose-fermenting organisms absent in 100 c.c. with a negligible total count, so no further remarks with regard to this section are necessary, beyond stating that the period covered is the dry season of the year.

Period (1). A summary of the results of the 74 examinations carried out is as follows:—

Samples showing absence of lactose-fermenting organisms in 100 c.c. . .	55
Samples showing presence in 100 c.c. . .	14
Samples showing presence in 10 c.c. . .	3
Samples showing presence in 1 c.c. . .	2

The Total Count.—The reading of the total count in 1 c.c. on agar was never above 100 colonies, and in the majority of examinations was below 10 colonies per c.c..

The above tests being presumptive, it was impossible to give an opinion one way or the

other as to the quality of the water, especially as the presence of lactose-fermenting organisms even in 1 c.c. of water was always associated with a low total count. For this reason it was necessary to proceed further with the examination of these lactose-fermenting organisms and determine their nature and origin.

The most interesting feature, however, about these results was that they served to show that rainfall was followed by the presence of lactose-fermenting organisms in the water. For instance from 1st May to 12th May the reading of the results was recorded as "lactose-fermenting organisms absent in 100 c.c." The reading on 13th May, after a fall of 2½ inches of rain on 12th May, was "lactose-fermenting organisms present in 10 c.c.," followed the day after on examination of a sample collected on the 14th, by a reading of "lactose-fermenting organisms present in 1 c.c." The behaviour of this tube well water is similar to that of any surface water after a heavy shower of rain preceded by a period of dry weather. The effect of rainfall on the quality of the water in so far as the presence or absence of lactose-fermenting organisms is concerned was a noticeable feature observed during the rainy season. This observation is being recorded as an interesting finding without any present attempt to explain it.

Period (2). The results of the 119 examinations are summarised as follows:—

Lactose-fermenting organisms absent in 100 c.c.	..	72
lactose-fermenting organisms present in 100 c.c.	..	29
lactose-fermenting organisms present in 10 c.c.	..	12
lactose-fermenting organisms present in 1 c.c.	..	6

Ten lactose-fermenting colonies isolated from the MacConkey's broth tube showing the presence of acid and gas in the smallest quantity of water were inoculated into citrate media and gave the following results:—

In 42 samples, organisms capable of utilising citrate were found.

In 5 samples, organisms incapable of utilising citrate were found, and these on further examination were identified as follows:—

<i>B. neapolitanus</i>	..	2
<i>Bacillus</i> No. 74	..	2
<i>Bacillus</i> of the Grunthal group	..	1

Total count in 1 c.c. on agar.—In 6 samples out of 119 examined the reading of the total count was "innumerable," and in four of these the high count was due to the presence of *B. pyocyaneus*. The count in the remaining samples, including those where lactose-fermenting organisms were found in 10 and 1 c.c. of water, was below 100 organisms per c.c. *B. pyocyaneus* was also isolated in 6 other samples, making a total of ten, distributed among three tube well supplies.

The points of interest in the above results were:—

(1) The continuance of the feature already cited as regards the presence of lactose-fermenting organisms and their association with rainfall.

(2) The isolation of *B. pyocyaneus* from ten samples.

Opinions regarding the sanitary significance of *B. pyocyaneus* when found in water supplies, vary. It has been referred to by various authorities as pathogenic and is often found in pathological conditions in man. It has on more than one occasion been implicated in a dysentery-like outbreak which was water borne.

Thresh and Beale(1) record a serious outbreak of epidemic diarrhoea in the borough of Chelmsford; also one of dysenteric diarrhoea reported by the New York Board of Health, both of which were attributed to the presence of *B. pyocyaneus* in the water supply. They further state "They are chromogenic organisms found in blue and green pus and their presence in water is a certain sign of some dangerous source of pollution, since they never occur in natural waters."

Greer, Tonney and Nyhan(2) are of opinion that "*B. pyocyaneus* may or may not be pathogenic when ingested, but its presence in water should not be ignored." In their experience it is usually associated with *B. coli*. This fact, combined with its potential infective properties, should condemn a water from which it is isolated.

Adams(3) in his review of a *pyocyaneus*-like organism found in water concludes that its presence is not desirable, but that there is considerable doubt as to its pathogenicity.

CONCLUSIONS.

1. Tube well water in Rangoon during the dry months has been found to be of a very high standard of bacteriological purity.

2. During the monsoon, though lactose-fermenting organisms are present, they are generally citrate utilisers of non-animal origin, and are usually associated with a low total count, and bacteriologically therefore the water is usually above suspicion.

3. The sanitary significance of the presence of *B. pyocyaneus* in water supplies is still a debatable point, and whether its presence can be ignored is a question of some importance. Its presence in tube well water, however, may have a totally different significance to that of its association with surface waters, and more work in this connection will have to be carried out before any opinion as to the importance or otherwise of this finding can be given.

4. Rainfall does to a very noticeable extent affect the condition of the water in so far as presence of lactose-fermenting organisms is concerned.

PLASMOCHIN COMPOSITUM IN THE TREATMENT OF MALARIA.*

By P. V. KARAMCHANDANI,

CAPTAIN, I.M.S.,

Indian Military Hospital, Quetta.

It has been shown by numerous observers that plasmochin combined with quinine is far more effective in subtertian malaria than quinine alone. In the present paper I propose to offer a rational explanation for these observed facts, and to quote further cases in support of these observations.

That quinine has very little effect, if any, in destroying the crescentic gametocytes of *P. falciparum* is universally accepted at the present day. Dr. Manson-Bahr of the London School of Hygiene and Tropical Medicine has stated that it actually "encourages the formation of crescents"† (*Lancet*, 7th January, 1928, p. 25.) I have also observed the same fact as in the case of Nursing Orderly Kidar Singh, quoted in a former paper (*Indian Med. Gaz.*, May, 1928), in whose blood parasites were found after he had taken 510 grains of quinine sulphate. Plasmochin, on the other hand has a selective action on crescents—the most resistant forms of the malaria parasites—a fact noted by many workers, including Dr. Manson-Bahr. Recently, however, I have had a case in which crescents persisted in spite of the patient being on full doses of plasmochin. This appeared paradoxical at first, but when I combined plasmochin with quinine in minimal doses (plasmochin 0.02 gm. with quinine sulphate 0.25 gm. t.d.s.) I discovered that the crescents rapidly disappeared from the blood stream. This led me to conclude that the crescents found, when the patient was on plasmochin only, had developed from early trophozoite forms which the plasmochin had left unaffected; but that when quinine was added to the plasmochin, it destroyed these early forms, so that crescents did not develop when the patient was taking both drugs. The paramount effect of plasmochin in destroying the crescents after they were formed, remained unaffected. It follows from the above that (1) the action of plasmochin and quinine in combination is synergic, and (2) plasmochin compositum is quite effective in subminimal therapeutic doses.

* Published by permission of the Director of Medical Services, India.

† It is universally admitted that quinine has no destructive action on the gametocytes of *P. falciparum*; whilst several authors have claimed that it actually stimulates crescent production; the most important paper in this connection being that by Clark (1927). *Amer. Jour. Trop. Med.*, VII, 15.

There is the possibility of a fallacy here, however Sinton has shown that the output of crescents bears a distinct relationship to the asexual schizogony cycle; reaching its maximum some ten days after the maximum output of merozoites. If, now, quinine be administered during the schizogony period, the swarm of crescents will appear ten days later, and this may be attributed to the quinine administration; whereas it seems more probable that quinine does not prevent, but does not especially favour, crescent production.—Editor, *I. M. G.*

Dr. Oswald Urchs, M.D., the medical adviser to Messrs. Haverro Trading Company Ltd., in the correspondence columns of the *Indian Medical Gazette*, September 1928, p. 551, stated that the effective part of plasmoquine preparation is "N-diethyl-amino—isopentyl—8-amino—6-methoxychinolin." This complicated structure of plasmochin places it in the category of chemotherapeutic agents. According to Ehrlich these substances possess haptophoric and toxophoric groups. The haptophoric groups attach themselves to chemo-receptor groups in the parasites by chemical affinity, while the toxophoric groups have a lethal action on the parasites.

At the present day the sterilizing action of even quinine on malaria parasites is questioned and some observers assign an explanation based on phagocytosis (Gergusson, *Clinical Medicine and Surgery*, August, 1927). Whatever the real fact may be, it is admitted that large doses of quinine cause leucopenia, whereas small doses (gr. 3 to 4 t.d.s.) have no such action, even in combination with plasmochin. This has been well illustrated in my previous paper.

Further, quinine in small doses is a stimulant. By combining plasmochin with quinine we forge a weapon which not only assails the parasites from different points of attack—a combination of two therapeutic substances at the same time—but also the tonic effect of quinine in small doses stimulates the vital functions in the body—a fundamental principle in the field of therapeutics. Professor Bernard Nocht in his lecture given at the International Continuation Course in Public Health on the 28th November, 1927, stated that parasitotoxic action is greatly enhanced by the combined use of different chemotherapeutic substances, and so plasmochin plus quinine has the maximum effect in subtertian malaria. The *sine qua non* of success in therapeutics is (1) the annihilation of the enemy numbers, (2) destruction of their lethal properties, (3) augmentation of friendly resources. All of these equally important factors for success are provided by this combination of plasmochin and quinine, in that plasmochin has a destructive action on crescents, whilst quinine destroys the trophozoites. Further, quinine being tonic in small doses not only increases the phagocytic power of the blood, but by stimulating the liver and other excretory organs eliminates and destroys the toxic products. This in my opinion is the rational explanation of the superiority of plasmochin compositum over either of these drugs alone.

The only argument against the use of plasmochin brought forward by some observers are the untoward effects which may appear in the following forms:—

- (1) Epigastric pain.
- (2) Cyanosis and,
- (3) Methæmoglobinæmia

of which the last named two may be alarming. During my last three years experience with this drug, I have come across only one case of intolerance. The dose in which plasmochin has

been administered by me has never exceeded 0.02 gm. t.i.d. and in almost all cases I have given it in combination with quinine. I am of opinion that the combination of plasmochin with quinine mitigates in most cases the toxic effects. Plasmochin is a vaso-constrictor, whereas quinine is a vaso-dilator, and the combination of both therefore counteracts the toxicity of each. Further, as suggested by Manson-Bahr (*Lancet*, 8th September 1928), the addition of glucose in 1-oz. doses does away with all the toxic ill effects. As regards the epigastric pain this can be prevented or its evil effects mitigated by taking the drug after meals.

I append notes with temperature charts on the following very unusual cases treated with plasmochin compositum.

Case 1.—Sepoy Sardara Ram, 24th Bombay Grenadiers, was admitted to the Indian Military Hospital, Pishin, on 8th February, 1928, with lobar pneumonia and concurrent malaria, a mixed *P. vivax* and *P. falciparum* infection. He was given pneumonia treatment and plasmochin 0.02 gm. with quinine sulphate 0.25 gm. t.i.d.

10th February, 1928.—Temperature, 102°F.; pulse, 104; respirations, 48 p.m. Leucocytes, 16,968 per c.mm. Injection of sodium nucleinate. Plasmochin and quinine as above.

12th February, 1928.—Temperature, 101°F.; pulse, 116; respirations, 44 p.m. Leucocytes, 18,125 per c.mm. Treatment as above.

on 8th March, 1928, for bronchio-pneumonia with concurrent malaria—a *P. vivax* infection. He was put on to pneumonia treatment with quinine sulphate, 30 grains a day; and injections of sodium nucleinate were also given.

12th March, 1928.—Temperature, 100°F.; pulse, 90; respirations, 30 p.m. Blood films show *P. vivax* present.

CASE 1.

Name. Sep Sardara Ram Age. 28 yrs. Dis. P.L.C. Malaria D.T. F.M.T.

CASE 2

Name. Cook Lalchand. Age. 23 yrs Disease. B P C Malaria D.T.R

13th February, 1928.—Temperature, 100.8°F.; pulse, 118; respirations, 36 p.m. Leucocytes 21,875 per c.mm. Blood films show no *P. vivax*, but scanty *P. falciparum*.

14th February, 1928.—Temperature, 99.2°F.; pulse, 108; respirations, 48 p.m. Plasmochin stopped.

15th February, 1928.—Temperature, 99°F.; pulse, 100; respirations, 42 p.m. Leucocytes, 18,750 per c.mm.

16th February, 1928.—Temperature, normal; but *P. vivax* and *P. falciparum* both numerous in blood films. Given quinine sulphate gr. 10 b.d.

18th February, 1928.—Temperature, normal. Leucocytes, 6,800 per c.mm. *P. vivax* and *P. falciparum* both present.

20th February, 1928.—No parasites seen in films. Patient discharged.

Case 2.—Lalchand, cook, 24th Bombay Grenadiers, was admitted to the Indian Military Hospital, Pishin,

Leucocytes, 8,906 per c.mm. Plasmochin 0.02 gm. plus quinine 0.25 gm. t.i.d.

13th August, 1928.—Temperature, 99.6°F.; pulse, 96; respirations, 30 p.m. *P. vivax* present. Treatment as before.

14th March, 1928.—Temperature, normal. Plasmochin stopped. Quinine sulphate 30 grains a day.

18th March, 1928.—Temperature, 102°F., and a rigor developed. Blood films showed *P. falciparum*. Plasmochin 0.02 gm. with quinine 0.25 gm.

19th March, 1928.—Temperature, 102°F., with rigor. Blood films show *P. falciparum*.

20th March, 1928.—Temperature, normal. No parasites seen in films. Plasmochin stopped.

1st April, 1928.—Discharged well.

Case 3.—Cook, 24th Bombay Grenadiers, admitted to the Indian Military Hospital, Pishin, on 12th September, 1928, suffering from malaria—a *P. falciparum*.

infection. He was given 30 grains of quinine sulphate daily, and the picric acid test for quinine in the urine was positive.

At midnight on the 14th and 15th September, 1928, the patient became delirious and cerebral malaria developed. During the previous 36 hours he had received 50 grains of quinine orally. He was given 10 grains of quinine acid hydrochloride intravenously and 20 grains orally.

15th September, 1928.—Patient delirious. Passed feces and urine in bed. Quinine acid hydrobromide 5 grains intravenously.

CASE 3

Name Cook Nantaram Age 19 yrs Dis. Malaria M.T.R.

16th September, 1928.—8 a.m. Temperature, 99°F. Patient semi-conscious, exhausted, tongue dry and covered with black crusts. Blood films show *P. falciparum* ++++. Quinine acid hydrobromide 10 grains intravenously.

8 p.m. Temperature, 101°F.; patient violent. Sulfarsenol, 0.36 gm given intramuscularly, and 20 grains of quinine acid hydrochloride per rectum.

Thereafter 30 grains of quinine was given daily by the mouth.

18th September, 1928.—Temperature normal, but patient's mental state is vague. *P. falciparum* still present in films. Plasmochin 0.02 gm. with quinine 0.45 gm. given orally t.i.d.

Intravenous injection of 1.2 c.c. of a 1 per cent. solution of plasmochin with quinine 20 grains and pituitrin 1 c.c. in 20 c.c. of aqua distillata.

After this the temperature remained normal, and on the 20th no parasites could be detected in films. The plasmochin compound was continued t.i.d. until the 24th September, thereafter twice daily till the 30th, and once daily till October 4th. The patient was then discharged.

Cases 4, 5 and 6.—Three other cases of cerebral malaria in children, one aged 4 years, and the other two 5 years, were successfully treated by intramuscular injections of plasmochin (dose for an adult 1.2 c.c. of a 1 per cent. solution) with quinine acid hydrobromide (adult dose 5 grains in 1 c.c. of water) given deeply into the triceps.

Case 7.—Budhe Singh, cook, was admitted to hospital on the 23rd September, 1928, with a temperature of 102°F., a spleen enlarged to the umbilicus, and *P. falciparum* present in blood films. He was given 30 grains of quinine sulphate orally a day and an intravenous injection of 5 grains of quinine bihydrobromide.

24th September, 1928.—Temperature rose to 102.8°F. Plasmochin 0.02 gm. with quinine acid hydrochloride 5 grains t.i.d.

1st October, 1928.—Plasmochin-quinine reduced to twice daily.

4th October, 1928.—Plasmochin stopped. Quinine 30 grains orally a day.

5th October, 1928.—Evening rise of temperature.

9th October, 1928.—Plasmochin compound again administered, as above, t.i.d.

15th October, 1928.—Plasmochin compound twice daily. The temperature rose to 99°F. Plasmochin 0.02 gm. with quinine 10 grains given twice daily.

21st October, 1928.—Plasmochin only given once daily.

23rd October, 1928.—Plasmochin stopped.

The patient now made a sound recovery. On discharge his spleen was only slightly palpable.

Dr. Urchs placed at my disposal 70 ampoules of plasmochin containing 1.2 c.c. of a 1 per cent.

Case 7.

Name Cook Budhe Singh

Age 23 years

Disease Malaria M.T.F.

17th September, 1928.—8 a.m. Temperature, normal. Tongue moist and clean, but *P. falciparum* still present in films.

8 p.m. Temperature, 101°F.; patient violent. Same treatment as on the night previously.

solution and I administered these intramuscularly and intravenously alone, as well as combined with quinine acid hydrobromide, without noticing any ill effects. I have suggested to him to put on

the market a preparation of plasmochin which can be given subcutaneously combined with quinine acid hydrobromide. If such a preparation is made available it would be of great value in malaria therapy.

I cannot close without expressing my gratitude to Col. A. H. Safford, A.D.M.S., Baluchistan District, for encouragement and help, and thanks to my former assistant Sub-Assistant-Surgeon Prem Singh, I.M.D., for willing co-operation.

A RECORD OF MALARIAL CASES IN THE BENGAL-NAGPUR RAILWAY CONSTRUCTION HOSPITAL, TITLAGARH FROM JULY 1928 TO AUGUST 1929, WITH SOME OBSERVATIONS ON MOSQUITO FINDINGS AND CONDITIONS OF TRANSMISSION.

By W. D. SPEEDY, M.B., B.Ch. (Dub. Univ.),
Medical Officer, Raipur-Tizianagram Construction,
and
A. K. ADHIKARI, M.B.,
Assistant Surgeon, Malaria Investigation.

THE following figures taken from the laboratory records of the above hospital, have been collected in response to the appeal in the *Indian Medical Gazette* for August 1929, for information regarding the parasitology of malaria in India:—

mixture until two other slides taken on subsequent days give no positive result. There is thus very seldom any necessity for classifying cases as "clinical," for in practically all genuine cases parasites are found, especially in the thick drop preparation.

Films are made, both thick and thin, on the same slide. Diagnosis for treatment is made from the thick, and final differentiation of species from the thin film.

The staining used is either Leishman's or

July	11	8	72·7	7	Nil	Nil	1	3	213
August	20	7	35·0	9	2	Nil	Nil	9	213

Note:—Total blood films examined over the period was 257. Of these 160 were found with malarial parasites giving a 62·5 per cent. positive result.

The routine followed is, that all cases reporting with fever have a blood film taken. Those showing parasites are at once put on quinine or plasmoquine with quinine, and those negative to malarial parasites on an alkaline or diaphoretic

recourse in doubtful films is made to the Malaria-ologist of the Railway.

A certain proportion of negative findings must be attributed to the unofficial taking of quinine or patent medicines containing it, and in such

cases the diagnosis must be of necessity "clinical," but these are rare. Reference to Table II shows a very small percentage of gametocytes; this may be due to the conscientious "following up" of cases by the Assistant Surgeon in the hospital and insistence on a complete quinine course.

It is noticed that out of 160 positive cases, some 82 are from a better paid class, while 78 are menials. This, however, is not advanced as a proof that better feeding conditions, etc., are without value, for the latter group are nearly all local inhabitants and their staple food, rice, is cheap and plentiful, while acclimatisation no doubt plays its part.

and the adults are able to survive, though not evident in any great numbers, that fresh cases occur. Thereafter although humidity is still favourable in January and February the incidence of fresh cases is very small and remains so until practically one month after the outbreak of the rains, i.e., until the middle of July, when fresh cases rapidly increase. (The rains usually break about June 10 to 15th.)

It is probable that this period of a month, with its favourable humidity, and breeding conditions, gives time for a number of carriers to develop, become infected and transmit. Another factor, however, deserves consideration, i.e., that at a distance of under a mile, a *nala*, diminishing in

TABLE III.

Month.	Rainfall in inches	Average humidity 8 A.M.	Larval findings.	Locality.
July .. 1928	17.4	85.7	<i>A. culicifacies</i> .	Scanty in uncultivated paddy fields with fresh rain water.

August .. "	20.8	79.8	<i>A. culicifacies, rossi</i> (few).	Young cultivated paddy.

Note:—From the middle of November to middle of June, the main breeding grounds, i.e., the paddy field area, are surface dry. Only the *nala* referred to remains wet and this in May and early June as stagnant pools.

TABLE IV.

Month.	Maximum 24 hours. temperature.	Minimum 24 hours. temperature.
October ..	32.7° C	23.3° C
November ..	29.0° C	13.3° C
December ..	26.6° C	11.1° C
January ..	29.0° C	11.6° C
February ..	32.7° C	12.7° C
March ..	39.4° C	17.2° C

The breeding grounds which would appear to affect the settlement from which the bulk of the patients come, are collections of fresh rain water in the uncultivated fields, and later these same fields in their flooded condition during early paddy cultivation.

September appears to mark the close of the greater part of *A. culicifacies* breeding in the above localities, and it is noticed that for some three months after this, during which period the humidity remains favourable for transmission,

size as the hot weather advances, and found in March and April as a mere trickle, to be swarming with *A. culicifacies* larvæ and pupæ, may provide an anopheline population, harmless in the dry heat of April, May and part of June, but potentially dangerous shortly after the outbreak of the rains.

Two possible explanations for the practical cessation of cases after December are suggested. (1) that the allotted span of a mosquito's life would appear to be roughly three months, and (2) that the temperature which varies, as seen in Table IV actually either prevents, or is inimical to, the development of sporozites during the period from the end of November up to the end of February, at which time the humidity is favourable, and from March onwards the picture is reversed, i.e., temperature favourable but humidity not so.

The above observations may be of interest to those who, in common with the inhabitants of this district and so many others in India, experience this annual outbreak over a limited period, and it is specially so to the writers, contrasting so sharply as it does with another

district within fifty miles where climatic conditions and breeding places are entirely different and where the disease is endemic throughout the year.

Our thanks are due to Dr. A. M. Leake, v.c., F.R.C.S., the Chief Medical Officer, for permission to publish these notes, to R. Senior-White, Esqr., F.R.S.E., the Malariologist, for reading them over, and to Dr. J. B. Sen, Assistant Surgeon at the above hospital, who has recorded the readings for the humidity table over the period, and has co-operated in every way.

A Mirror of Hospital Practice.

A CASE OF FILARIAL ABSCESS.

By H. W. ACTON,

LIEUTENANT-COLONEL, I.M.S.,

Director and Professor of Bacteriology and Pathology,
and

S. SUNDAR RAO, L.M.P.,

Darbhanga Scholar,

Calcutta School of Tropical Medicine and Hygiene.

A CASE of filarial abscess has recently been studied at the Carmichael Hospital for Tropical Diseases, Calcutta, which confirms some of the views expressed by Acton and Rao (1929) on the rôle of secondary organisms in the causation of filarial diseases. This is an interesting case in which from a filarial abscess in the right femoral region a hæmolytic streptococcus was cultured; an organism of the same strain was subsequently isolated from the urine of the patient, and was finally traced to a focus of infection in the teeth.

S. C. M., aged 24, was admitted into the hospital with high fever and an abscess in the right femoral region. The temperature ranged between 102°F. and 104°F. for a week prior to admission. This patient was previously examined in connection with a severe form of urticaria which he was suffering from; during the routine tests, he was found to be sensitive to micro-filariae.

The abscess was opened and cultures were taken on blood-agar; the cultures showed a pure growth of a long-chain hæmolytic streptococcus. From inside the abscess, two long bits of live adult filariae measuring 22 and 10 mm. long and 103 μ to 145 μ thick (head end 60 μ to 68 μ thick) were recognized and separated out from the blood clot. Only the head end was obtained, the tail end being missed. These worms were full of eggs and nearly mature embryos. These observations show that the abscess was a typical filarial one.

Attempts were now made to locate the source of secondary infection of the abscess and an examination was made of the nose, nasopharynx

and tonsils; these examinations gave negative results. The left antrum gave defective illumination when tested and it was suspected that it might be a source of the infection; this was explored with a negative result. Blood was cultured on glucose broth in two different days and no growth was obtained. Stools were examined for ova, protozoa and cultured for non-lactose fermenters; the results were entirely negative.

A catheter specimen of the urine was then cultured and it revealed a pure growth of a faintly hæmolytic strain of streptococcus. This organism gave the same sugar reactions as the one isolated from the abscess; i.e.,

Sugar reactions:

Glucose = A; Mannite = O;
Saccharose = A; Salicin = O;
Litmus milk = C.

A skiagram was taken of the teeth and it was found that a few teeth showed marginal infection. Cultures were taken from these teeth and a streptococcus was isolated which gave the identical reactions found in the case of the organism isolated from the filarial abscess and from the urine.

The stools were plated for streptococci every day, for over five days and the results were negative. There was no skin lesion of any importance.

As a routine procedure, the blood was examined for parasites, with negative results, except for microfilariae seen in blood smears taken at night. The following was the total and differential leucocyte count:—

Leucocytes	..	17,000 per c.mm.
Polymorphs	..	76 per cent.
Lymphocytes	..	18 per cent.
Mononuclears	..	1 per cent.
Eosinophiles	..	5 per cent.

The investigations in this case show how from a focus of streptococcal infection in the teeth, the filarial abscess had derived its secondary infection, the presence of the organism in the urine, without any pathological symptoms in the genito-urinary system, showing that this occurred *via* the blood stream.

In another paper, the authors (Acton and Rao, 1929a) have discussed the process by which the defensive mechanism of the tissue is weakened as a result of the invasion by the filaria. When this has taken place, it is easy for the secondary organism from some focus of infection to get into the weakened tissue through the blood stream and to produce either local inflammation ending in an abscess, as in the present case, or lymphangitis. This depends on the tissues affected by the parasite; if it is purely local, as in the present instance, a local inflammation is produced. If it is a more generalized irritation affecting the

lymphatic trunks, lymphangitis is produced. If it affects the smaller lymphatics, the clinical condition known as cellulitis is the result.

A CHRONIC ENCYSTED MAMMARY ABSCESS SIMULATING SCIRRHOUS CANCER.

By COLONEL B. H. NANAVATTY, C.I.E., F.R.C.S.

F.C.P.S., etc.,

Medical Corps, Indian Territorial Force. Ahmedabad.

THE notes of the following case will probably prove interesting alike to the student and the practitioner, and teach him how very necessary it is to be cautious in arriving at the correct diagnosis after the fullest possible consideration. He will also find from the notes given below, how puzzling it is at times to recognize one disease from another.

About a few years ago I was consulted by a lady for a slowly growing tumour of the left breast. The brief notes then recorded were as follows:—Age about 55; is the mother of two children and has passed the climacteric; well built and healthy looking. There is no history of injury to the part or of family predisposition to any particular disease. Examination of the heart and other organs as well as of urine reveals nothing abnormal.

The breast is enlarged and swollen. An indurated lump (of the size of a small orange) is detected within and it does not appear to be incorporated with the breast substance. The skin over almost the whole of the breast has a brownish dusky hue. It is free and uninvolved, whilst the breast itself is movable over the deeper parts and is not adherent to the pectoral fascia. There is no pain on pressure and beyond the fact of the breast being enlarged, heavy and swollen, the patient has no other complaint to make. The nipple is not drawn in or retracted, but the axillary glands are enlarged and swollen, but not painful on touch or pressure. No fluctuation can be detected. The right breast has a normal appearance and is not affected in any way.

*Later appearance of the breast (after six to eight weeks).—*When seen again after a lapse of six weeks or so the tumour has distinctly increased in size, but in other respects the signs and symptoms remain almost the same as before. The patient now sometimes complains of a severe neuralgic pain in the breast, though in other respects it still continues as an almost painless tumour; the discoloration of the skin has become more marked. An important sign has now developed: the nipple is found to be retracted. As time advanced the nipple was still more retracted, the axillary glands more enlarged and the breast itself became slightly painful on pressure. Though carefully looked for no fluctuation could be detected and the tumour to all outward appearances presented many of the classical signs and symptoms of a scirrhus cancer of the breast. It may be added there was no fever at this stage or before.

An exploratory puncture was now proposed, but the patient being a nervous lady it was not allowed. A

friendly consultation was now held with an experienced surgeon of Bombay who happened to be with me for a day and he too felt doubtful as to the nature of the case without making an exploratory puncture. He, however, felt inclined to the belief that it was a scirrhus growth, inasmuch as the lady had lost weight, had grown weaker to some extent and the axillary glands had still further enlarged.

*Appearance of the tumour later on (10 to 12 weeks after).—*A month later the breast presented much the same appearance as before, but was distinctly more enlarged. For the first time a slight pain was complained of and this was increased by pressure. On palpation an indistinct sense of fluctuation was now felt. With the development for the first time of this additional symptom it became clear that the tumour in all probability was an encysted chronic mammary abscess, and not a scirrhus, as was at first suspected. The tumour, however, still continued to be circumscribed, firm and hard and the nipple was almost completely retracted. The patient was certainly thinner than before but cannot by any means be said to be of a cachectic appearance.

Briefly speaking the tumour presented many of the ordinary symptoms of a scirrhus growth, and though a few certain signs were wanting to complete as it were the picture of the latter disease, most of the symptoms vaguely pointed in that direction. As, however, fluctuation, even though slight, was now felt on deep palpation, it seemed probable that the case was one of a chronic deep seated abscess. The lady was therefore pressed again to allow an exploratory puncture to be made. This after a good deal of persuasion was allowed under chloroform, and on this being done the nature of the case became at once evident and a stream of thin viscid pus, unmingled with blood, came out. It was now clear that it was a case of chronic encysted mammary abscess of the breast and the rest of the procedure was simple enough. The abscess was freely opened under aseptic precautions, and the loculi within broken down and free drainage allowed. The wound gradually healed up in about three to four weeks time.

After results.—The subsequent recovery and convalescence were uneventful. The patient rapidly regained her health and is alive at present. It may here be added that the patient now recollects having had a fall from the top of a staircase about 8 months previously. But this she had entirely lost sight of when first questioned on the subject. She does not remember however that her breast was in any way injured even then.

Differential diagnosis.—The condition might have been mistaken for any of the following:—

(1) Chronic lobar mastitis, (2) Chronic lobular mastitis, (3) Cystic growths, (4) Adenoid tumours (e.g., adenoma, adeno-fibroma, adeno-sarcoma and the cysto-adenoma), (5) Cancers of the breast.

Remarks.—The case was interesting and in a way rather puzzling for the following reasons:—

1. The outward appearance of the tumour, the rather hard—but not stony hard—firm and circumscribed growth, the retraction of the nipple, the enlargement of the axillary glands, the age of the patient, the absence of fever, also of pain until a later date, were all more or less suggestive of scirrhus tumour of the breast.

2. The absence of history of trauma, of fever at any time previous to the onset of the disease, and the fluctuation (absent till a later period), diverted the attention for a time, from the case being considered as one of abscess.

3. The refusal of the patient to allow an exploratory puncture to be made when first suggested, delayed diagnosis at an earlier date.

NOVEMBER.

RESEARCH IN FILARIASIS.

FILARIASIS is a subject which has from time to time attracted the research worker, but in view of its importance—its very extensive distribution and the severity and permanency of the lesions that so frequently occur in this infestation—it has not received the attention which it deserves, especially in recent years.

It is difficult to see the reasons for this. Possibly it is felt that the transmission problem is solved and that the treatment problem is hopeless; a little consideration will, however, show that in neither instance is it the case. (The word filariasis can be applied to infestation by any of the filariæ; but here it is used in its more restricted sense to mean infestation by *Filaria bancrofti*.) Manson, as long as 1878, first incriminated the mosquito as intermediary host, but he was under the impression that transmission occurred through the agency of water which had become contaminated by the mosquito. Later, Low showed that the filaria entered the proboscis of the mosquito, and subsequently the true transmission cycle was worked out—*the mosquito feeds on a person with microfilariae in his blood; after a short time in the mosquito's stomach the ingested microfilariae wriggle out from their sheaths and penetrate into the thoracic muscle of the mosquito; here they undergo development: they progress forward towards the head, eventually coming to rest in the labium of the proboscis; when the mosquito next takes a feed on a suitable host the immature adult filaria escapes on to the skin by working its way through the inner lining of the labella (Dutton's membrane), usually at the tip; and finally it penetrates the skin of the new host. When it has gained access to its new host the filaria passes from the lymphatics of the skin to the larger lymphatic channels, through the various sets of glands, and if not in any way checked in its progress, it eventually reaches the main lymphatic trunks or even the receptaculum chyli. Here the female lays large numbers of embryos which again pass into the blood stream and complete the cycle. The different clinical manifestations of the infestation are dependent on the fate of the worms during their progress from the point of entrance towards their goal; at any point their further progress may be barred. Roughly speaking two pathological changes may occur; there may be complete blocking of the lymphatics of a part of the body; this will eventually lead to the develop-*

ment of elephantiasis, a condition which is most commonly seen in the limbs. Or there may be partial blocking; this will eventually lead to distension and varicosity of the lymphatic vessels, usually of the abdomen and pelvis. Practically all the clinical manifestations of filariasis can be explained on the basis of the occurrence of one or other of these two changes, combined with secondary bacterial invasion.

It has been observed in some endemic areas that embryos are present only in about 5 per cent. of persons suffering from elephantiasis, and that less than half those persons with numerous embryos in their blood show any clinical manifestations of the disease. This has led to doubt arising regarding the association of this infestation with some of the clinical conditions, more especially elephantiasis, which have been attributed to it. These conditions are now, however, universally accepted as being at least sequelæ of filarial infestation. The points of evidence in favour of this can be summarised shortly as follows:—

The close correspondence of the distribution of *Filaria bancrofti* and elephantiasis.

The frequent association in the same locality and even in the same individual of certain clinical types of lymph varix and glandular enlargement, conditions which have been proved to be due to filarial infestation, with elephantiasis.

It has been shown that the filariæ block the lymphatics; extensive blocking of the lymphatics, from whatever cause, will eventually lead to the development of elephantiasis.

The absence of microfilariae from the blood of individuals with elephantoid conditions is explained on the ground that a large and important skin area is cut off from the central lymphatic system and therefore from the blood stream; filariæ that gain entrance through the skin in the area distal to the block cannot penetrate beyond a certain point, and either they fail to reach maturity, or, if they do, their larvæ cannot reach the blood stream. It also seems possible that, on account of the very large number of filariæ which are caught up in the narrowed lymphatic channels in an elephantoid limb and destroyed, some lytic substances may be formed which adversely affect filariæ in other parts of the body.

Numerous investigations have been made in various countries to ascertain the local carrier. In India *Culex fatigans* is the principal carrier, though other mosquitoes have been found to harbour filariæ in Nature, and in the laboratory to be potential carriers. Many other problems connected with the disease have from time to time been tackled; one of the most fascinating subjects of research, but more frequently of pure speculation, has been the problem of filarial periodicity. In most endemic areas the microfilariae only appear in the blood at night; during the day time no embryos are present, as darkness approaches a few appear, their number increases, reaching its maximum during the night and then

decreases towards morning. There are a few other areas, e.g. Fiji, where there is no periodicity, the embryos being present both during the day and the night. This periodicity is not a chance one as it corresponds in time with the feeding habits of the main carrier mosquitoes of the locality, but no satisfactory explanation of the mechanics of this periodicity has been yet put forward. Attempts have been made to explain it on the grounds of posture, of capillary constriction during the day, and, recently, of cyclical parturition on the part of the adult worm. Most of the theories are dependent on isolated observations and none of them appear to fit in with half the known facts. Thus it remains one of the minor, and practically not very important, mysteries of tropical medicine.

The treatment of the disease has been consistently disappointing. It can be said quite fairly that no substance has been yet found which has any effect on the longevity of the adult worm. Here we are up against a very serious difficulty: the worms live in the lymph stream and we know no drug which will penetrate to the lymph in anything but the minutest traces. Drugs can be injected directly into the blood stream and it is quite conceivable that one could be found which would destroy the microfilariae, but this would be waste of time as microfilariae cannot possibly do any harm to the individual in whose blood they are circulating. However, chemotherapy has made such great advances during the last few years that there is considerable hope that a drug with the necessary properties will eventually be found.

In the production of the various clinical manifestations of filariasis the part played by secondary infecting organisms has been recognised and attempts have been made to attack these by means of vaccines; so far this is the only line of attack which has shown any promise, and it is one that should be followed up. For the grosser lesions the aid of surgery has had to be called in; this is a frank admission of weakness.

Some important papers on the subject of filariasis have appeared in this journal during the current year. These papers report the work on this subject which has been carried out at the Calcutta School of Tropical Medicine and Hygiene during the preceding 5 or 6 years. In the March issue Chopra and Sundara Rao reported the results of therapeutic experiments in the treatment of the disease. The results, as far as destruction of filaria was concerned, were unfortunately entirely negative, but with one drug, tryparsamide, slight clinical improvement was noted in some cases, and chyluria, where this was present, usually disappeared, temporarily at any rate. However, as the treatments were carried out carefully, often in hospital, and the progress of the patients observed, both clinically and by examination of the blood, the negative evidence thus obtained is of considerable value and further investigation with most of these drugs

has been rendered unnecessary. These writers were also able to show that in the daily filarial counts there were considerable normal variations, which probably accounted for the apparent success with certain drugs that have been reported from time to time. In another paper, Acton and Sundara Rao reported the results of investigation and treatment of another series of cases of filariasis; in these cases they concentrated their attack on the secondary bacterial infections, and they achieved considerable success. They point out that wherever there is a secondary bacterial infection, there must be some focus from which this arises; the focus may be a temporary, external focus, such as tinea with secondary streptococcal infection, or a more permanent, internal focus, such as an apical abscess, enlarged and septic tonsils, or intestinal ulceration. In some instances they have been able to recover the same organism from the filarial abscess, from the septic focus and from the urine, thus showing that the blood stream is the connecting link between the focus and the lymphangitis or abscess. Treatment consists in eradication of the focus, by suitable treatment and giving autogenous vaccines for the local condition. The treatment of this condition by means of vaccine is not entirely new, but these writers have emphasised the importance of finding and eradicating the septic focus and have given us a clearer conception of the processes by which secondary infection of the local filarial lesion occurs. The publication of a second paper by the same two writers constitutes a very distinct advance in our knowledge of the pathology of the disease; this paper appears elsewhere in the present number of the *Gazette*. The following is their conception of the pathology of the disease:—

In the production of the lesions of elephantiasis there are two quite distinct factors at work, the filarial toxin and the bacterial toxin; the former may be liberated by the female worm during parturition, or at its death, following trauma or strangulation. The evidence which is adduced for the existence of the filarial toxin is, (a) analogy with *Filaria medinensis*, (b) the presence of a higher eosinophilia in those cases in which there is no obstruction, and in which the filariae become fully mature and numerous microfilariae appear in the blood stream, and (c) the periodic attacks of urticaria, headache and other signs of intoxication, unaccompanied by local suppuration, from which filarial patients suffer. Distinction can be made clinically between the local conditions produced by the filarial toxin and those caused by streptococcal invasion, but not always between the former and the milder staphylococcal lesions. Pathologically, however, there is a marked difference between the tissue reactions to the filarial and to the bacterial toxin; in the former there is formation of eosinophilic granulation tissue, as against abscess formation or diffuse cellulitis in the latter.

The sequence of events in the production of the various lesions is as follows:—Wherever the

Nov., 1929.]

female comes to rest irritation is produced in the walls of the lymph vessel; this is always more marked at the head end—which is also the vulval end—of the worm; the inflammation thus produced causes obstruction; and periodic obstruction leads to varicose formation. The constant irritation also causes endothelial proliferation, the formation of papillomatous growths—which are easily damaged and may bleed, causing the formation of hæmatomata—and finally complete occlusion of the vessel. This blocking diverts the lymph flow through the collateral vessels, which become dilated, and the formation of the typical lymph varix with its sequelæ, chyluria, chylocele, etc., follows. The passage of the adult worms is also impeded; these are diverted into the varices where they mature, parturate, and die, aggravating the local condition. This is the usual sequence of events in the pelvic and abdominal lymphatics where the collateral circulation is good, but in the limbs where this is not so well developed alternate courses for the lymph flow are rapidly exhausted and complete obstruction eventually occurs.

In their passage from the point of entrance, usually in the extremities, the immature worms meet with little resistance at first, so that the majority get through into the abdominal and pelvic vessels. In their passage through the lymphatic glands they inevitably cause some damage to these structures. Scars which mark the track of a worm can often be seen in sections of a gland. Repeated scarring will lead to the replacement of most of the gland substance by fibrous tissue, until eventually the through-passage of the worm is obstructed. Worms are caught in the glands and eventually die; there is a local eosinophilia and giant-cell reaction to this foreign protein, a cytolsin is probably produced by means of which, aided by giant-cell phagocytosis, the worm is absorbed. This process, however, entails the formation of much granulation tissue which become vascularised, so that eventually the whole gland is replaced by fibrous tissue and the lymph flow is completely obstructed. If the obstruction is in the inguinal glands, the lymph flow from the leg is deflected into the scrotum causing the lymph pressure to rise so that the skin lymphatics, being ill supported in this region, dilate and form small cysts which eventually burst, lymphorrhœa and the condition of "lymph scrotum" being established. When the obstruction is in the femoral glands the lymph flow from the limb is completely cut off; there is dilatation of the surface lymphatic spaces, hypertrophy of the papillæ, fibrotic infiltration of the deeper structures, destruction of the sweat glands, and eventually production of the typical thick, harsh and dry elephantoid skin. When such a condition has come about the filariæ which enter the skin in this limb cannot possibly get into the larger lymphatics so that very few of them become mature, and, even if they do become mature, their larvæ are unable to pass the obstruction and reach the blood stream.

The filarial toxin and the damage done to the lymph vessels and glands by both living and dead adult filariæ produces a condition of local kataphylaxis. Streptococci and staphylococci, carried by the blood stream from some septic focus in the body, settle in these damaged tissues; a new septic focus is formed and the usual sequelæ follow. The tissue reaction to the bacterial invasion undoubtedly speeds up the process of lymphatic obstruction, though theoretically it is quite conceivable that the whole process might occur without this secondary bacterial invasion, but it would take a longer time. The nature of the clinical manifestations will be dependent on the site of the new focus and on the species of the organism involved; they are very protean in character and vary from the so-called filarial colic, which is caused by a streptococcal invasion of the retroperitoneal lymph varices and which often ends fatally, to a subacute inflammation of a lymphatic gland around a dead worm, a condition which is caused by a staphylococcus and one which quite often subsides without coming to abscess formation. Kataphylaxis of the epiblastic tissue also occurs; the elephantoid skin in which keratinisation has been interfered with is liable to direct secondary invasion of bacteria from outside the body.

The writers of this paper have been able to demonstrate practically every stage in this process in pathological specimens which they have collected during the last few years, both from living patients and at the post-mortem table; a number of photomicrographs from their collection have been reproduced to illustrate their paper.

Another extremely interesting feature in this paper is the very ingenious explanation which the writers give for the differences in the clinical manifestations which predominate in the various endemic areas in India. In those parts of the United Provinces where filariasis exists chyluria is the predominant clinical manifestation, hydrocele and lymph varix of the cord occur, but elephantiasis is very rare; in Bengal and Orissa all types of the disease are observed; whereas in Southern India elephantiasis is the predominant manifestation, chyluria being rare. The explanation is that in the first-named area there are about two months in the year* when the climatic conditions are suitable for the transmission of the filariæ and the microfilaria rate in the general population is low, less than 10 per cent.; thus, only a small number of filariæ gain access to the patient and these only during a short period of the year; they pass unimpeded from the extremities to the abdominal lymphatics, damaging the lymphatic glands on their way, but the damage they do is very slight and quite insufficient to cause obstruction. Each year

*Sundara Rao and Iyengar have shown that a high degree of humidity combined with a moderately high temperature is essential for transmission; a paper on the subject by these two workers is in the press.

more worms find their way into the abdominal lymphatics where eventually, after 20 years or so, they produce lymph varix. On the other hand in Southern India the climate is suitable for transmission for about nine months of the year and the microfilaria rate in the general population is often 20 per cent. or higher; here a continual stream of filariæ pass through the glands—the superficial inguinal or axillary—for most of the year; these glands very soon become damaged, and the train of events, detailed above, is started. Consequently complete obstruction frequently occurs in very young patients; these patients suffer from elephantiasis, but the filariæ are unable to pass the obstruction so that few gain access to the pelvic and abdominal lymphatics and microfilaria are not found in the peripheral blood. In the intervening endemic area, Bengal and Orissa, both the microfilaria rate, and the age incidence and nature of the clinical manifestations are intermediate between these two extremes. In each of these areas there will be a percentage of the population who are not susceptible to the filarial toxin; in these persons the filariæ live and produce larvæ, but, as there is no tissue reaction to their presence, although microfilaria are found in the peripheral blood, there are no clinical manifestations of the infestation.

Some observers have suggested that different varieties of *Filaria bancrofti* are responsible for the different clinical manifestations, but the explanation put forward by Acton and Sundara Rao appears to be far more feasible.

These recent researches suggest that filariasis is not an entirely sterile subject for investigation, and one hopes that in the near future more workers will be found to tackle other aspects of this very important problem.

There are many gaps in our knowledge of the transmission problem which require filling; much work requires to be done on the question of the season during which infections occur in the different endemic localities, and the potentialities of other species of mosquitoes as carriers require further investigation. With regard to treatment, only the fringe of the problem has been touched, up to the present. Many patients have been successfully treated, in that the progress of the pathological changes which occur has been arrested and the acute condition cured; even this treatment is not available for the mass of the population as it is laborious, and demands the individual attention of skilled workers. There are three ways in which the problem could be tackled:—(a) Transmission of the disease could be prevented, either by destruction of all the mosquito carriers or by protecting the population from the bites of these mosquitoes; this would be a very difficult problem in India; (b) By treating the whole population by some drug which would destroy the adult worm; a drug that will do this has still to be found, or (c). Finally, by desensitizing the individual, so that the worm could live harmlessly in his large lymphatic

vessels; this last measure, even if it could be achieved, would be highly unsatisfactory, as it would mean that the danger of infection to the rest of the population was not only not decreased, but actually increased. The chemotherapeutic method would appear to offer the greatest possibilities as a public health measure, but, as we have already said, the problem is a difficult one. If some highly parasitotropic drug could be discovered which, when injected locally into the extremities, would be absorbed by the lymphatics and not by the blood stream, it would not only kill the worm in its progress up the lymphatics, but would destroy those that had already reached the pelvic and abdominal lymphatics. The intravenous route which up to now has been mainly employed offers little hope of success, even the oral route of administration should prove superior to this, as a drug absorbed from the intestinal tract passes almost immediately into the main abdominal lymphatics where it would encounter any worms which had penetrated as far as this.

Medical News.

THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

As our readers are aware, the new London School of Hygiene and Tropical Medicine was formally opened by H. R. H. the Prince of Wales in July of this year. This immensely important project owes its existence firstly to the generosity of the Rockefeller Foundation; secondly, to the determination of the British Government to organise and subsidise the creation in London of a central organisation for the study of tropical diseases throughout the British Empire. The new school has now been opened, and the possibilities which lie ahead of it are immeasurable. We have received a full account of the organization and constitution of the school from its Secretary, and it is of such importance that we publish it below *in extenso*.

The great building which H. R. H. the Prince of Wales opened on July 18th in the presence of a distinguished company is the outcome of the recommendations made in 1921 by the Committee, under the presidency of Lord Athlone, appointed by the Minister of Health of that day, Sir Alfred Mond, now Lord Melchett. This Committee, finding that the post-graduate teaching of public health in London was inadequate and uneconomic, advocated the establishment of a central institution, affiliated to the University of London, wherein full provision should be made for instruction in all branches of preventive medicine.

The chief difficulty in the way of carrying this recommendation into effect was financial. The country, hard hit by the war, was staggering beneath a burden of debt and its trade and industries had not recovered from the conditions which had convulsed Europe, and indeed the whole world. Happily the Trustees of the Rockefeller Foundation in New York came to the rescue and Great Britain gratefully acknowledges the timely assistance which that wonderful and wealthy Foundation generously extended to it in time of need. Impressed by the results of their inquiries in many lands, the Trustees had reached the conclusion that, if the gospel of hygiene, a gospel of hope and comfort, a gospel of vital importance to mankind, was to be adequately served, a great teaching centre of the type envisaged by the Athlone Committee was a necessity. Furthermore, they recognised the peculiar advantages which London presented

Nov., 1929.]

as a site for such a school, in consequence of its traditions in public health work and organization, its medical associations, its prestige as a world capital, its position as a huge sea-port, its general relations to commerce and industry, the facilities it presents for studying well-nigh every type of hygienic problem, and accordingly the offered the Ministry of Health a sum of £460,000 towards the attainment of the project. This large sum was to be expended on the purchase of a site and on the building and equipment of an institution of the type required. The only accompanying condition was that the British Government should contribute adequately towards its maintenance.

In taking this action the Rockefeller Trustees paid a tribute to the proud position held by Great Britain as the cradle of modern hygiene, in other words, as the country which had led the way in placing public health administration and legislation upon a sound basis, and they expressed the hope that the School, while serving national and imperial needs, would have a yet greater scope, and would become a centre of world-wide influence, both in the way of training public health students and research workers and of furthering research into public health problems. To quote Sir George Newman, Chief Medical Officer to the Ministry of Health and a member of the Board of Management of the new School:

"The situation is something more than imperial, it is international: it is to create here in London a complete school of preventive effort, capitalized by American benefaction, maintained by student fees and Parliamentary grant and open to all nations."

Hence, the primary function of the School was to train medical men and women desirous of entering public health services in Great Britain and abroad, to undertake research work in all branches of preventive medicine, to instruct research workers, and to foster and encourage research in those sciences which must be studied and mastered if the progress of public health is to be assured. Very soon, however, the rôle of this School of Hygiene was notably enlarged.

As is well known, Mr. Joseph Chamberlain, when Colonial Secretary, founded in 1899, at the instance of Sir Patrick Manson, the father of modern tropical medicine, a school for the study of diseases of the tropics. This, the London School of Tropical Medicine, which for many years occupied premises at the Albert Docks and after the war removed to Endsleigh Gardens, was, from its commencement, under the aegis of the Seamen's Hospital Society, and had carried out most excellent and useful work and been of great service to our Colonial possessions. Negotiations with the Society led to the union of the new School of Hygiene with the London School of Tropical Medicine and there was thus formed the London School of Hygiene and Tropical Medicine, which was incorporated by Royal Charter on August 1st, 1924.

The union was timely, for it is now recognized that there is no sharp dividing line between the diseases of hot climates and those with which we are familiar in temperate latitudes. There are scarcely half a dozen diseases strictly limited to the tropics and sub-tropics and of these only one or two are of importance. Again, the principles governing hygiene in the tropics are identical with those followed in temperate regions. At the same time, the diseases nowadays chiefly encountered in the tropics require special attention, both clinically and with respect to those sciences which have an intimate bearing on their causation and spread. Apart from the bacteria, that group of vegetable micro-organisms to which the bacilli of plague and cholera belong, lowly forms of animal life—the protozoa—must be studied, for certain of them are responsible for diseases like malaria, sleeping sickness and one of the more important forms of dysentery. Some of the great tropical diseases are due to parasitic worms or helminths such as the hookworm and the flukes which pass part of their life-cycles in water-snails and with these the student must become familiar. Insects, like the mosquito, the tsetse-fly and the flea, are concerned in the transmission of serious tropical maladies and so entomology, or the study of insects, acquires a greater medical importance than

it does in Great Britain where, however, insect transmission of disease is by no means a negligible quantity, as witness the iniquities of the house-fly and the rôle of the louse in typhus fever, a disease happily now rare. The hygiene of the tropics also requires special study, for though it is governed by the principles which are followed in safeguarding and improving the public health in Great Britain, the application of these principles often differs markedly in the tropics from the practice of hygiene followed in Europe and elsewhere.

The School, therefore, is charged with the duty of continuing and enlarging the instruction given in the old London School of Tropical Medicine and of providing facilities for research on the lines which have made that School famous the world over. The Rockefeller grant was generous and the idea of the School and its work, as formulated by the Board of Management, has been conceived in no niggardly spirit.

The type of building required for such a diversity of interests was the subject of long and careful consideration and, when preliminary plans had been prepared and details worked out, a limited number of architects with experience in laboratory construction was invited to submit designs. The successful design was submitted by Mr. P. Morley Horder, and Mr. Verner O. Rees, A.R.C.A., in association with Mr. Horder, has carried through the execution of the design so submitted. He has devoted himself whole-heartedly to the work and the result has justified his skill and care.

Particular attention has been directed to the library and museum. The former will eventually be a large and representative Library of Hygiene, using this word in its widest sense, and how wide that is, only those who have made the study of preventive medicine their life work can fully appreciate. The Museum, of a comprehensive and graphic type, consists of three parts, namely, sanitary engineering, hygiene in the general sense and tropical medicine. It marks a new departure in Great Britain, for the assistance of numerous large commercial interests was sought and most generously granted. A number of leading firms, whose business is concerned with public health activities of various kinds, have co-operated to present to the Museum exhibits of great educational value, and have kindly offered to keep these exhibits completely up-to-date.

The Museum will be open to the public and cannot fail to become a centre of propaganda and a guide to methods of safeguarding and improving the health of the people, both at home and overseas.

The Library and Museum of the old London School of Tropical Medicine have served as the nucleus of these developments.

The School, as now constituted, has the following Divisions:—

(1) *Public Health*.—This connotes a very large number of subjects. The term includes not only much that concerns environmental hygiene and the control of infectious diseases but all that relates to the health and welfare of the individual.

Long ago, in the days of the great Napoleon, that remarkable pioneer, Johann Peter Frank, "a modern of the moderns," whose name, with those of twenty other pioneers, has been placed on the façade of the new building, insisted on the importance of personal hygiene and discoursed on maternity and child welfare, the health of the school child and a multitude of other matters which have only engaged our serious attention on a large scale since the beginning of the present century. In this division also there is a section devoted to the physiology of hygiene. In this and in other directions the activities of the public health division will be brought closely into contact with industrial problems and should play a notable part in assisting both the employer of labour and the employed.

(2) *Epidemiology and Vital Statistics*.—The two subjects are closely linked and the division itself stands in close relationship to all the other divisions and should play a great part in training students to become careful observers and recorders, the while it continues to cast light in dark places and to subject the results of research work to the acid test of statistical accuracy.

(3) *Bacteriology and Immunology*.—This, a most progressive division, has already, in temporary quarters, been doing fine work in training men and women who have decided to follow bacteriological careers, both at home and abroad. Its activities in teaching and research will undoubtedly increase in variety and value when housed in new and commodious quarters and provided with all those facilities which modern science demands.

(4) *Biochemistry*, including a Department of Chemistry as applied to Hygiene. It is often said that "the future lies with the biochemist," and there can be no doubt that many of the most important problems in preventive medicine can only be solved by his skilled help. Questions of diet and of growth, of bodily function, of the resistance of the body to disease, these and many other abstruse subjects fall within his purview. The biochemical work will in the main be of a research nature but the Department of Chemistry, while not ignoring research, will be largely concerned with training the public health student in the analysis of water, sewage and food, in the examination of disinfectants, and in the relations which chemistry bears to industry so far as hygiene is concerned.

(5) *Medical Zoology*.—This large division, embracing the departments of protozoology, helminthology and entomology, to which subjects reference has already been made, is, apart from the prosecution of research, chiefly concerned with the training of medical men and women destined for the tropics. At the same time instruction will be afforded students proceeding to degrees and diplomas in public health, to those attending the School at the instance of the League of Nations for the study of malaria, and to others professing one or more of the three subjects abovementioned. An aquarium and large insectarium are features in the equipment of this division.

(6) *Tropical Medicine and Tropical Hygiene*.—This embraces the all-important clinical work in diseases of the tropics for which facilities are afforded by the Hospital for Tropical Diseases, Endsleigh Gardens, now Gordon Street, which, under the auspices of the Seamen's Hospital Society, will continue in close touch with the School.

Associated with this clinical work is the study of applied pathology, as distinct from the pathology of protozoal and helminthic infections. It is concerned largely with questions of technique and is of the utmost importance to the physician practising in the tropics.

Tropical hygiene figures in this division and its study indicates the modifications which the climate and conditions of countries in the torrid zone impose upon the pursuit of the hygienic ideal.

Such is the constitution of the School for teaching and research work. Its staff being in contact with other official research organisations, exceptional opportunities will be forthcoming whereby students may acquire experience of the way in which large scale investigations of public health problems are planned and conducted, while its association with officials of the public health service will ensure adequate practical instruction in field work, both urban and rural.

It possesses an experimental station at Farnham Royal and, thanks to the support of Agriculture, an Institute of Agricultural Parasitology at St. Albans, which provides opportunities and material for teaching and research work in medical zoology.

On the tropical side it co-operates with the Government of Southern Rhodesia in the work of a field station at Salisbury, and frequently sends members of its staff abroad for purposes of study and research. In its new home it will look forward confidently, provided ample funds for maintenance are forthcoming, to an extension of its work and to the full attainment of the great purpose for which it has been brought into being and which may be expressed shortly, simply, yet adequately, in four words, "the Welfare of Mankind."

THE INDUSTRIAL ANTI-MALARIAL ADVISORY COMMITTEE OF THE ROSS INSTITUTE.

We have received, and read with very considerable interest, the report of the inaugural meeting of the

Industrial Anti-Malarial Advisory Committee of the Ross Institute, held on Monday, July 15th, 1929. Representatives of the Ceylon Association, the South Indian Association, the Rubber Growers' Association, and other important industrial concerns in India and Ceylon figure prominently in the list of names of those present. Mr. A. W. Still (Rubber Growers' Association) was elected to the chair; the Advisory Committee was formed, and it was resolved to hold quarterly meetings.

Sir Malcolm Watson then addressed the meeting. The following is an abstract of his remarks:—

Sir Malcolm Watson said that the outstanding fact to-day, thirty years after Ross made one of the most important scientific and practical discoveries in the world, was that only one or two countries had made any use of this discovery, although it afforded a means of controlling the disease which cost more in money and lives than any other in the world.

It is well known that there are many different kinds of mosquitoes which carry this disease. Without an exact knowledge of the habits of these mosquitoes it is difficult to deal with them, and in some cases an impossible task.

In one area, jungle has to be cleared and the disease disappears entirely; in another, jungle must be preserved over streams to control malaria. Water is taken underground in subsoil pipes in one place; and in another open drains suffice. Sometimes it is cheaper to remove buildings than exterminate the mosquitoes which cause the malaria.

In Assam there are three different problems at least. There are swamps which are quite harmless, although they are the winter resort of the bad mosquito. When the rains come the mosquito moves up into nullahs, which were dry in the cold weather. Then they begin to breed and spread the disease. In such places the swamps which appeared dangerous are really harmless, and the harmless-looking dry nullahs are very dangerous. Sometimes the whole of the malaria on a large estate only comes from a couple of little streams, and wide stretches of wet rice land are harmless.

It is still a complicated problem which a very few people really understand. Unless sound advice is available, money and time can easily be wasted carrying out unnecessary work and leaving the really dangerous places.

The Malaria Department was hung with plans, diagrams, maps and photographs, and as each problem was mentioned Sir Malcolm referred to the corresponding exhibits.

He continued: In India many medical men still believe that it is quite impossible to control the mosquito economically anywhere; and that has been the accepted opinion until recently.

In Assam comparatively little has been done, although the disease is widespread and destructive. The remedy is to get estate doctors, Managers, Engineers, etc., to come to the Ross Institute when on leave, and learn what can be done to control malaria. Already three men are working here and going through a practical course of malaria control, and a number of others have arranged to come.

Sir Malcolm Watson then outlined the practical course he proposed to give at the Ross Institute. He advised members to send their men to the Malaria Department of the Ross Institute to acquire this practical knowledge. It has taken considerable time to work out the many problems of malaria control in different countries. The Institute is now able to offer advice based on that knowledge in many cases. It is desirable that men should bring with them plans of their estates, statistics, etc., to facilitate the solving of their problems. Finality has by no means been reached, and the more difficulties that are brought to notice the more we shall learn. It is the aim of the Institute to have experts in the Tropics who can go out and advise industrial concerns on the spot.

One of the things that made for the success of malaria-control in the Federated Malay States was that the Malaria Advisory Board would not approve of any

Nov., 1929.]

expenditure unless a proper scheme was put up. He intended to follow up the same policy at the Ross Institute.

Mr. G. H. Masefield said that a few years ago he visited the Federated Malay States, and was amazed to find places which in Ceylon it would be impossible to live in free of malaria. When he was Chairman of the Ceylon Association in London he wished to bring home to the members how far Ceylon was behind the Federated Malay States. At that time Sir Ronald Ross offered to go out to Ceylon on malaria-control. The result of his visit was very satisfactory, and created much interest, and the planters were now working together for the common good. The Ross Institute could help to supply knowledge, and instruct men to whom planters could turn for information and advice, then malaria-control in the East will only be a matter of time.

Sir Malcolm Watson explained that, as, except in a few places, little anti-malarial work had been done, there were few men with practical experience who could advise. He mentioned places where good work had been done.

The Executive Committee had arranged a subsidy for certain men who were doing special work in malaria-control in the tropics. Malaria-control is not necessarily a question for the medical man, but for the entomologist and the engineer. Local Committees should be formed, and these would send their problems home to the Central Advisory Committee.

Mr. Crosbie Roles raised the question of controlling malaria in Bengal, and Mr. Still suggested that Governments, when making appointments, should require that a certain percentage of their men who have already had a general training should have some practical training, such as might be obtained at the Ross Institute. When it came to the question of individual estates, good health is one of the most vital and important factors of success. Those in control require just that guidance which is wanting at present, and which might most advantageously be given under the proposals which have been made. If Companies can be persuaded that it would be to their advantage to send their men to the Ross Institute for a three months' course, to acquire knowledge to enable them to detect the actual nature of the trouble, then they would repay themselves tenfold for their expenditure.

Sir Malcolm Watson stated that he proposed that this Committee would direct its energies principally to industrial concerns. As regards Governments, some officers had already arranged to come to the Institute. Any Government doctor or official is welcome at the Ross Institute, either to obtain advice in the Malaria Department or to have free facilities to use the research laboratories, and he hoped Governments would take advantage of this.

Mr. Mackie asked how long it would take to give estate managers the necessary instruction.

Sir Malcolm replied that useful knowledge could be acquired in three months, but that even in a week much valuable information could be gained. It would be advisable for men to come in groups.

In addition to photographs and plans, the Institute has the equivalent of 15,000 feet of standard film, illustrating malaria-control throughout the tour just made in India, Assam and Ceylon.

Speaking of malaria in Bengal, Sir Malcolm said that it is only within the last 70 years that malaria had spread in a severe form in Western and Central Bengal. There are two opinions as to the cause of the disease. One that the embankments prevent flooding, which is Nature's way of controlling mosquitoes there. This party says that embankments must be removed. The other opinion is that embankments are necessary, and drainage, not flooding, is required. Bengal will follow the way of Ceylon if something is not done soon to control malaria. Two-thirds of Ceylon is now uninhabitable on account of malaria.

(Whilst we cordially wish the Ross Institute every success in its endeavours to arouse interest in malaria-control in the tropics, we do not think that conditions in Assam and Bengal are quite as black as Sir Malcolm Watson makes them out to be. The crux of the matter,

of course, is want of money; not the want of trained malariologists. The very successful campaign against kala-azar in Assam means that there is but little money available for anti-malaria measures; and the same is true, to a less extent, in Bengal.

Yet there is much malaria-control going on in Assam. There have been very successful schemes introduced by the Public Health Department of that province at Lumding and Pasighat, whilst the Eastern Bengal Railway employs the services of a malariologist, Captain Chlam. On the tea gardens the work of such medical men as Dr. Ramsay in Cachar, Dr. Murphy in South Sylhet, and Dr. Williams of the Assam Frontier Tea Co. in the Upper Assam valley all shows what can be done in the way of malaria-control on the tea gardens. The Indian Tea Association are very fully awake to the importance of this problem, and have shown every intention of financing anti-malaria measures. Dr. Strickland's surveys of malaria in the Assam tea gardens and in the Dnars have given a general outline of the problem and of the measures necessary.

In Bengal, apart from the important work of the Co-operative Anti-Malarial Societies (with which Sir Malcolm Watson is familiar), there is excellent work being carried out by the Malaria Department of the Public Health Department. We have recently perused no less than thirteen reports on various malaria surveys carried out in Bengal within the last two decades. One of the most strikingly successful malaria-control schemes was that carried out during the construction of the Sara Ghat bridge—one of India's greatest engineering feats—where the main line of the Eastern Bengal Railway crosses the treacherous bed of the Ganges. There is nothing about this work in the journals, but the fact remains that most successful measures were taken to control both malaria and cholera among the labour force employed. Further south, the new construction by the Bengal-Nagpur Railway of a line from the Central Provinces to Vizagapatnam in connection with the construction of a new first class harbour at the latter port would have been impossible without the services of a malariologist (Mr. R. Senior White). An account of the malaria problem in connection with this scheme was published in our columns in 1928 by Mr. Senior White.

Further, our readers must be well aware of the classes of training in field work in malaria held by the Malaria Survey of India at the Ross Experimental Field Station at Kurnal; whilst there is to be a chair in malariology in the new Rockefeller Institute of public health in Calcutta. The trouble is not that India has no facilities for training men for malaria-control in the field—the contrary is the case; but that funds are lacking).

THE BRITISH SOCIAL HYGIENE COUNCIL.

The British Social Hygiene Council announces that Mr. L. S. Amery, M.P., has accepted the Chairmanship of its Imperial and International Committee, which besides co-ordinating and disseminating information and experience on matters relating to venereal diseases, also interests itself in the study of the scientific foundations of Social Hygiene as related to the different conditions of the Empire.

Following immediately upon the conclusion of the Fourth Imperial Social Hygiene Congress which was held in London last July, Mr. Amery's acceptance of this position will mark a very definite step in advancing the study of the social hygiene problems which present themselves in an extraordinary variety of ways to health and education administrators, missionaries and other social workers throughout the Empire.

The desirability of providing them with a knowledge of the subject before they go abroad, and with facilities for keeping abreast with the latest developments and methods of approach has been recognised. In this connection a diploma course has been instituted at Aberystwyth University, and in the near future courses will be established at other universities.

Mr. Amery, when in office, keenly interested himself in bringing these facilities to the notice of the Colonial

Governments, suggesting that they should offer scholarships for the purpose. Definite steps have also been taken by the Council to secure the extension of preparatory courses available to Colonial officials before proceeding overseas to take up their positions.

A further development has been the establishment of a Joint Committee of the British Social Hygiene Council and the Board of Study for the Preparation of Missionaries, with a view to equipping those who are about to enter the missionary field, or are on leave at home, with opportunities of acquiring scientific knowledge of the subject.

The proceedings of the Imperial Social Hygiene Congress this year emphasised the need for the creation of a biological general staff for the Empire to think out and direct research and inquiry, not only into national resources but also into the development of the health and well-being of the diverse races within the Empire.

BENGAL COUNCIL OF MEDICAL REGISTRATION.

THE Council have found Dr. Sailendranath Mitra, M.B. (Register No. 3187) guilty of infamous conduct in a professional respect and have directed that his name be erased from the register of registered practitioners maintained under the Bengal Medical Act, 1914. They will be ready to consider an application for the restoration of his name to the register should it be made a year after the date of their decision, viz., the 25th July, 1929.

THE ROYAL INSTITUTE OF PUBLIC HEALTH, LONDON.

So many medical men from India nowadays proceed to Great Britain to take out a Diploma in Public Health that the recently published syllabus of the course of instruction for 1929 at the Royal Institute of Public Health, 37, Russell Square, London, W.C. 1, may be of interest to some of our readers.

The following is a résumé of the scope and work of the Institute, taken from the syllabus.

In view of the claims being made elsewhere which may lead to misconception as to the national and international position held by The Royal Institute of Public Health, the Council of the Institute think it necessary in justice to the Fellows, Members and Associates, who have for so many years supported its work and made its continued advancement possible, to make a brief statement as to its position.

The Royal Institute was the first, and has been for many years the only, central school for teaching and research work in all branches of preventive medicine, for the training of post-graduate students, and especially of students proceeding to Degrees and Diplomas in Public Health. The Institute has been in active operation since 1886 and was instrumental in securing for the nation that adequate foundation upon which the public health services of the country now rest, and particularly in 1888 securing that a full qualification in public health must be held by all Medical Officers of Health of districts with 50,000 or more inhabitants, and that a detailed and uniform curriculum should be prescribed for use by the General Medical Council for practically all examining bodies. The qualification was subsequently rendered necessary for all such appointments in Scotland, and indeed to-day, no appointment in the Public Services at home or abroad of a public health character can be obtained by a candidate without its possession.

There existed in London at that time no central school for complying with the provisions of this curriculum and the Council of the Institute acquired and adapted the present premises for the purpose. The bacteriological and chemical laboratories are recognised as amongst the best equipped in London. The Lever Museum, added through the generosity of the late Viscount Leverhulme, a lecture room, a reference library and a common room are other features.

The provision thus made for complying in all respects with the regulations was recognised by all the Universities and Medical Colleges as fully qualifying candidates

for admission to the examinations for Degrees and Qualifications in Public Health. From 1905, when the training courses opened, to 1929 no fewer than 829 students have entered and many of the Institute's successful students fill Public Health appointments of the first importance in all parts of the world.

Of the candidates presenting themselves for the Examinations for the Diploma in Public Health the average number of successes is 84 per cent.

The international position of The Royal Institute of Public Health is evidenced by the series of Annual Congresses which have been held under its auspices in Great Britain and Ireland and in the leading Continental cities. Amongst the foreign cities thus visited may be mentioned Berlin, Paris, Brussels, Bordeaux, Ghent and Zurich.

Amongst the awards at its disposal, are the Harben Gold Medal and the Harben Lectureship, which are bestowed by the Council irrespective of nationality. Amongst the recipients of the former are Simon, Pettenkofer, Lister, Koch, Metchnikoff, Behring, Roux, Gorgas, Kitasato, Pasteur and Ronald Ross, and the Harben Lectureship has been held by Klein, Woodhead, Calhette, Gruber, Ronald Ross, Metchnikoff, Ehrlich, Nuttall, Pfeiffer, Uhlenhuth, Flexner, Bordet, Vaillard, Houston, Madsen, Levaditi, Topley, etc.

The Council of the Institute look forward to the continuation and development of its work for the advancement of knowledge in the great field of public health, the training of workers entering that field, and the bringing together for co-operation and conference of those already engaged in it both at home and abroad.

The Council have recently acquired a site in a commanding central position in close proximity to its present building, where it is proposed, to erect a more commodious building worthy of the Institute's international position and increasing usefulness.

REGULATIONS FOR DIPLOMA IN PUBLIC HEALTH.

(Adopted by the General Medical Council, May 22, 1922) which came into force January 1, 1924.

Under the Regulations the Course of instruction must cover at least twelve calendar months subsequent to obtaining a registerable qualification, and must include:—

PART I.

Laboratory Work and Practical Instruction (during a period of not less than five months) in:—

A. Chemistry and Physics (at least 90 hours), of which 70 hours shall be occupied in practical laboratory work.

Meteorology and Climatology (at least 10 hours).

B. Bacteriology and Parasitology (at least 180 hours), of which 150 hours shall be occupied in practical laboratory work.

PART II.

C. Instruction in:—

Principles of Public Health and Sanitation (at least 30 hours).

Epidemiology and Vital Statistics (at least 20 hours).

Sanitary Law and Administration (at least 20 hours).

Sanitary Construction and Planning (at least 10 hours).

D. Work with M.O.H.

Every candidate shall produce evidence that he has during a period of not less than six months, been engaged in acquiring a practical knowledge of the duties, routine and special, of Public Health Administration under the supervision of a Medical Officer of Health, who shall certify that the candidate has received, from this Officer or other competent Medical Officer, during not less than three hours on each of sixty working days, practical instruction in these duties, and also those relating to:—

(a) Maternity and Child Welfare Service.

(b) Health Service for Children of School Age.

(c) Venereal Diseases Service.

(d) Tuberculosis Service.

(e) Industrial Hygiene.

(f) Inspection and Control of Food, including meat and milk.

Certificates of having received the prescribed instruction in Public Health Administration must be given by a Medical Officer of Health who devotes his whole time to public health work; or by the Medical Officer of Health of a sanitary area having a population of not less than 50,000, or in Ireland the Medical Superintendent Officer of Health of a County or County Borough having a population of not less than 50,000.

The following are the names of the professorial staff of the Institute:—

Principal.—Col. Sir W. R. Smith, M.B., D.Sc., D.P.H. (Camb.), F.R.S.E.

Chemistry.—Dr. A. W. Stewart, D.Sc., A.I.C.

Applied Bacteriology and Immunology.—Dr. E. G. Rawlinson, M.D., D.P.H. (Oxon.).

Hygiene and Sanitation.—Dr. A. E. Thomas, M.A., M.D. (Oxon.), D.P.H. and Dr. G. E. Oates, M.D. (Lond.), D.P.H. (Camb.).

Public Health Administration.—Dr. C. W. Hutt, M.A., M.D. (Camb.), M.R.C.P., D.P.H. (Oxon.).

Port Sanitary Administration.—Dr. C. F. White, M.D., D.P.H., D.T.M., Medical Officer of Health to the Port of London.

Meat Inspection.—Mr. C. Slatter, Inspector, Smithfield Market.

The Harben lectures for the year are to be given by Dr. R. A. Peters, M.A., M.D. (Oxon.), whilst a special series of ten lectures by eminent authorities on problems of personal and public health is also to be given during the session.

As will be seen, the staff of the Institute is a very strong one, and medical men from India desiring to take out a Diploma in Public Health in Great Britain might do well to write for the full syllabus.

Current Topics.

Notes on Fractured Patella.

By A. P. BERTWISTLE, M.B. (Leeds), F.R.C.S. (Edin.).
(*The Lancet*, Vol. CCXVI, June 29th, 1929, p. 1349.)

Fractures of the patella may be classified in two main groups according to their causation and treatment, viz., those due to direct violence, and those caused by muscular action. Whilst all are in agreement about the treatment of the former, that of the latter is by no means standardised. This is all the more surprising, as the patella was the second of all bones to be wired, and this procedure gives as good results as any other of its class. The olecranon was the first bone to be wired, and to credit of wiring the patella, is also due the Cameron preceded Lister, who performed this operation, is also due the credit of wiring the patella, though Cameron preceded Lister's boldest surgical effrontery. P. Turner recently reported a case operated upon by Howse 38 years ago; he probably used the carbolic spray and kept the limb on a back splint for six weeks. At that time Malgaigne's hooks were considered effective, but the pain and irritation they caused led to their abandonment.

Fracture from Direct Violence.

Fractured patella may occur in several members of the same family and refracture at the same or a different place is not uncommon. Both these facts suggest a congenital weakness. Bilateral fracture, of which I have seen an example, is not uncommon. Direct violence usually causes a starred fracture by crushing the patella against the femur, though transverse and longitudinal breaks are not unknown. The front of the joint becomes extremely swollen, partly from bruising, and partly from distension of the prepatellar bursa. It is only later that the joint itself becomes distended. Some movement prevents it later. The aponurosis and lateral expansions are not divided, and hold the fragments in position. The fracture may be simple or compound. Lateral plaques are usually found at the upper and outer angle of the bone and are often bilateral, a point of considerable

diagnostic importance. I have seen one, and Skudder depicts several. The discovery of these plaques after an accident may present considerable confusion, and the symptoms may be due to injury to them.

(a) *Simple Fracture*.—All are agreed that it is inadvisable to operate on the starred fracture. The first essential is to reduce or at least arrest the swelling by an elastic bandage or firm bandaging over wool; evaporating lotions are of some service. A moulded back splint or a calliper is applied so that the limb can be elevated to an angle of 45°, to relax the rectus femoris, which is more or less taut when the limb is in line with the body. Massage is applied daily to the quadriceps, which otherwise wastes rapidly. No active movement is permitted for three weeks, but passive movement should be recommended, or the clots and effusion organise into strong bands which may require open operation. The patient walks with a calliper which permits slowly increasing range of movement after the third week.

(b) *Compound Fracture*.—Fracture from direct violence may result in a compound fracture with a lacerated or punctured wound; the latter is liable to be overlooked, suppuration being the first indication of it. All compound fractures should be explored under anaesthesia and the wound carefully excised.

The immediate prognosis is good, bony union being the rule. There is, however, a liability to arthritic changes, since the joint may have been injured as well as the patella.

Fracture from Muscular Action.

By far the commonest accident is for the patient to have imagined a non-existent step while walking upstairs; he jerks his leg forward and collapses, so that the break occurs with the limb flexed. Lister's cases all occurred whilst the patient was in the act of extending the limb to prevent a fall. Immediately after the accident inspection reveals between the fragments a gap which is well seen in the silhouette-radiogram. Power to extend the leg is almost if not completely lost, though it may be possible to walk by swinging the leg forward and hyper-extending (Cotton). Effusion of blood and synovial fluid cause the joint to be distended earlier and to a greater extent than in the other variety of fracture.

The fracture is usually a clean, transverse one associated with a variable amount of laceration of the lateral expansions; the greater the laceration the wider the separation. A very important feature is that the aponurosis over the patella tears at a different level from that of the fracture and comes to dip down over one fractured surface; crepitus, if felt, is therefore soft. The gap may be anything from $\frac{1}{2}$ in. to 3 in. The lower fragment is usually tilted, so that its fractured surface is directed anteriorly.

The differential diagnosis is from: (1) dislocation; a radiogram clears up any doubt. (2) Ruptured ligamentum patellæ; the ligament is rarely ruptured, but usually evulses a flake of the tibial tuberosity, which is well seen in the radiogram, together with the wide separation of patella from tibia. (3) Torn quadriceps; a rare condition differentiated radiographically.

Treatment.

The knee-joint has the largest area of synovial membrane and the greatest number of vitally important ligaments of any joint in the body. It possesses the largest amount of avascular tissue in the form of cartilage. Its poor bony architecture and its exposed position favour synovitis, which may go on to arthritis; in fact, it is the commonest joint to suffer from these conditions. Draining the joint is fraught with danger to itself if not to life. An ankylosed knee is a most crippling deformity.

Two methods of treatment are in use, the conservative and the operative. Most surgeons would not operate unless the gap is very small, as only after operation can bony union occur. The aseptic surgeon of to-day does not consider that the behaviour of the patella differs from that of any other bone after operation. Pre-Listerian results of operation, especially on longstanding cases, surrounded the patella with an evil reputation which is not yet dissipated.

(a) *Conservative Method*.—From the start the limb is put up in the same position as has been described for the starred fracture. Means are taken to reduce the swelling. Some authorities use two loops of bandage, applied above and below the fracture, to maintain apposition, but these are not satisfactory and may cut the skin. Skudder's figures are probably as good as any, and yet he only secured 66.5 per cent. of serviceable limbs in six patients not treated surgically, whereas he had good results in 84.5 per cent. of operations; he does not say why some were operated upon and others not. Sir William deCourcy Wheeler records a perfect result with wide separation. Possibly the poor results are due to failure to elevate the limb during treatment.

(b) *Operative Treatment*.—The after-treatment is very much simpler and saves a considerable amount of time but—what is still more important—operation ensures bony union in most cases and, even if there is a gap, it is of little functional disadvantage. The objections were the fatalities and complications of pre-aseptic days. The former have almost disappeared; the latter are still with us and may be attributed to:—

(1) Faulty preparation of the skin. The whole limb from buttock to toes should be prepared with spirit soap and antiseptics for three days. Fomentations are useful for the rugæ around the knee. At the time of operation there should be no eczema or blisters, since the latter teem with micro-organisms. To operate immediately is risky.

(2) Unnecessary trauma. It is frequently observed that a surgeon who cuts and is gentle, yet not overfastidious as regards asepsis, gets results which compare favourably with those of one who tears and is rough, but who is scrupulously aseptic. One of the advantages of operation is the possibility of removing clots, but this must be done with the greatest gentleness with forceps and isotonic saline irrigations and not with gauze, since this tends to damage the cartilage and may cause the entrance of bacteria. A joint is well able to remove clot, as is seen in hæmophilic effusions. Trauma is very important in dealing with

(3) Devitalisation of the describes some dissections performed by Manning which demonstrated that the vascular arch supplying the patella was torn across the internal condyle. This cutting-off of the blood-supply explains the formation of sequestra in unopened fractures, of which Erichsen cites a case. Still more important is its bearing on cases where these form after operation. This devascularisation makes the patella an easy prey to sepsis.

Steps in the Operation.

(1) *Time of operation*.—Probably the fourth is the ideal day; the first should be devoted to reduction of swelling.

(2) *Application of a tourniquet*.—This useful measure is sometimes omitted. If any vessels are seen they can be ligatured; a firm dressing suffices to arrest capillary and venous hæmorrhage.

(3) *Flaps*.—These are horse-shoe shaped; if they are turned up their vitality may be better secured, but if they are turned down the resulting scar is outside the pressure-bearing area of the knee.

(4) After raising the flaps it is imperative to *change gloves* or, better, to remove the outer of two pairs worn at the start.

(5) *Tetra-cloths* must be arranged to prevent skin contamination.

(6) The field must be cleared of *blood-clot* and as much as possible removed from the joint with forceps and saline irrigation. Tags of tissue which are of no use for suture are removed.

(7) *Wiring*.—The number of methods in use is legion, suggesting that the ideal is yet to be sought, but Hey Grove's original method fulfils all that is necessary. Two wires are passed transversely and the ends twisted. If trouble arises later, all that is required is an incision over each twist, cutting the twist on one side and removing the rest of the wire. Surgeons generally advise that, if the lower fragment is too small, the wire should be passed through the ligamentum patellæ, and

this was actually found necessary in one of Lister's cases. It is in any case much better to introduce one wire through the ligament or rectus expansion, for this makes it much easier to correct any angulation without re-drilling. This tissue, moreover, resents a foreign body far less than such a vital structure as bone. A suture passing into the joint was once used, but no joint will stand such an insult.

(8) *Elevation of the limb*.—This is a most useful manoeuvre at the time of twisting the wire and one which, in a recent case at the Wembley Hospital, obliterated a gap of 1 in. with ease.

(9) *Suture of periosteum* over the patella.—Some surgeons, including Sir Robert Jones, rely entirely on suture of the periosteum and lateral expansions, but the omission of wiring precludes early movement.

(10) *Suture of the lateral expansions and tear in the capsule*.—This is of the greatest importance.

(11) *Suture of the skin*.

(12) A firm, bulky dressing arrests hæmorrhage and effusion and restrains movement. Some surgeons use a back-splint until the patient is round from the anæsthetic.

(13) *Removal of the tourniquet*.

After-treatment.

On the third day a less bulky dressing is applied and massage to the quadriceps is commenced. All dressings are removed between the seventh and tenth days, when the wound should be healed. The patella may with advantage be moved on the femur to prevent adhesions. The patient is allowed to walk with a stick after two or three weeks and should be able to resume his former occupation in three months.

It was observed during the late war that fractures united more quickly in the south of France, where it was warm, than in the north. Recently I have tried radiant heat for fractures; the patients were pleased and one case, where union had been delayed, united rapidly under heat.

Wire v. absorbable suture.—This is a very controversial subject. Wire permits early movement, which most surgeons consider advisable, though some, including Sir Robert Jones, keep a fractured patella six weeks on a back splint. Against the advantage of strength is the fact that wire is not well tolerated by some patients and may have to be removed or it may break months after insertion. Kangaroo tendon is good but scarce. Autogenous grafts, first used by Golding Bird, are awkward to use and lengthen the time of operation. Stout catgut possesses little tensile strength after a week.

Old Fractures.

To quote Lord Lister, "the ununited case is in every respect worse as a subject for treatment than the recent one." It is these cases which account for many of the failures of operative treatment. It is imperative to freshen the ends by sawing off a flake of bone, so introducing the all-important element of trauma. In addition to lengthening of the ligaments, there is often marked wasting and contracture of the quadriceps. The contracture may be so marked that the operation has to be performed in two stages, the first aiming at reducing the separation as much as possible with the limb elevated, subsequently allowing it to be lowered for a week or so. The second consists of making apposition. In severe cases the rectus femoris or even the quadriceps may need incisions to lengthen them. Extreme old age, debility, and infective conditions are the only strong contra-indications. Spinal or regional anæsthesia can be used where necessary. The outlook for diabetics has been completely changed since the advent of insulin and a properly controlled diet.

Summary.

(1) Starred fractures should be treated on conservative lines, elevating the limb to an angle of 45°.

(2) Transverse fractures with separation are best treated by operation.

(3) Complications and deaths after operation are due to sepsis caused by (a) faulty preparation of the skin, and (b) unnecessary trauma. They are predisposed to by devascularisation of the patella.

(4) Hey Grove's method of using two transverse wires is the ideal one.

(5) Elevation of the limb at the time of securing the twist is most helpful.

(6) Old fractures account for most of the poor results.

The Medical Management of a case of Gastric or Duodenal Ulceration.

By JOHN H. ANDERSON, C.M.G., C.B.E., M.D. (Melb.),
(*The Lancet*, Vol. CCXVI, June 29th, 1929, p. 1347.)

In days gone by medical measures were employed exclusively in the treatment of gastric ulcer, and though gastric surgery has advanced greatly in recent years, medical treatment has lost nothing of its importance whether or not it is combined with surgery.

Medical treatment can be divided into: (a) feeding entirely by the bowel, or (b) a graduated diet, with alkalis, by the mouth. The latter practice is the routine adopted at Ruthin Castle. Essentials for medical treatment are: (1) co-operation of the patient, (2) removal of septic foci, (3) rest, (4) diet, (5) alkalis.

Co-operation of the Patient.

When the diagnosis is established the patient is told that this disease may be treated medically or surgically, and unless there is some feature calling for surgery medical measures are advised. It is stipulated that a reasonable time be given for treatment, otherwise it is feared that the result will not be satisfactory to patient or physician. Three months is suggested as the minimum time required, of which the first month is spent in bed, about a month getting up and about, and a third month for a general return to active life. For the first two months institutional treatment is to be preferred; for it has been our experience that treatment undertaken at home is not so successful as that carried out under the constant supervision which is possible in a hospital. The diet also calls for a care and precision which it is difficult to organise in a private house.

For example, a man of 37 preferred to carry out treatment at home when he could attend to his work with the help of a telephone by the bedside and daily visits from a stenographer and his works manager. All symptoms ceased, but the anæmia did not improve and x-rays two months later showed no change in the gastric lesion, a small pre-pyloric ulcer.

During his time in bed an attempt is made by daily talks to get the patient to understand the reason for the various points in his routine, with a view to shaping his life after he leaves hospital. Lawrence has ably described the "diabetic life," and we attempt to lay down in these cases what may be called the "ulcer life," pointing out where dangers lie and emphasising the need of careful supervision by his medical attendant, and of a permanent routine after leaving hospital.

Removal of Septic Foci.

If not already done, the body is searched for sources of infection. In this quest mouth, throat, tonsils, nasal sinuses, teeth, bowel, gall-bladder, kidneys, and urinary bladder are systematically gone over and any lesion dealt with as far as possible. The importance of this procedure cannot be stressed too highly. If in this connection laparotomy is required, the opportunity is, of course, taken to examine the ulcer and carry out any further surgical procedure that seems desirable. We have seen a gastric ulcer without any deforming or crippling operation on the stomach. Even when the collaboration of a surgeon has been sought, and the case dealt with in the first instance by him it is felt that when the surgical condition has been relieved, the medical after-treatment should be in the hands of a physician.

Rest.

The whole body is rested by at least four weeks in bed, lying on the back, shoulders flat on the bed, and head raised by one or two small pillows. Daily massage helps

to keep up the muscular nutrition and to avoid the cramps and aches which otherwise so often occur, particularly in the first two or three days in bed, and later about the end of the second week. The stomach is rested by frequent small meals as indicated under "diet." Aperients are avoided, and at first an enema is given on alternate days. At a later stage liquid paraffin is added and, as a rule, before the patient is getting up the bowels are acting naturally.

Diet.

In former days fasting or rectal feeding was the routine method. The present method is a modified combination of the diet of Lenhartz, and the olive oil of Cohnheim and Walko. The régime cannot be applied as it is set forth to every, probably not to any, patient. Each case requires individual care and inquiry with resulting modification of the instructions.

The diet is graduated in 26 steps, starting with olive oil and alkaline water and working up gradually to a light diet. The best idea of it may be given by setting out three or four stages.

Diet on First Day.

(30 c.cm. = one ounce.)

8 a.m.	15 c.cm. of olive oil.
9 "	60 c.cm. of alk. water.
11 "	15 c.cm. of olive oil.
12 noon	60 c.cm. of alk. water.
2 p.m.	15 c.cm. of olive oil.
3 "	60 c.cm. of alk. water.
5 "	15 c.cm. of olive oil.
6 "	60 c.cm. of alk. water.
8 "	15 c.cm. of olive oil.
9 "	60 c.cm. of alk. water.
10 "	15 c.cm. of olive oil.

Food value = 770 cal. approximately.

A few patients cannot take olive oil at all, and in this case a milk cream mixture is substituted for the oil. This is made by mixing 180 c.cm. of milk, 60 c.cm. of lime water, and 60 c.cm. of cream. The alkaline water is made up of 15 grammes of bicarbonate of soda in one pint of water, and an extra 30 c.cm. is allowed between the olive oil feeds if the patient desires. It has been found possible to start gradually a diet of this nature three or four days after a hæmorrhage.

Diet on Third Day.

This consists of egg and milk mixture three-hourly with a dose of olive oil an hour before each feed.

8 a.m.	30 c.cm. of olive oil.
9 "	30 c.cm. of olive oil.
11 "	50 c.cm. of e.m. mixt.
12 noon	30 c.cm. of olive oil.
2 p.m.	50 c.cm. of e.m. mixt.
3 "	30 c.cm. of olive oil.
5 "	50 c.cm. of e.m. mixt.
6 "	30 c.cm. of olive oil.
8 "	50 c.cm. of e.m. mixt.
9 "	30 c.cm. of olive oil.
10 "	50 c.cm. of e.m. mixt.
			30 c.cm. of olive oil.

Food value = 1790 cal. approximately. F.an. mixt. = egg and milk mixture.

The egg and milk mixture consists of one egg in 100 c.cm. of milk, is taken in sips, and if possible is made to last from one dose of olive oil to the next. Alkaline water is provided and sips are taken when required for thirst at intervals of not less than 15 minutes. The olive oil is gradually reduced and the egg and milk mixture increased. On the seventh day boiled rice is added, and on the eighth day minced or pounded chicken.

Diet on Twelfth Day.

Here four meals are given, olive oil before the two chief ones, and extra feeds of egg and milk at 2 p.m. and 9 p.m. 30 g. = one ounce.

Breakfast, 8-30 a.m.—One egg; dry toast (25 g.); butter (10 g.); milk and water (100 c.cm.).
11-30 a.m.—30 c.cm. of olive oil.

Lunch, 12 noon.—Minced or pounded beef (56 g.); dry toast (20 g.); butter (5 g.).

2 p.m.—Egg and milk mixture (150 c.cm.).

Tea, 4 p.m.—Thin bread and butter (20 g.); milk and water (170 c.cm.).

6-30 p.m.—30 c.cm. of olive oil.

Dinner, 7 p.m.—Boiled rice (30 g.); milk and water (100 c.cm.); dry toast (20 g.); butter (5 g.).

9 p.m.—Egg and milk mixture (150 c.cm.).

Food value = 1930 calories approximately.

The alkaline water is still allowed for thirst. The milk and water mixture consists of 55 c.cm. of milk and 35 c.cm. of water. The allowances are increased gradually, as is shown by the diet on the twentieth day.

Diet on Twentieth Day.

Much the same as the preceding, but with more variety.

Breakfast.—Egg or fish; dry toast; butter; milk and water.

11-30 a.m.—30 c.cm. of olive oil.

Lunch.—Chicken; mashed potatoes; dry toast; butter; rice pudding; milk and water.

2 p.m.—Egg and milk mixture.

Tea, 4 p.m.—Dry toast or dried bread and butter; sponge cake; milk.

6-30 p.m.—30 c.cm. of olive oil.

Dinner, 7 p.m.—Steamed fish; toast and butter; macaroni or vermicelli; milk pudding or custard; water or soda water.

10 p.m.—Milk and rusk or Bengers' food.

Food value = 3000 calories approximately.

If pain or discomfort recurs the diet is kept the same for a day or two or is taken back to an early stage, and increased again later.

As the patient gets up, more foods are added, and the diet on leaving is made up as follows:—

Diet on Leaving.

A light ordinary bland diet.

Breakfast.—Porridge, fish, cold fat ham, egg; toast; butter; cream; flavoured milk or weak China tea.

Lunch.—Chicken, mutton, or lamb; potato; sieved greens; milk or light steamed pudding; cream; sieved fruit.

Tea.—Bread and butter; sponge cake; milk and water or weak tea.

Dinner.—Fish, chicken or sweetbread; potato; sieved greens; macaroni or vermicelli, milk pudding, cold sweet, sieved or puréed fruit; toast; butter; cream.

It must be repeated that in all cases variations are necessary to meet personal likes and dislikes and ingenuity is often severely taxed. It is surprising, however, how few failures there are in keeping fairly close to the desired diet if patience, tact, and humanity are displayed in the dealings between doctor and patient. Visiting at meal times is often a great help.

Alkalis.

Various alkalis are used, such as sodium bicarbonate, sodium citrate, cremor magnesiæ, magnesium carbonate or hydroxide, and calcium carbonate. Bismuth oxychloride is generally given three times a day in water as a routine; sodium bicarbonate is in the alkaline water which the patient takes steadily throughout his time in bed, and the other drugs are used from time to time as required. The magnesium compounds are especially useful if constipation is a feature, and the cremor magnesiæ if gastric flatulence is a leading symptom. The well-known combination of the carbonates of bismuth and magnesium and the bicarbonate of soda should be specially recalled. Another useful powder is one made up of equal parts of bismuth oxychloride, sodium citrate, and mag. carb. lev., one teaspoonful as a dose three times a day after meals in water. If there is any looseness of the stools calcium carbonate is substituted for the magnesium carbonate. No case of alkalosis has been seen.

General.

While in bed the mouth is cleaned after each feed, and sleeping helped when required with small doses of

medinal or dial ciba. If wakefulness is complained of, a small feed through the night is often more useful than a hypnotic. Smoking is discouraged.

Progress.

Progress, as a rule, is uneventful and is checked by: (a) disappearance of symptoms; (b) examination of stools for blood, visible and occult; (c) radiography of the stomach. The pain gradually eases and, as a rule, is gone by the sixth to seventh day, though intermittent discomfort may be present for a few days longer. If pain is still prominent by the end of the second week, the case is reconsidered in all its bearings with a view to deciding whether medical treatment should be continued or surgery advised. At this time of alleviation of symptoms it is advisable to point out to the patient that his improvement does not mean a cure, but is merely an indication that cure would appear to be possible and even probable. He is told that the "ulcer is skinning over," but that time must be given for the new covering to become several cells thick. Histological work has shown that this process takes a long time; and it cannot be hastened. A useful analogy can be drawn between the healing of the internal ulcer and the gradual scarring of a deep abrasion of the skin. Blood disappears from the fæces at an early stage of healing, and the later progress can be judged from an x-ray photograph of the ulcer site. The diet is steadily increased as has been shown, and more latitude of movement is had allowed, and finally the patient is allowed to get up in a chair and out of doors as weather permits. Walking is carefully graduated, and violent exercise prohibited. He is cautioned that absence of symptoms does not mean that liberties may be taken. Lord Moynihan has stated the position in his aphorism that "clinical silence does not mean pathological inactivity," and this point is emphasised to the patient as clearly and as forcibly as possible. A normal life, with certain limitations, is resumed gradually, and on leaving hospital some simple instructions are given, in addition to the suggested diet as already described.

Example of Instructions.

The diet should consist of simple foods, avoiding beef, pork, pastry, vinegar, pickles, twice-cooked foods, and foods containing shreds and hard pieces. Hot fats and raw fruit should be taken sparingly, and all fruit and greens should be passed through a sieve.

For the present rest a full hour in the middle of the day and in the evening. Bed not later than 10 p.m.

Exercise daily in the open air, increasing the time gradually, but not to the point of fatigue.

The return to work should be gradual; at first not more than two hours a day, gradually increasing as strength is regained. Work should be so planned as to avoid long-continued effort or hurry. Enough time must be allowed for meals.

Alcohol is not advised. Smoking is not advised for the present, and when resumed should be limited to the half-hour immediately after a meal.

Continue the liquid paraffin, dose modified as required, and the olive oil before meals. Half a teaspoonful of bicarbonate of soda or of the prescribed powder, in water, should be taken an hour after meals.

The return to full strength will be gradual and no alteration in the régime must be made without medical advice.

Results.

The method of treatment here described has been used at Duff House and Ruthin Castle for 15 years, and has yielded good results in cases of gastric and duodenal ulceration in which there is no direct call for surgery.

In cases with much pyloric or duodenal deformity, those in which symptoms persist after a fair trial of medical measures and, above all, those with any suspicion of malignancy, operation is advised, not as a different method, but as an incident in the course of the treatment. In our experience this occurs in about one case in five of gastric ulcer, the other four do well under medical treatment and, as far as can be ascertained, most of them go on well if a reasonable life is followed. In

the last 30 cases of gastric ulcer four were advised operation. One died as a result of the operation, one refused operation and died later from a perforation, and the other two benefited from the operation.

Pernicious Anæmia : Preliminary note on the after-results of treatment with liver.

By J. F. WILKINSON, M.B., M.Sc., Ph.D., F.I.C.,
and

W. BROCKBANK, M.A., M.D. (Cantab.), M.R.C.P.
(*The Brit. Med. Journ.*, July 6th, 1929, p. 12.)

We have been investigating the after-results of all cases of pernicious anæmia admitted to the Manchester Royal Infirmary during and since 1925, and are publishing our preliminary observations in the hope that they will be of interest to other workers investigating this disease.

The cases fall naturally into two sections: (a) Those that received the usual treatment of arsenic and hydrochloric acid before the introduction of the Murphy-Minot diet. (b) Those that received the liver treatment, often in addition to the drugs mentioned. The total number of cases studied has been 80, of which 47 belong to the first group and 33 to the second. Briefly our observations are as follows:

(1) Of the 33 patients who left the hospital on the liver diet about 50 per cent. are very well and 15 per cent. in good health except for the symptoms of subacute combined degeneration of the cord, at an average interval of twelve months from their discharge. Only two (6 per cent.) are dead; one did not take the diet after discharge, the other took it regularly until he died (aged 66) fifteen months later.

(2) Of the 47 patients who were not prescribed the liver diet 50 per cent. are dead, at an average interval of ten months from discharge. The remainder, almost without exception, are now on the diet. Their progress is being watched.

(3) The patients who have done best are those who have taken the liver raw or half-raw. Those who have eaten it well cooked have not done so well.

(4) A history of tingling and numbness of the fingers and toes, presumably the earliest symptoms of involvement of the cord, was given by 44 per cent. of all our patients. Of those that are still alive and on liver treatment 52 per cent. have no such symptoms now; 11 per cent. are better, and the remainder (almost all of whom had alterations from the normal reflexes) are no better or are definitely worse. This suggests that liver treatment has no effect on the symptoms of subacute combined degeneration of the cord, once the reflexes show that there is organic disease in the central nervous system. The symptoms gradually become worse, although the patient's bodily health is much better.

(5) Relapses do occur even when the patients are taking liver regularly, but they are not nearly so common (only six cases noted in our series) as they were before liver treatment was tried. Five of these cases were taking the liver well cooked, the sixth was taking it raw, but the relapse followed an attack of influenza.

(6) Of the 47 cases of pernicious anæmia sent out without liver, only 2 had ever worked regularly before the advent of the liver diet; whilst of the 33 cases sent out on the diet 14 are back on full work and 5 are doing part-time work—a total of 57 per cent. at work.

(7) During their periods as in-patients (an average of forty-five days in each case) the following alterations in the constituents of the blood were noted:

	Erythro- cytes.	Leuco- cytes.	Hæmo- globin.
Patients not on liver.	+46%	-8%	+49%
Patients on liver	+94%	+41%	+77%

Of the patients who have done well, almost all have retained some degree of anisocytosis and poikilocytosis;

all have abundant platelets, and in all the staining of the erythrocytes is normal.

(8) Diarrhoea and gastric disturbances appear to have been cured by the liver treatment, only one case of recurrent diarrhoea having been noted in a patient who is otherwise quite well. There are no indications that treatment by hydrochloric acid has any appreciable influence—most patients discontinuing its use after discharge. Inadequate liver diet, however, frequently causes a return of gastric discomfort.

(9) Reinvestigation of the condition of the stomach by fractional test meals shows the following results:—

(a) Achlorhydria persists in nearly every case. Only two exceptions have been noted, and these will be discussed in a later paper.

(b) The total acidities of all samples withdrawn are greatly diminished, being equivalent to 1.5 to 10.9 c.cm. (average 4 c.cm.) of N/10 alkali per 100 c.cm. gastric contents.

(c) Total and mineral chlorides, whilst showing parallel titres, give widely varying values in different cases.

(d) Peptic activity is very considerably diminished or negligible.

(e) The fasting contents in over 80 per cent. of the cases are less than 38 c.cm., the remainder falling between 50 and 80 c.cm.

(f) In practically all cases mucus is present in very marked amount in the fasting contents and frequently in the earlier samples of the test meals.

(g) Lactic acid is invariably absent.

(h) The stomach empties on an average in one to one and a quarter hours.

(10) Several sequelæ of the diet have been described in the literature. Our observations on them are as follows:

(a) Persisting eosinophilia (5 to 14.75 per cent.) occurs in patients taking the liver diet.

(b) Albuminuria has never been found.

(c) One case of venous (femoral) thrombosis has been observed.

Treatment of Pruritus Ani and Anal Fissure; the use of Anæsthetic Solutions in oil.

By W. B. GABRIEL, M.S.

(*The Brit. Med. Journ.*, June 15th, 1929, p. 1070.)

FROM a practical point of view cases of pruritus ani may be divided into two main groups:—

(1) The group in which some definite local cause is present. This is usually some lesion which causes an abnormal amount of perianal moisture; amongst the commoner of these may be mentioned prolapsing piles, external piles, fissure, fistula, hypertrophied papillæ, rectal polypi and tumours, threadworms, proctitis, etc. Treatment of cases in this group, is limited to removing the exciting cause, together with treatment of the perianal region with simple lotions and powders, is usually effective.

(2) The second group is that in which patients complain of persistent severe itching, but examination reveals none of the obvious causes enumerated above. The rectum is smooth, and examination, as a rule, is negative, except that some evidence is found to confirm the patient's complaint of irritation. The perianal skin is often somewhat thickened and thrown into rugæ radiating from the anus, with a varying amount of excoriation of the skin or fissuring.

It is cases in this second group which are the great problem as regards treatment. It is probable that a chronic neuritis of the sensory nerves in the anal region is present in most cases of long duration, and hitherto the recognized treatment of cases which have failed to respond to local treatment of the dermatitis has been either (1) operation—Ball's operation or any of the various modifications designed towards sectioning the cutaneous nerves of the anus; (2) the subcutaneous injection of various solutions such as absolute alcohol, quinine-urea, hydrochloric acid, etc.; (3) x-radiation.

After working for the last eight years in the out-patient department of St. Mark's Hospital, I have been impressed with the unsatisfactory results generally obtained by these methods. Judging from the number of patients who attend who have previously had one or more courses of x-ray treatment, the conclusion is forced upon one that the relief obtained, if any, is often of short duration, and the necessity for repeated courses of x-rays is dangerous. X-ray dermatitis and x-ray carcinoma of the anus are well-known catastrophes. As regards Ball's operation, it is true that, if properly done, patchy anaesthesia results at once in the flaps outlined by the operation, but it seldom lasts more than a few months; the extensive wound never heals by primary union, and although there may be relief for a time, the irritation often returns after a few months. There is then quite often the added trouble that an atrophic condition of the skin flaps is liable to develop; the perianal skin within the two curved incisions appears thin, shiny, and discoloured, often with patchy excoriation; this may be partly a trophic condition from section of the sensory nerves, and partly due to the impaired vascular supply; it is, I think, a serious objection to Ball's operation.

Pruritus being essentially a local condition, it is reasonable to expect a local treatment to relieve it, and subcutaneous injection of an anæsthetic solution appeals to me as being a sensible method likely to succeed. I was therefore greatly attracted by the report of Drs. Yeomans, Gorsch and Mathesheimer on the use of benacol in the treatment of pruritus ani. This solution was introduced to me last autumn by Dr. Frankfeldt of New York, who very kindly provided me with a supply for trial at St. Mark's. To quote Dr. Yeomans: "Benacol is a solution of equal parts of para-amino-benzoyl-benzoate and phenethylol in 90 parts of rectified sweet almond oil. It is non-toxic, highly anæsthetic, moderately antiseptic, and, as far as investigated, has a mild depressant action on peripheral nerve endings."

The use of an oily as opposed to an aqueous solution would appear to be particularly valuable as a method of delaying absorption of the local anæsthetic, and therefore of extending the duration of its action. As an alternative solution to benacol, I have tried and found equally satisfactory a solution known as "A.B.A.," prepared for me by Messrs. Allen and Hanburys, which is now available. "A.B.A." is a 3 per cent. solution of anæsthesin with benzyl alcohol 5 per cent. and ether 10 per cent. in sterilized olive oil.

Method of Injection.

The contents of an ampoule of benacol or "A.B.A." previously warmed by immersion in hot water, in order to render it more fluid, are drawn into a 2-c.cm. Record syringe. A fine hypodermic needle is attached, and the solution is injected subcutaneously in a fan-shaped manner around and up to the anal margin. The first injection is usually made under the area of maximum irritation. Two ampoules (4 c.cm.) can safely be injected at a time. The injections are usually repeated at intervals of three to seven days until the entire perianal region has been injected, when areas of continued irritation can then be reinjected.

Results.

A slight burning pain has been complained of by some patients either during the injection or some hours later. There has been no general reaction and no complication (particularly inflammation or sloughing of skin) has occurred. No medicinal treatment (bromides, etc.) has been given to any of these patients, and only the simplest applications have been made to the local dermatitis. Sixteen cases have been treated since September, 1928—7 females, 9 males. The irritation in 10 may be classified as severe, in 6 as moderate. The number of sessions has varied from one to six, and the greatest amount of benacol or "A.B.A." that any one case has yet received is 22 c.cm., the average being 8 c.cm. It is too soon as yet to speak of "cure," but all of these patients have been relieved, and 8 have been so much improved that they are now practically free from all symptoms. In at least 4 cases with severe

dermatitis the visible improvement in the perianal skin has been most dramatic.

Anal Fissure.

Spasm of the external sphincter ani is undoubtedly the cause of the chronicity of anal fissures, and hitherto the various methods of treatment advocated have in reality been directed—and rightly so—towards relieving sphincteric spasm. These methods may be classified into: (a) those which promote relief of pain and consequently the spasm; (b) those which attack the spasm first.

Under the first heading are the following favourite methods: (1) insertion of analgesic ointments such as those containing cocaine, anæsthesin, chlorotone, opium, and belladonna; (2) local application to the surface of the fissure of an albumin-coagulating agent such as silver nitrate, mercury perchloride, nitric acid, or ichthyol; (3) injection under the base of the fissure of an anæsthetic solution such as quinine-urea. The second method of treatment includes the old operation of forcible stretching of the sphincter muscle under local or general anaesthesia, and the various degrees of "incision" ranging from partial to complete division of the sphincter.

All of these methods have been useful, but the chief drawback has been their unreliability. The palliative methods have often failed to relieve the sphincteric spasm, and I have several times seen a recent fissure—in spite of treatment—gradually become chronic and undermined, until finally operation has had to be undertaken. The operation of divulsion of the sphincter is often successful, but, on the other hand, I have known cases where the fissure has failed to heal, with return of sphincteric spasm within a few days after the operation. The operation of incision of a fissure is a very excellent one when applied to the chronic undermined fissure, and is usually the only certain method of getting these cases to heal, but no one will deny that the after-treatment is a painful one; the wound takes three to five weeks to heal, and it is a severe operation to undertake for a recent fissure.

In the last eight months I have been using benacol and "A.B.A." for the treatment of anal fissures, and as an ambulatory method this promises to cure rapidly a very large percentage of cases. It is, in effect, a combination of the two methods outlined above, and consists in the injection of these solutions into the external sphincter muscle and under the base of the fissure.

Method.

For treatment of the usual dorsal fissure the patient lies on his right side and the anus is painted with tincture of iodine. A 2-c.cm. Record syringe is filled with "A.B.A." and with a hypodermic needle the skin is punctured one inch behind the anus in the middle line. The left forefinger is passed into the rectum as a guide and the needle is thrust deeply into the sphincter, first on one side of the middle line and then on the other, about three-fourths of a cubic centimetre of "A.B.A." being injected into each side. The needle is then partially withdrawn and is directed forwards in the middle line under the base of the fissure where the remainder of the solution is slowly injected. This completes the first treatment, but if desired an application of pure ichthyol to the surface of the fissure may be made. In one case in this series I injected an anterior fissure in a similar manner with success.

A varying amount of pain is complained of during the actual injection, but it is seldom severe. Some cases have had pain three or four hours after the injection, but only in a few very nervous subjects has this late pain been at all marked. In every case of fissure injected great relief has been noted, or even complete absence of pain within the first twenty-four or forty-eight hours after the injection.

When re-examined, between the third and seventh days after injection, the local result is invariably very striking. Sphincteric spasm has usually completely disappeared; the finger is admitted readily without pain and the margins of the anus can be separated in a normal manner. In a number of cases at this stage a sentinel

pile, if present, has been excised with scissors without further anaesthesia and without more than a faint sensation being noticed by the patient. Pure ichthyol is applied at this stage to the surface of the healing fissure, and the usual course of events now is for the fissure to be found completely healed about two or three weeks after the first injection, with the patient quite free from any symptoms. I do not consider the presence of a small sentinel pile at the outer end of the fissure to be a contra-indication to the use of this method. The sentinel "pile" is usually a small oedematous tag which on several occasions I have observed to disappear when sphincteric relaxation has been obtained by injection of "A.B.A." In other cases the tag has subsequently been excised, either without further anaesthesia or after injection of a few drops of novocain. I believe this method will sometimes prove of value, even in the case of an undermined fissure; if the sphincter has been made to relax I see no reason why an undermined tag should not be removed locally and successful healing obtained. In a few cases I have given a second injection of "A.B.A.," but as a rule the relaxation lasts sufficiently long for the fissure to heal, and the spasm then does not return. In one case, injection of "A.B.A." was of particular value in that it allowed adequate examination of the rectum (at first impossible on account of pain) to be performed a week later, when a large fibrous polypus in relation to the upper end of the fissure was discovered and accordingly removed. In no case has there been any history of incontinence from lack of sphincteric tone.

To summarize the results; 30 cases from my out-patients' clinic at St. Mark's Hospital and from my private practice have been injected; 18 have been discharged healed, mostly within a period of ten days to three weeks after the injection of "A.B.A."; 6 cases remain under treatment. Two cases with indurated fissures were injected with "A.B.A.," but on further consideration I decided that operation would be more suitable and certain. Finally, 4 cases of recent fissures were injected once, but have not reported for re-examination. So far as I am aware, no patient has had to lie up or discontinue work while under treatment.

Conclusions.

As an ambulatory treatment for pruritus ani the subcutaneous injection of anæsthetic solutions in oil, such as benacol and "A.B.A.," would appear to be safe, of considerable value, and worthy of extended trial.

In the treatment of recent anal fissures the method described can be promised to effect a rapid and brilliant cure, and this early stage is obviously the best for treatment to be undertaken. In fissures of some duration, relief of pain and healing are likely to be obtained in a considerable proportion of cases.

The Treatment of Pernicious Anæmia by Liver.

By C. H. MELLAND, M.D. (Lond.), F.R.C.P.
(*The Brit. Med. Journ.*, July 6th, 1929, p. 9.)

THE liver treatment of pernicious anæmia was introduced by Minot and Murphy in America, and their first series of cases was published about three years ago. Several of my patients started this treatment as early as July 1927.

Since then I have had about forty cases under my care on this mode of treatment, and one can now draw some general conclusions as to its value, particularly its value as compared with methods of treatment previously employed.

It may be said in general that with the exception of four patients who were very ill when first seen, and who has been impossible to trace or who failed to persevere with the treatment, all are alive and reasonably well to-day—the majority very well and following their regular work. One has died from intercurrent disease. In most cases the period of treatment has been little more than a year and a half, and a good deal less than this in many, and I find, on going through my

records, almost as satisfactory results in a good many cases from our older methods of treatment. For a fair estimate of its value, therefore, it must be compared with some of the results in these older cases.

Summary.

From my study of these cases there are certain general conclusions at which I have arrived.

(1) On our older lines of treatment, if efficiently carried out, many, if not most, cases of pernicious anæmia may be given many years of useful life; but there are practical difficulties in getting the treatment effectively applied, which consequently result in a large proportion of failures.

(2) The introduction of the liver treatment has undoubtedly greatly increased our power of dealing with the disease; the improvement is more rapid and the advance in the number of red corpuscles is higher.

(3) Continued treatment by liver will maintain the improvement, and it will do this more easily and with less meticulous attention to details than will our older methods alone. Consequently, though not necessarily more successful—as I have already demonstrated—it is undoubtedly, more simple to carry out, and so there is much less risk of failure.

(4) At the same time whilst relieving the symptoms it does not appear to strike at the root of the disease, so as to produce a complete and lasting cure. So far as we can say at present, treatment must be continued, and, if given up, or insufficiently followed out, relapse will occur.

(5) Though 6 or 8 ounces of minced liver ("potted liver") in the day is usually advocated, I have found in general that when combined with the older methods of treatment 4 ounces or even 3 ounces may be quite effective. This is of importance in the case of those who dislike the liver and take it only with reluctance.

(6) When the red corpuscles have been raised to 4,000,000 or over a smaller amount of liver—3 or 4 ounces every other day, or even as little as 1½ lb. in the week—will maintain the improvement, at any rate, if combined with some continued or occasional courses of treatment, in moderate degree, of the older methods of treatment.

(7) It is important not to push the dose of liver too high or to keep on with the use of full doses too continuously. There is some reason to suppose that over-use may risk the production of gout or chronic nephritis. As in all other methods of treatment, its use must be guided by the consideration of the condition of the blood.

(8) In those who have insuperable difficulty in taking the fresh liver, liver extracts, either solid or liquid, may be used. They appear to be equally effective with the fresh, but are very expensive.

(9) Although it has been supposed that the liver treatment leaves the nervous symptoms untouched, I am not sure that this is the case. In three cases in which these symptoms were prominent and in which arsenic had appeared, whilst curing the anæmia, to aggravate the nervous symptoms, slow improvement has occurred with the use of liver and dilute hydrochloric acid. In many cases the slighter nervous symptoms, the numbness and tingling about the fingers and toes, have been materially improved.

(10) Lastly, accurate diagnosis of the disease is of greater importance than ever it was.

Difficult Labour.

By R. W. JOHNSTONE, C.B.E., M.A., M.D.,
F.R.C.S. (Edin.).

(*The Brit. Med. Journ.*, June 22nd, 1929, p. 1105.)

EVERYONE with obstetrical experience will agree that the commonest cause of difficulty in labour is the occipito-posterior position of the vertex. Probably the second most frequent cause is breech presentation.

Occipito-Posterior Presentations.

Considering how small is the deviation from the normal, the amount of trouble and worry which

occipito-posterior positions cause is astonishing. Difficulty, of course, arises mostly in those cases in which the occiput fails to rotate spontaneously to the front, and this is due mainly to a lack of complete flexion of the head. It is elementary knowledge that an imperfectly flexed head throws larger diameters across the pelvis than a completely flexed one, and in the case of occipito-posterior positions this results in, first, late engagement of the head at the brim of the pelvis; secondly, a tendency to arrest and impaction of the head when it is in the cavity; and thirdly, great difficulty in the birth of the head, face to pubes.

The late engagement or arrest of the head at the brim, which occurs in some occipito-posterior cases, is largely due to the wide posterior part of the head trying to get into the pelvis through the sacro-cotyloid diameter, which is rather small for it. An important corollary is that this arrest of the posterior part of the head tends to a still further undoing of flexion and a consequent increase in the antero-posterior measurements of the head thrown across the pelvis. The degree of misfit which is thus present between the presenting part and the brim of the pelvis may lead to the membranes protruding through the partially opened os in a sausage shape; and, as always, such membranes are peculiarly liable to early rupture. Cases, therefore, in which there is considerable arrest of the head at the brim of the pelvis are often further complicated by the labour becoming a dry one. The result in such cases is a prolonged and painful first stage, dragging on hour after hour and it may be day after day, with intervals during which the pains, in some cases never properly efficient or regular owing to the lack of proper pressure by the head and the bag of membranes upon the region of the internal os, tend to cease altogether.

In time, however, the cervix becomes completely dilated and the moulded head slowly passes down through the pelvis, delay being experienced throughout, owing to the large diameters of the head. The crucial point is when the head reaches the pelvic floor. Where the flexion has been complete and the first stage more or less normal, the occiput rotates to the front without any great difficulty, but in the cases which we are considering, where flexion is imperfect, there is often great delay in the occurrence of rotation. In many cases the head remains in the oblique diameter of the pelvis simply because the uterus has become too exhausted to cause rotation; in other cases the deflexed head becomes impacted upon the ischial spines, while in still others, in which the degree of deflexion is even more marked, the sinciput becomes the leading part of the head, and is rotated to the front, while the occiput slips into the hollow of the sacrum. Delivery with the head in this position involves the passage through the outlet of the pelvis of diameters which are probably from a half to three-quarters of an inch longer than in a normal labour, with the consequence that great force must be exercised either by the uterus or by the forceps, and that a deep tear of the perineum is almost inevitable. All of us have experienced cases illustrating difficulty at any or all of the stages I have mentioned, but it may be helpful to consider them calmly in an atmosphere more judicial than the lying-in chamber.

Diagnosis.

Before making any remarks with regard to treatment I must refer to diagnosis, because every year's increasing experience has brought it home to me that failure to recognize the occipito-posterior position is a more fruitful source of worry and suffering and disappointment than almost any other diagnostic error in midwifery practice.

Ante-natal examination will, in most cases, reveal the occipito-posterior position. The method of examination is abdominal and depends in the main upon failure to recognize the continuous resistance of the back running down the front of the uterus on one or other side of the middle line. Secondly, the small parts of the fœtus are palpable with ease on both sides of the middle line. Thirdly, the trunk of the child may be felt well round to one or other flank, usually the right. Fourthly, the

fœtal heart is best heard well round to the flank, but may sometimes be heard also anteriorly on the opposite side of the abdomen. This last is a point of importance, as it indicates that the child is lying with its spine straightened and its chest thrown forwards, and this implies a degree of undoing of the flexion of the head.

Owing to the difficulty which the head, especially if incompletely flexed, may have in entering the brim of the pelvis, it tends to remain movable above the brim, even in a primigravida, until the commencement of labour. Failure of the head to engage in the brim of the pelvis at least a fortnight before labour in a primigravida woman should always make one think hard, and lead, if necessary, to revision of the pelvic measurements; but if these are quite satisfactory, then the posterior position of the head is enough to account for the failure to engage. Up to about five or six weeks before full time the child may quite readily change its position spontaneously, and come to lie occipito-anterior; but it rarely changes within the last fortnight, indeed comparatively seldom within the last month, and I think that cases of occipito-posterior position diagnosed in the later weeks should be treated by an effort to correct the position.

The only method that I know which affords any prospect of success is the one described by Dr. R. C. Buist of Dundee. The patient is asked to come back, bringing with her two pillow-slips and a bolster-slip. One pillow-slip is folded into a firm cylindrical pad or roller, which is then placed on the right flank (I am assuming a right occipito-posterior position in this case), in order to press the anterior shoulder of the child towards the middle line. The other pillow-slip is folded in four and placed as a firm pad on the left side of the lower abdomen to press back the limbs of the child, while the bolster-slip is fixed as a firm abdominal binder to keep the pads in position. The patient is then told to go home, to rest as much as possible during the next forty-eight hours, and to take a dose of castor-oil the morning after the pads have been applied. In a series of close upon a hundred cases, regarding which careful notes were taken in our ante-natal department, Haultain found that the occiput rotated to the front in rather over 80 per cent. Once it has come round to the front the head tends to engage, especially if a firm binder be kept in position to press it into the pelvis, and relapse cannot occur. After the head has begun to engage with the occiput posterior, any attempt to rotate it by means of pads is, of course, useless, and the first stage of labour must be allowed to complete itself before any question of intervention arises.

During labour the diagnosis can again be made by the abdominal method, but an aseptic vaginal examination will further confirm it. The main point here is the recognition of the anterior fontanelle lying to the front, and it is important to try to feel also the posterior fontanelle, usually pretty high up in one or other posterior quadrant of the pelvis, and to attempt to assess the relative levels of the two fontanelles. This gives one an idea of the degree of flexion of the head. If, at the end of the first stage, there is still any doubt as to the exact position of the head, the point can be settled beyond all question by feeling the ear of the child. The one or two fingers which are sufficient to make the vaginal examination in a normal case are quite inadequate in an abnormal case. The secret of correct diagnosis in all cases of difficult labour is "chloroform and the whole hand." Under anæsthesia, and with aseptic precautions, the hand is slipped up the side of the head until the ear is felt, and when it is flattened out on the head, the pinna points towards the occiput. The importance of this method of diagnosis is very great, because, as I have already indicated, so many disasters result from allowing the case to drift on without the attendant having an accurate knowledge of the position of the head, and therefore of the real cause of the delay.

Difficulties are likely to be encountered only where the head is imperfectly flexed; if, therefore, we can at a comparatively early stage recognize that we are dealing not merely with an occipito-posterior presentation, but

with an imperfectly flexed head, then we are in a position to consider whether or not early intervention is advisable. Signs which point significantly to imperfect flexion are, first, delay in the engagement of the head; secondly, sausage-shaped membranes; thirdly, rupture of the membranes early in the first stage; fourthly, ability to hear the foetal heart through the chest of the child; and fifthly, the anterior fontanelle lying on a lower level than the posterior, as felt by vaginal examination.

The moral to be drawn from experience is that if we can definitely recognize a lack of complete flexion from the presence of two or more indications we may justifiably and advantageously intervene early, in the interests of both mother and child; experience tends to show that when intervention has to be undertaken late in labour both patients are more exhausted, and the actual intervention itself is more difficult.

Management.

I am no advocate of unnecessary intervention in labour, very much the contrary, indeed. In the great majority of occipito-posterior cases the occiput will rotate to the front, if given sufficient time; it is only where one has definite evidence that in a given case the head is so deflexed that it will probably not rotate spontaneously to the front that I think one should intervene early. Such cases will probably form only from 10 to 20 per cent. of all occipito-posterior presentations. The method of intervention indicated is manual rotation, and with the head at the brim this is an easy operation. It is important to visualize exactly what we propose to do before the hand is introduced, just as in a case of internal version. Without this precaution, we may find ourselves attempting the operation in a strained attitude or with the hand which is obviously less convenient than the other hand would have been. It is important to try also to rotate the body of the child by external manipulation, and this can be helped in many cases by grasping the anterior shoulder between the tips of the first and second fingers *in utero*, while the palm of the hand is spread over the side of the child's head, and actually produces rotation of the head. Some authors have, I think, exaggerated the risk of rotating the child's head without the rotation of the shoulders. The child's neck is capable of rotation without injury to an extent considerably beyond the capacity of the adult, and I have again and again rotated the head without succeeding in rotating the body, and the child has been in no way affected. At the same time, it is certainly desirable to make every effort to rotate the shoulders, and there is a greater likelihood of the head going back to its original position if the shoulders are not turned.

When we come to the question of the arrest of the head on the floor of the pelvis we have to decide whether to attempt to rotate or to deliver by forceps as a face to pubes case. I confess that I very much prefer rotation to forcible delivery face to pubes; indeed, I think that to deliver a child of normal size as a face to pubes case should be regarded either as a failure in diagnosis or as a confession of failure in efforts to rotate. It is the most undesirable method of all, because it inevitably necessitates undue force and laceration. With regard to the methods of rotation, manual rotation is much safer than forceps rotation. Rotation of the head in the cavity is not, as a rule, a difficult matter. All that is required is that the head should be gently pressed back a little so as to undo any actual impaction; flexed, if possible, so as to throw smaller diameters across the pelvis; and then, if the side of the hand is spread out over the side of the head, a mere movement of rotation of the hand will produce a corresponding rotation of the head. As before, a similar effort should be made to rotate the shoulders by external manipulation through the abdominal wall. Lastly, in this connection, we must not forget that, although the position is unquestionably the rarest of all, yet the left occipito-posterior position does exist. Therefore, if difficulty is found in trying to rotate the occiput round the right side of the pelvis, an effort should be made to rotate it round the left side before giving up manual rotation as impracticable. Should manual rotation fail, then forceps rotation, provided

great care is used to avoid injury to the maternal soft passages as well as to the child's head, is a useful method of treatment. One of the secrets of success is to sweep the handle of the forceps gently and slowly round the arc of a considerable circle, so as to reduce to a minimum the movement of the blades inside the pelvis.

Where rotation has been effected by hand, the head should be well pressed down on to the floor of the pelvis by fundal pressure, and the remainder of the labour either left to nature or shortened by forceps, as circumstances indicate. When the head has been rotated by forceps, then I think that the rest of the delivery should also be conducted instrumentally by the rapid reapplication of the instruments with the blades in their proper position.

In cases where the delivery, for one reason or another, is being conducted face to pubes, and where considerable tearing is likely, I strongly advocate the deliberate incision of the perineum—that is to say, an operation of episiotomy. Personally I prefer to make this incision in a postero-lateral direction, so that any extension of the incision will avoid involvement of the anal sphincter. The subsequent stitching of a clean cut like this is very much easier, and the anatomical restoration of the parts simpler than in an irregular laceration, while the additional room which it gives shortens very materially the latter part of the delivery.

Breech Presentations.

The next most common cause of difficult labour is, I think, breech delivery, and an analysis of the complications and difficulties which we have met in recent hospital experience of 233 breech deliveries in three years clearly indicates that the main causes of trouble are the impaction of the breech, especially in cases of frank breech, and, secondly, arrest of the after-coming head, due either to imperfectly dilated passages or to some undoing of the flexion of the head by pulling on the limbs. In these 233 cases we had 8 maternal deaths, but in only one could death be attributed even indirectly to the nature of the labour—a death from septicæmia following impaction at the brim. All the other 7 cases were very seriously complicated by eclampsia (2), concealed accidental hæmorrhage (2), acute rheumatic fever, acute pulmonary oedema, and grave cardiac disease with heart failure. The foetal mortality (78) in these 233 cases varied from 3 per cent. in one year to 18 per cent. in another, after complications such as placenta prævia, contracted pelvis, accidental hæmorrhage, extreme prematurity, etc., had been deducted.

I am not able to explain the great difference in different years. It may just be a matter of good or bad fortune, but it is quite possible that it is an indication of the skill of the house-surgeon at the time, because it is a well-known fact that the foetal mortality in breech cases depends in considerable measure upon the knowledge, skill, and presence of mind of the obstetrician.

The greatly increased difficulty and danger, especially to the child, in a breech case in the primigravida is so well recognized that we invariably make an effort to correct this malpresentation where it is met with in such patients in the ante-natal department. During the three years in which we dealt with these 233 cases there were to our knowledge an additional 44 cases so averted by external version.

Management of Breech Labour.

With regard to the general management of breech labour I have nothing to say that is in any sense new, but some points in the old and sound teaching may bear repetition. Masterly inactivity in the early stages is unquestionably the keynote of success. My old master, Sir Halliday Croom, used to sum it up in the words, "Hands off the breech," and this certainly may be said to summarize the whole management of a normal breech case up to the birth of the lower limbs. Frank breech cases always tend to give more trouble than those in which the attitude of the child is one of complete flexion. The extended legs act as splints to the trunk and prevent the lateral flexion of the trunk, which is an essential feature in the descent of the breech through the pelvic

outlet. Impaction of the breech is therefore very liable to occur when it reaches the pelvic floor, and artificial assistance is often needed. This usually takes the form of bringing down one or sometimes both legs, and the fact that this diminishes the bulk of the breech as it passes through the outlet of the vagina, and that the soft passages are therefore not so completely dilated as they would otherwise have been, leads not infrequently to subsequent difficulty in the birth of the head.

In the 233 breech cases we had 21 cases of frank breech. Artificial assistance of one sort or another was required in 20 of these—that is, in over 95 per cent. The assistance took the form, in most instances, of extraction of the breech after bringing down a leg, and in 7 of these cases an episiotomy was performed in order to give more room for manipulation. No maternal deaths occurred, but 7 still-births—that is to say, a foetal mortality of 33 per cent. in this particular set of cases. The cause of death was cerebral hæmorrhage in 4 instances, and asphyxia in 2, while one child was dead *in utero* on admission of the mother to hospital.

Treatment of Impaction.

This leads me to speak briefly of the treatment of impaction. If it occurs at the brim, the cause is almost always either the mere bulk of the breech or a contracted pelvis; if it occurs when the breech has reached the pelvic floor, the cause is usually a frank breech. With the breech at the brim, the treatment is to push the breech gently out of the pelvis and to bring down one foot, the foot lying anteriorly by preference. Unless there are definite indications for the rapid completion of the labour it is much safer for both patients to leave Nature to drive the half-breech slowly through the pelvis rather than to proceed immediately to the extraction of the child. To overcome the impaction is usually all that is needed, and intervention at this stage should preferably stop there.

When the impaction occurs at the pelvic floor—due usually to a frank breech—an attempt may be made to hook down the breech by passing the finger into the groin. The breech hook should be used only if the child is dead. No great degree of force can be exercised by the finger or fingers in the groin, and, if we fail, we may sometimes succeed in extraction by the use of forceps; but the grip is not a very satisfactory one, and I do not regard the breech as at all a good indication for the use of forceps. I believe that better results follow if, with the patient in the Sims' position, the breech is gently pressed back to the brim and one foot is brought down as before. The risk of doing this is undue stretching of the lower uterine segment, but if the patient is deeply anesthetized, and if the manipulation is gently and slowly done, the risk is not great.

When intervention is required for the extraction of the after-coming head or for the bringing down of a displaced arm, the great danger is that the obstetrician may become flurried. It is perfectly true that there is no time to lose, but it is equally true that "the more hurry, the less speed." To be successful the intervention must be carried through exactly according to the book. I say this because, to the man who is anxious and flurried, and who dreads that he is going to have a still-birth, the temptation to pull, in the hope that with a little extra force he will be able to extract the head, although it may be partially extended, or although one arm or even two may be displaced alongside it, is almost irresistible. The sooner that man realizes that in such an effort he is wasting valuable time and endangering the child's life, and that there is no road to success except the high road, the better for his obstetric practice. Two other small points in this connection are: first, that no attempt to bring down an arm should be made until the trunk is born as far as the scapula—in other words, the arm must be brought well into the cavity of the pelvis and within reach, otherwise the attempt to get it down will fail; secondly, that in a case where intervention is hindered by a tense perineum, and in all cases of a primigravid breech labour, an episiotomy ought to be made, because the additional room which it gives is

an enormous advantage in the necessary manipulations, and in the subsequent birth of the head.

Lastly, the Prague seizure is generally to be condemned as a crude and somewhat brutal method of extraction, in which one has little control over the force exerted. It is not comparable in efficacy with the Mauriceau-Smellie grip with the child astride the forearm and two fingers placed well back over its tongue. The essence of the manœuvre is to produce flexion of the head simultaneously with the extraction, and this can unquestionably be best brought about by the fingers on the tongue pulling down the face, while the occiput is forcibly lifted up against the symphysis pubis in the movement of extraction.

The After-coming Head.

The application of forceps to the after-coming head is a method of treatment which is more ignored than it deserves to be. If the forceps are sterilized and ready, it does not take more than a few moments to apply them to the after-coming head with the trunk and limbs of the child swung well forward and out of the way by an assistant; and there is no question that the forceps give a degree of control over the movements of the head which is greater than that obtained even in the Mauriceau-Smellie manœuvre, while the application of the force to the head and not to the neck is probably safer for the child. I always like to have forceps ready in a breech delivery, and I have found them a most satisfactory means of delivering the after-coming head. Herman described it, without qualification, as "the best treatment where help is needed in the delivery of the after-coming head."

From the figures I have already quoted with regard to still-births in frank breech cases, it will be seen that cerebral hæmorrhage is one of the commonest causes of death. This exceedingly important observation is based on the incontrovertible evidence of a large series of post-mortem examinations. The hæmorrhage is due in most cases to tears in the ligaments of the brain, the falk cerebri, and, in breech cases especially, the tentorium cerebelli, and the injury to these structures is unquestionably due to the fact that in the rapid extraction of the after-coming head the skull is exposed to rapid changes of shape, putting a sudden strain upon its internal structures which they are incapable of sustaining. In a head-first labour the slow moulding of the head allows very considerable changes in the shape of the head to occur without corresponding damage, but this is simply because the moulding forces are applied so slowly. As showing the frequency of these intracranial injuries Holland, in an examination of the bodies of 16 infants delivered by the breech, found such injuries in no fewer than 14, while Heidler, in a recent examination of 99 cases of still-born breech deliveries, found tears of the tentorium in 68; in 11 he found death to be due to asphyxia, while in the remaining 20 cases the skull was not dissected, so that no actual diagnosis was made. Browne, on the basis of an examination of 200 still-births in the Edinburgh Maternity Hospital, showed that cerebral hæmorrhage was ten times more common in breech than in vertex cases.

The moral to be drawn from these observations is that intracranial injuries resulting from the rapid extraction of the after-coming head are a considerably greater source of danger to the child than is asphyxia from delay in the birth of the head. It is generally accepted that the foetus can exist for at least ten minutes without receiving fresh supplies of oxygen. Bourne, in his valuable little book, *Recent Advances in Obstetrics and Gynaecology*, refers in this connection to the apnoeic condition of children born after a prolonged period of "twilight sleep," and who, if left severely alone but merely kept warm, remain motionless for perhaps ten minutes or a quarter of an hour while the heart beats quite regularly, and then quietly and gradually establish respiratory movements. As one who uses "twilight sleep" to a large extent, I have had a great many instances of this, and I can confirm it absolutely. But the application of the matter at present is that it emphasizes the need for care and deliberation in the extraction of the head, and the danger of "hurry."

Nov., 1929.]

White Asphyxia.

There is far too much done in the way of violent efforts at resuscitation of the asphyxiated child, and there is no question in my own mind that in many cases the child who is in this condition of suspended animation actually has the flickering spark of life extinguished by these misguided efforts. Clearing out the mucus and liquor amnii from the throat by means of a soft rubber suction tube, warmth to the surface of the body, and a little old brandy on the gums and palate, and in severe cases the intramuscular injection of one or two minims of pituitary extract, have in my experience proved most successful. The main general point to remember is, however, that infants who pass into a condition of white asphyxia are suffering from a condition akin to shock, and should be treated along appropriate lines, warmth and extreme gentleness of handling being the essentials.

Reviews.

RECENT ADVANCES IN TROPICAL MEDICINE.—By Sir Leonard Rogers, C.I.E., M.D., F.R.C.S., F.R.S. Pp. 439 with 15 illustrations. London: J. & A. Churchill, 1929. Second Edition. Price, 12s. 6d.

The first edition of this notable book was reviewed in our issue for April 1928. It says much for Sir Leonard Rogers' facile pen and immense industry that a second edition should have been called for in little more than a year from its first publication. The book is one which every practitioner of medicine in the tropics should read again and again, for nowhere else will he find so vivid, so succinct, and so forcible a presentation of the subject. It is almost an essay-review in the best style of the *Tropical Diseases Bulletin*, expanded into a book; and a brief book at that. Every section is packed with information; whilst the list of references at the end of the chapters will be appreciated especially by those who wish to look up literature on the particular subjects with which they are dealing.

We have already reviewed the first edition; so need not say much about the second, except to say that it is an improvement on the first. The entire work has been most carefully revised. New sections have been added on Oroya fever and verruga peruana, on helminthic infections, granuloma inguinale and climatic bubo; new illustrations have been introduced, whilst some old material has been eliminated. Throughout the book the author keeps the treatment of tropical diseases before him as his main theme, and to the medical man working on his own, away from the facilities of a library, this book ought to make a special appeal.

A few misprints and typographical errors are to be noted, and should be corrected in future editions. On p. 31, when dealing with kala-azar in India, "the endemic areas of North-West India" should undoubtedly read "the endemic areas of North-East India."

The style of publication is admirable, and both the author and his publishers are to be congratulated on a work which will make a special appeal to all medical workers in the tropics. There is no other book which can quite take its place.

R. K.

THE ORIGIN OF MALIGNANT TUMOURS.—By Theodor Boveri. Translated by M. Boveri. London: Baillière, Tindall & Cox. 1929. Pp. IX plus 119. Figs. in the text 2. Price, 11s. 6d. net.

The author's extremely ingenious and careful cytological studies of the nuclear changes that occur during the development of double fertilised eggs of the sea urchin have made his name famous in science. In sea urchin's eggs, he showed that there are three types of dispermy, i.e., the tetraster, the triaster, and the double spindle type of mitosis. The tetraster type of division was produced by adding a very large quantity of sperm to the eggs and violently shaking or pressing the ova; the resulting larvae were nearly all pathological, and only a few normals were found. The triaster type of

division was produced by shaking the eggs immediately after fertilisation; these gave rise to a large number of normal as well as pathological embryos. The double spindle type occurred more rarely after the above procedure and gave rise to normal larvae, or at the most asymmetrical larvae. Boveri then showed that the pathological defects in dispermy were not due to the protoplasm, but to a wrong combination of the chromosomes in the nuclei. From these cells of the first division, daughter cells were formed that had a definitely abnormal chromatin-complex (*chromatin bestand*). Hausemann later showed that the nucleus of the malignant cell also contained this abnormal chromatin-complex. Boveri now states that the malignant cell is one possessing an irreparable defect of the nucleus, which is due to a definite and wrongly combined chromosome-complex and is the cause of the tendency of these cells to undergo rapid multiplication. Eighteen reasons are given in support of the view, which discuss how the different predisposing causes, viz., irritation, chemical, parasitic, etc., may all produce these changes in the nucleus; the cell then inherits a disposition to divide rapidly and form malignant tumours. This book is a classic and should be read by all who are interested in the theory of the causation of malignant growths. Boveri discusses his theory very ably, but largely from a cytological point of view, and in doing so gives a very clear picture of how aberrant mitosis may be caused, and in turn give rise to abnormal cell proliferation (growth). The explanation of how these cell proliferations give rise to (1) benign growths, where the proliferation is slower, the cell development normal and the tissue reaction marked, i.e., capsulated; or (2) malignant growths, when the proliferation is more rapid, cell development abnormal and there is very little tissue reaction, so that lymphatic permeation occurs; is not made clear. The reviewer is very partial to the cell-rest theory:—congenital (Cohnheim), or acquired (Unna), and Boveri clearly shows how these cells may inherit an abnormal chromosome-complex predisposing them to multiply rapidly and form malignant growths. On the other hand there may be cell-rests with a normal chromosome-complex, so that the cells multiply normally and produce innocent tumours. Boveri discusses the exciting factors that give the stimulus to this cell multiplication, such as irritation, etc. Very little attention is paid by him to the local responses of the tissue against its invasion by these abnormal cells when this resistance is lowered (e.g., in X-ray burns, Kangri cancer, etc.), but sometimes it is very high as in atrophic carcinoma of the breast. With normal cells the growth is usually encapsulated. There are also general factors that inhibit or stimulate cell growth that are not discussed; and probably have an effect in determining the age incidence of carcinomas and sarcomas.

H. W. A.

THE DERMATOGESSES OF OCCUPATIONAL AFFECTIONS OF THE SKIN.—By R. Prosser White, M.D., M.B., C.M.Ed., M.R.C.S. (Lond.). London: H. K. Lewis and Co. Ltd. 1928. Third Edition. Pp. XI plus 784 with 52 plates including 58 figures in the text. Price, 35s. net.

This is the third edition of this well known work on *Occupational Affections of the Skin*, and is illustrated with exceptionally fine photographs. The book is a mine of information on the subject, and as the author states in his preface, Miss Anne Newbold's unstinted help and intimate acquaintance with contemporary dermatological literature has added much to the usefulness of the work by the numerous references given on each page, as well as a general index of authorities. Naturally there are several small points in this book that one would quibble at, such as the use of the term "dermatogesses," and towards the end of the book "war dermatoses," etc. Sequeira has stated in his book that veldt sore is caused by the Klebs-Loeffler bacillus, and everyone is now quoting this statement. This disease was first described by Bishop Harman during the South African war, and he thought the causative agent was an intracellular coccus. The two lesions are totally different clinically, as well as bacteriologically.

The book should be in the possession of every dermatologist and medical officer who has to deal with occupational diseases, as it will give him all the knowledge he requires to diagnose the different lesions seen in the skin of workers in the different trades.

H. W. A.

A SHORT PRACTICE OF MEDICINE FOR STUDENTS AND JUNIOR PRACTITIONERS.—By U. P. Basu, M.B. (Cal.), M.R.C.P. (Irl.), Teacher of Medicine, Calcutta Medical School. Pp. 827. Calcutta: Kamala Book Depot. 1929. Price, Rs. 10 net.

THIS work is an attempt to present to the Indian medical student the essentials of his medical teaching in short compass. The author quotes in his preface an editorial in this journal suggesting that the medical curriculum in India is over-loaded, and that it ought to be revised and reduced. In the present work he has attempted this task—to present the minimum essential for the medical student in the tropics, and to eliminate the non-essentials.

The arrangement of the chapters in the book is in consequence new and interesting. The author deals first with the chief tropical diseases, then with world-wide specific infectious diseases, then with diseases of the different systems, and finally with the diseases of children. This plan has much to recommend it from the practical point of view in the tuition of medical students in India. A special feature of the book throughout is its numerous prescriptions; to the medical practitioner who has largely forgotten his *materia medica* these will be especially useful.

The book is not especially original, though it is essentially practical. The section on diseases of the circulatory system will command special attention, since the author has especially studied this subject, and was for some time cardiologist to the Howrah General Hospital. In general, it may be said that the book is a reproduction of the author's lectures to his students.

A special feature of the book are the 15 half-tone reproductions of diseased states. These vary in merit. Some are very good indeed.

The coma of typhoid fever, the swelling of epidemic dropsy, the cancrum oris of kala-azar, are very well illustrated, also—especially—the photograph of a patient suffering from amyotrophic lateral sclerosis. A few of the reproductions however are very disappointing; for example, the publishers must surely have made some mistake about the illustration facing p. 221, showing a case of cerebro-spinal fever. One supposes that it is intended to illustrate Kernig's sign, but it is very defectively reproduced.

The book is written especially from the Indian standpoint, and will therefore make a special appeal to Indian medical readers. It is the result of several years of study and teaching under Indian conditions, and therefore to be recommended. There are a number of typographical errors which we should like to see corrected in a second edition; but, on the whole the get up and format are excellent; the volume is of a most convenient size, neither too large nor too small for the subject which it covers.

R. K.

A TEXTBOOK OF PHARMACOLOGY AND THERAPEUTICS.—By Hugh Allister McGuigan, Ph.D., M.D. Philadelphia and London: W. B. Saunders Company, Ltd. Pp. 660. Illustrated. Price, 28s. net.

WITHIN the last few years a number of textbooks have been published on pharmacology and therapeutics, and the appearance of another book may seem superfluous. A perusal of Professor A. McGuigan's book, however, will convince the readers of its intrinsic worth and special field of utility. The aim of the author is to present the important facts in pharmacology with special reference to their therapeutic and clinical application, so that the student or the practitioner of medicine, instead of being guided by pure empiricism, will have a scientific and rational knowledge of the changes produced in the system by the drugs which he employs. In fact the real interest of pharmacology lies more in its relation to the treatment of disease than its purely biological

aspects. With this idea in view the author has attempted to connect together the essential facts of pharmacology with physiology, biochemistry and clinical medicine, and in this he has been eminently successful. At the beginning of almost every chapter there is a concise and clear exposition of the physiological principles on which a proper understanding of the pharmacological facts depends which is very illuminating to the reader.

Schematic diagrams have been freely inserted in the description of "cathartics," "digitalis," "pharmacology of the ganglia," etc. These are very instructive and are calculated to arouse keen interest in the contents of the chapter. In the chapter on digitalis the different forms of cardiac irregularities have been discussed in small print, a section which at once makes the subject more readable and acceptable to students who are saved the trouble of referring to books on medicine to refresh their memories.

Credit must be given to the author for including almost all the recent developments in the realm of pharmacology and therapeutics in a short space. Egglestone's rapid method of digitalising a patient, the action and uses of colloidal metals, the use of quinidine in heart diseases, the newer derivatives of quinine and cocaine, etc., are worthy of mention in particular. It is strange that the newer conceptions about post-pituitary extract have not been included, and in view of the growing importance of physical chemistry to pharmacology, the primary principles of ionic theory and the theory of salt action might have been considered in a little more detail.

The most important drawback of the book—and this it possesses in common with most other books of English and American origin—is the lack of proper consideration of the drugs used in tropical diseases. Thus antimony in kala-azar and schistosomiasis, the cinchona alkaloids in malaria, chanmoogra oil in leprosy, etc., are all dealt with very briefly, and these sections are not likely to satisfy the requirements of students in the tropics. The new bismuth preparations for the treatment of syphilis have not received the amount of attention they can legitimately claim, and ephedrine has been awarded only an insignificant corner which fails to impress readers with its importance in therapeutics. Kymographic tracings—so essential in pharmacology—are curiously enough very few.

The book is well printed, is written in a readable style, and we have no hesitation in recommending it to students and practitioners alike.

R. N. C.

A HANDBOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY.—By Aughtore Nath Das, Teacher of Medical Jurisprudence and Toxicology, Bankura Medical School. Pp. 232. Calcutta: the Book Co., Ltd. 1929. Price, Rs. 3-8 net.

THIS little book is intended mainly for students for the Licentiate of the State Medical Faculties in India, and is a welcome addition to the already considerable volume of reliable, yet cheap, textbooks for Indian medical students. The book is based upon the author's lecture notes and his 28 years' experience of medico-legal work in Bengal. The book follows upon the usual lines, but it is well put together, and written with special reference to Indian conditions, which adds to its value. The printing and type are good, and the general get up of the book excellent. Useful appendices deal with those sections of the Indian Penal Code which are applicable; detailed instructions with regard to sending specimens to the Chemical Examiner's department for examination, and question papers set at examinations.

Both the author and the publishers are to be congratulated on an eminently practical and useful work, which will make a special appeal to Indian students and practitioners.

R. K.

ALCOHOL AND HUMAN LIFE.—By Courtenay C. Weeks, M.R.C.S., L.R.C.P. London: H. K. Lewis and Co., Ltd. 1929. Pp. 201 with 5 illustrations. Price, 3s. 6d. net.

Alcohol and Human Life is a revised edition of the well-known book by Sir Victor Horsley, but in an

Nov., 1929.]

entirely new guise. It has been thoroughly rewritten, entirely recast, and much additional matter has been incorporated, in order to bring the subject-matter up to date and in a line with the present development of sociological ideals. The aim of the author, as has been set forth in the preface, is to deal with the alcohol question from a scientific point of view and to convince the readers of the great calamity that indulgence in alcohol is bringing to mankind, so that social workers may have a clear idea of this scourge to the nations' life.

After a note on the harmful effects of alcohol on the different systems of the human body, in the course of which the author has tried to put down his ideas in as clear and lucid a manner as possible, he passes on to deal with the great national question "the child and racial poisons." In this chapter he discusses the three racial poisons—lead, venereal disease, and alcohol—and has tried to bring forth in a comprehensive way the truth of the dictum "alcohol is a menace to child life in all stages of existence." Dealing with the influence of alcohol on national life, he tries to impress on the mind of the reader that alcohol is responsible in a direct and indirect way for national degeneration and misery. He has given statistical proof in support of his various arguments, and throughout the body of the book we find numerous records of facts and figures which the author has taken great pains to collect, and these have added greater weight to the arguments and conclusions that he has put forward.

When dealing with the sociology of the subject, the author speaks with conviction and emphasis and this makes the book especially interesting. A fresh chapter indicating the lines on which an anti-alcoholic campaign—a vital question—could be carried out would have been much appreciated by the social service workers and would certainly have enhanced utility of the book still further.

R. N. C.

AIDS TO PHARMACEUTICAL LATIN.—By G. E. Trease, Ph.C. London: Baillière, Tindall and Cox. 1929. Pp. 168. Price, 3s. 6d. net.

Aids to Pharmaceutical Latin is a small handbook of the *Students Aid Series* giving a concise account in English of Latin grammar, phrases, abbreviations, etc., used by pharmacists in general. The need for a book of this nature is perhaps not likely to be keenly felt at the present time, in view of the fact that the Latin terms used in medicine and pharmacy are being so largely replaced by directions in English language. Nevertheless there is no denying the utility of this book. It is an admirable book for purposes of reference to students and practitioners who are confronted with difficulties regarding the interpretation of technical Latin phrases and abbreviations which so commonly come into medical practice. The Latin-English vocabulary at the end is a comprehensive chapter and it will certainly prove useful to everyone in finding out English equivalents of pharmaceutical Latin. The section dealing with phrases and abbreviations used in prescriptions is worthy of special mention and will be much appreciated by students.

R. N. C.

MEDICAL GUIDE FOR INDIA AND INDEX OF TREATMENT.—By E. I. O'Meara, O.B.E., F.R.C.S. (Eng.), D.P.H. (Cantab.), Lt.-Col., I.M.S. (retd). Third Edition. Revised, rewritten, and enlarged throughout. Calcutta: Butterworth and Co. (India), Ltd. 1929. Pp. XIV plus 1138. Illustrated. Price, Rs. 15 net.

O'Meara's *Medical Guide for India* is an old friend of medical practitioners in this country and the appearance of a third edition after a period of five years will certainly be welcome. To those who are familiar with the previous editions, the present volume will cause surprise, inasmuch as it has undergone a complete change and it is difficult to recognize the original in this edition. The book has been thoroughly revised and in many places entirely rewritten. Incorporation of new material has been carried out with a free hand so as to bring the book up to date and in line with the recent developments of medical science. There is also plenty of evidence of

rearrangement and regrouping of the subject-matter in different sections of the book. The more important sections have been written by specialists in their own subjects. Sir Leonard Rogers has written the sections on malaria, cholera, leprosy and emetine; and a host of other eminent authorities such as Sir Arbutnot Lane, Colonel Graham, etc., have also enriched the book with their contributions. The task of selection of subject-matter for the book again must have been a difficult task in view of the enormous and ever-increasing output of literature on all manner of subjects, and credit must go to the author for the admirable way in which he has tackled the problem.

The *Index to Treatment* does not appear to have received the consideration it should have done at the time of revision. Little attention has been paid to the subject of filariasis. Pregnancy anaemia has not been mentioned in spite of the fact that recent researches have definitely proved its separate entity from pernicious anaemia. Some of the prescriptions seem to be rather old fashioned. Such ingredients as koto, jambal, paraira, sarsa, rhamni, purshiani cortex, etc., are useless relics which are not easily available nowadays and will not be served with good grace by the present-day dispensers.

The addition of a bibliography at the end of every chapter is another feature of note and importance. It sums up the latest and most important literature on the subject without attempting to be too detailed and complete. The book we have no doubt will be useful to general practitioners in this country.

R. N. C.

CROOKS OF THE UNDERWORLD.—By Charles George Gordon. London: Geoffrey Bles. Price, 5s.

WHEN Mr. George Dilnot, who has written several books of the *Famous Trial Series*, was editing *The Detective Magazine* he received a visit from a personage who produced entirely satisfactory credentials as being one of London's master crooks, and Mr. Dilnot vouches for the authenticity of these remarkable reminiscences of London's underworld.

Gordon is of course an assumed name. It was the late Mr. A. C. Fox Davies, the well-known barrister, who defended Gordon in the treacle plaster case, who suggested that Gordon who has a long criminal record should write his exploits and experiences. It is the plain unvarnished tale of a man who took to crime from the age of thirteen and who claimed to have made £5,000 a year by every possible means of refined swindling and burglary, and who as a result has spent several years of his life in prison. Tired of this mode of precarious living, especially on release after serving a sentence of seven years for a crime of which he and his counsel declare he was entirely innocent, he resolves to "go straight" for the rest of his life.

The fallacy of the dictum once a criminal always a criminal is well exemplified by Gordon's attempt to successfully sublimate his criminal propensities after many struggles, by adhering to the new leaf that he has turned over.

It is the story of a tragedy written with a certain vivacity; and is also a concise exposition of the numerous methods of "graft" that are known to the underworld. The vivid descriptions of prison life contain abundant food for thought for those who pose as reformers of our penal system, for it seems incredible that such penalties as the "no talking order" and "cold storage" still exist.

J. N. J. P.

C. MENSE, HANDBUCH DER TROPENKRANKHEITEN.—Fifth Vol. 3rd Edition. Joh. Ambr. Barth, Leipzig, 1929. Pp. XI plus 846. Illustrated. Price, Rm. 90 (£ 4-4-0).

THE present volume is the last one of this voluminous handbook—at least the last dealing with human diseases; a sixth volume will discuss the veterinary ailments peculiar to hot countries.

The present volume contains the following chapters: "Diseases caused by worms" by G. Sticker (under collaboration of Schueffner and Sweißengrebel);

"Recurrent fever" by H. Ruge, followed by smaller chapters on Nanukayami (Japanese seven-day fever), bronchial spirochaetosis, *sodoku* and various other spirochaetoses by the same author, "Chagas' disease" by Chagas and da Rocha Lima, and "Yellow fever" by Couto and da Rocha Lima. A very useful editorial appendix (by Mense) deals with many more locally important troubles, alphabetically arranged according to their most popular vernacular name. Of course, only such diseases are mentioned to which references in the world's medical literature exist, like "spider-lick," "Rhine valley fever," "sutika," etc.

The larger half of the volume is devoted to the first chapter; this is divided in two parts, the first one dealing with general views, biology and zoology of the different helminths pathogenic to man, their geographical distribution, diagnosis, laboratory methods, general treatment and prophylaxis. A very interesting paragraph discusses the possible importance of worms in the spreading of infectious diseases (e.g., typhoid). A short introduction to the first part gives an admirable account of the history of worm diseases, the knowledge of which is traced back as far as to the Ayyurveda and papyrus Ebers (the latter mentions *Ascaris*, *Tenia* and *Dracunculus medinensis*).

Whereas the biological and zoological section is well up to date, we regret to state that the chapter on treatment is not at all satisfying. The arrangement is not lucid at all and one fails to trace the point of view according to which it is done. Old and obsolete methods are mentioned, which might belong equally well to the historical introduction or might even be omitted altogether. The practitioner of to-day is not at all interested into the use of tin or corallina officinalis in the treatment of ascaris or *tænia* infections and we doubt whether he will agree that extr. filic. mas. is still the safest and most effective drug against hookworm. And here is the weak spot of the whole chapter; the learned author does not seem to be very familiar with or at least to have a wide personal experience of the modern ways of treating helminthic diseases. The value of carbon-tetrachloride is nowadays beyond all doubt, and if deaths were reported in the beginning from various quarters, still anybody working in tropical countries knows how to avoid such accidents. The same applies to the antimony treatment of schistosomiasis: it sounds strange indeed, that the author should doubt the possibility of ascertaining the cure-rate among 6,500 bilharzia patients (Khalil); tropical diseases are mostly mass diseases, where everything depends upon the method employed. A physician used to mass-treatment is certainly also familiar with the control of the same. The toxicity also of tartar emetic and more especially of the modern organic antimony compounds is certainly overrated: after all, antimony is to-day the only life-saving drug in schistosomiasis and certain risks have to be faced and, if possible, overcome.

The second part of this chapter deals with the special diseases. According to their importance, filariasis, schistosomiasis and hookworm are especially considered. The section on hookworm seems to us the best of the whole chapter, although we again can hardly agree with the remark: "CCl₄ is not to be recommended for mass-treatment." After all, CCl₄ has been used for mass-treatment for many years and a modern handbook on tropical diseases should not overlook this fact.

Besides these points, which we hope to see corrected in a next edition, we find much valuable information, and the epidemiological and pathological chapters are extremely well dealt with.

References are given to the latest publications on helminthology only; the older literature is referred to in various hand- and textbooks.

The monograph on relapsing fever by H. Ruge is certainly the best part of the book, and from the first to the last page it affords interesting and sometimes fascinating reading. This rather difficult subject is exhaustively dealt with in 108 pages and shows the great personal experience of the author. The section on transmission shows wonderful enlarged photographs of the 16 most important species of *Argas* and

Ornithodoros; to each photograph a schematic sketch is added and a table gives in a clear and comprehensive manner the important distinctive characteristics; thus the text on this difficult subject is cut down as much as possible, but whatever is omitted in the text is explained much more clearly through the pictures and diagrams.

The part on the different spirochaetes responsible for relapsing fever is very extensive and up to date. So is the chapter on serology. The clinical paragraphs are very detailed: the Russian-European and the African (East- and West-African) type of the disease is considered in length, but also the East-Indian type is dealt with in full with references to the work done by Carter, Graham, Mackie, Cragg and others. The bibliography includes 1,170 references.

The next chapters on various spirochaetoses are also very comprehensive, and of special interest to readers in India is a short paragraph on bronchial spirochaetosis, which the author believes to belong to the group of fuso-spirilloses. We cannot but congratulate the author on this comprehensive section.

There follows a large chapter on the American trypanosomiasis, Chagas' disease, written by Chagas with the collaboration of Enrico Villela and H. da Rocha Lima. There is nothing to say about this very learned monograph, which gives a clear picture of this comparatively only recently studied disease.

The last chapter by M. Couto and H. da Rocha Lima deals with yellow fever. History, symptomatology and epidemiology of this dramatic disease are extensively dealt with. Rocha Lima gives an excellent account of pathology and histology. The question as to the aetiology of the disease naturally forms the centre of the monograph and we may say that it is completely up to date. The researches of the late Dr. Noguchi are given in full detail and we follow, as in a thrilling novel, the foundation and erection of his monumental hypothesis and again its dramatic destruction, started by Manson-Bahr, Schueffner, Aragao, completed by the self-sacrificing work of Stokes, Young and their collaborators and buried with the gallant inventor. Finally an editorial note by Mense considers the most recent work of Kuscinsky, Berlin, who in the early months of 1929 considered the *Bacillus hepatodystrophicus* as the causative organism, and who with his laboratory assistant, Frä. Hohenadel, underwent the "experimentum crucis" and developed a typical yellow fever; but with more luck than their unfortunate predecessors, Noguchi, Young and Stokes, both recovered.

In conclusion, we may say that the last volume of Mense's handbook is again packed with valuable information. The print is excellent and one cannot but admire the multitude of splendidly coloured plates and photographs. The book is undoubtedly a most valuable contribution to the library of any medical man practising in the tropics.

O. U.

(Note.—This book has not been sent to us for review but, as the subject-matter is likely to be of interest to our readers, we are printing this review which was written especially for the *Indian Medical Gazette*.—EDITOR, I. M. G.)

CANCER.—By G. Jeanneney. Translated by J. Gibson M.C., M.A., M.D., and J. H. Watson, F.R.C.S. Pages XIV plus 186, with 33 illustrations. Price, 7s. 6d. net. London: H. K. Lewis & Co., Ltd. 1929.

This is a small handbook translated from a French work by Professor Jeanneney, and is intended for the general practitioner.

The essential point in the treatment of cancer is to make an early diagnosis and this rests with the general practitioner. The book deals entirely with clinical findings. No words are wasted and the descriptions are clear and sharp cut. The English translation is in many ways reminiscent of that famous work Lejar's *Urgent Surgery*.

Every surgeon will benefit by reading it, and every general practitioner should read it carefully and

Nov., 1929.]

repeatedly. In its 186 pages he will find all he needs to know about malignant diseases affecting any part of the body.

The book concludes with a chapter on the methods adopted in France for the prevention and treatment of cancer, and one on the cancer campaign in Great Britain.

A. H. P.

MEDICINE, ITS CONTRIBUTION TO CIVILIZATION.

—By E. B. Vedder, A.B., M.D., F.A.C.S. 1929. London: Baillière, Tindall and Cox. Pp. 393 plus IX. Price, 22s. 6d. net.

THE object of this book is to present to the lay reader in simple language, devoid of technicalities, a brief account of the achievements and the ideals of Western medicine. Such an undertaking is not so simple as might at first sight appear, for the author has to avoid over-technicality on the one hand and an equally strong tendency to 'talk down' to his readers on the other. On the whole, Colonel Vedder has successfully accomplished his difficult task.

The book is divisible into two parts—Part I (comprising 254 pages) deals with the causes of disease and Part II with 'Present Accomplishment in Disease Prevention and the Problems of the Future.' Any criticisms the reviewer has to offer deal with minor points.

Table 13, giving the composition of ordinary food materials, extends over five pages and appears to be a little too exhaustive for the purposes of the present work. Beyond the brief remark that 'In some cases that recover the mind is permanently deteriorated,' nothing is said of the appalling sequelæ of encephalitis lethargica. In the experience of competent workers the number of persons who have been rendered mentally defective by this disease runs into thousands—in Great Britain alone. It is doubtful whether the classification of goitres (on p. 200) is intelligible to a non-medical reader; *per contra* there is no mention of plasmochin in the treatment of malaria.

Of actual errors there are a few calling for comment. We thought we had detected one such at page 5 in the author's statement that.....'there are roughly two billions of human individuals on the earth'.....until we recollected that in America a billion means a thousand millions not a million millions as in England.

On page 76 there is a misquotation of Kipling and we are still puzzling over two sentences on the page following, viz., that "The tertian parasite (of malaria) requires seventy-two hours to complete this development".....(the human cycle) and that "The quartan parasite requires eighty-four hours to complete its cycle of development".....

Surely *Trypanosoma gambiense* is not carried by *Glossina morsitans* under natural conditions? (p. 85). It is not, in our opinion, desirable to use the phrase 'black water fever' (p. 95) as synonymous with 'Texas cattle fever'; 'red water fever' is the more usual term for this piroplasm infection.

There are also some printing errors, the most outstanding of which (at p. 263) is the translation of the Roman emperor Justinian to a remote period when the founders of Rome's future greatness were clinging precariously to their seven hills on the Tiber.

Binding and general format are good and the price is reasonable.

J. M. H.

Annual Reports.

ANNUAL REPORT OF THE UNION MISSION TUBERCULOSIS SANATORIUM, AROGYAVARAM, NEAR MADANAPALLE, SOUTH INDIA, FOR 1927-1928.

This annual report is always of interest, for the Arogyavaram sanatorium is one of the very few bright spots in the tuberculosis problem in India. It is most efficiently managed, and is situated in an ideal climate free from dust.

The report for 1927-28 is written by Dr. R. H. H. Cohen, B.A., M.D., in the absence on leave of Dr. C. Frimodt-Møller. The report, as usual, is illustrated by most interesting photographs, showing the types of open-air wards adopted for a tropical climate, the surrounding scenery, X-ray rooms and laboratory department. The sanatorium was officially opened in 1915, and has done splendid work ever since. Its grounds cover more than 100 acres with some 90 buildings in them. The climate is dry and temperate; the institution is financed by fourteen missionary societies, but is very largely dependent on the income from paying patients and on voluntary contributions. The lines of treatment adopted are essentially those adopted in up-to-date clinics in Europe. There are 8 general wards with a total of 116 beds; 2 semi-general wards, each with 4 beds; also special wards; the total accommodation being for 182 patients.

During the year 312 patients were admitted and 284 discharged, the daily average number of patients under treatment being 164. The patients are of all communities, castes, and races, whilst no less than 284 came from outside the Madras Presidency—a sufficient indication of how widespread are the activities of the sanatorium, and how badly it is needed.

Results emphasise the imperative necessity for the diagnosis and treatment of pulmonary tuberculosis at a far earlier stage than is at present the case in India generally. The figures are as follows:—

		Arrested.	Much improved.	Improved.	
Stage I	..	85.3	9.8	3.2	per cent.
Stage II	..	23.1	42.3	5.8	"
Stage III	..	2.4	27.4	13.7	"

A second table shows how very important is the finding or otherwise of tuberculosis bacilli in the sputum on admission with regard to prognosis. In all stages those patients with bacilli present in the sputum show a much worse prognosis than those cases where the bacilli are so scanty as not to be found on microscopical examination. Fever, after admission, in the discharged cases lasts on an average for about 45 days. The average increase of weight in discharged cases was 11 lbs.

Artificial pneumothorax was tried in 57 cases during the year; induction was successful in 40, of whom 19 were discharged with positive results. Sanocrysin was tried in only 28 cases; and tuberculin B.E. in only 12. It is clear from these figures that, apart from artificial pneumothorax, which plays a very definite rôle in the treatment of pulmonary tuberculosis, the general tendency is towards rest and allowing the natural processes of healing to occur.

A recent feature of the work at Arogyavaram has been the institution of a well equipped laboratory and the increasingly arduous nature of its duties. It is run by Mr. R. M. Barton, M.A. (Oxon.), and an immense amount of laboratory diagnosis of all types is called for during the year. The new X-ray department has been in continuous use since August 1927, and is not only useful for routine examination of the chest, but also for other radiological examinations; in fact, in pulmonary tuberculosis, just as in leprosy, secondary infections and diseases appear to play a most important part in prognosis. Ultra-violet light treatment has been found to be especially valuable for the treatment of extra-pulmonary tuberculous complications.

During the year a new general male ward with 18 beds was opened; also 3 double wards with 6 beds in all. Medical training was given to both post-graduate and under-graduate students, and to laboratory assistants sent from different places. A sale of goods manufactured at the sanatorium helped by bringing in Rs. 400. The members of the staff have contributed a number of papers to medical journals, including two contributed to our columns by Dr. Frimodt-Møller. Income totalled Rs. 1,25,425 and expenditure Rs. 1,23,065, showing on how near a margin this splendid work is being carried on. A list of rules for admission, which should be most carefully studied by any medical practitioner wishing to send patients to the sanatorium, closes the report.

"Arogyavaram" is in the forefront of the campaign against pulmonary tuberculosis in India. We can only

wish the sanatorium a continuance of its most important sphere of useful and life-saving work.

UNITED FRUIT COMPANY. MEDICAL DEPARTMENT. SEVENTEENTH ANNUAL REPORT, 1928. BOSTON, MASSACHUSETTS. Pp. 381; PROFUSELY ILLUSTRATED.

We wish that considerations of space did not prevent us from doing full justice to this wonderful report. Year by year the annual reports of the Medical Department of the United Fruit Co. become more and more important contributions to tropical medicine. The present report is the equivalent of an annual volume of a monthly journal of tropical medicine. It is lavishly illustrated, and admirably published. The United Fruit Co. takes the health of its employees in the vast region over which its plantations are dotted very seriously; it has a very fine medical staff, splendid hospitals and laboratories, and an admirable medical organisation. The result is that this volume is more than a dry statistical report; the necessary statistics are included (at the end), but the entire volume is a notable contribution to tropical medicine. How up-to-date the Company is is illustrated by the photographs of the large aeroplane regularly used as a means of transportation of medical officers to various inland points in the Tela Railroad Division, and also utilized to bring patients from the interior to the Tela Hospital.

Dr. W. E. Deeks and the United Fruit Co. are to be congratulated on the notable contributions to the study of tropical medicine which these annual reports constitute.

Turning to the substance of the report, apart from the general report and statistical section, it includes no less than fifty-five papers dealing with different problems in tropical medicine and surgery, together with reviews by Dr. W. M. James of the last edition of Stitt's *Diagnostics and Treatment of Tropical Diseases*, and of Dobell and Laidlaw's recent studies of *Entamoeba histolytica*.

Malaria is very fully dealt with. Plasmochin and Plasmodin Co. have been exhaustively studied by the medical officers of the Company. Barner and Newman have confirmed the crescent-destroying action of this compound by mosquito tests on patients on plasmochin treatment. Brosius reports on "blanket treatment" with plasmochin—i.e., mass treatment of all persons showing gametocytes—as a measure of malaria control. Reports of malaria surveys follow, especially one by Clark which deals with conditions among the aboriginal Caribs of Central America, and is therefore of special value as determining malarial conditions in an aboriginal population in Central America. How thorough is malaria control by the United Fruit Co. is shown by the splendid set of photographs of hospitals which are included; there is not a window or verandah not properly screened. Rojas gives an interesting account of pernicious cases of malaria; indeed throughout the whole report its special clinical value is very great. Other papers deal with the value of adrenalin in malaria, observations on induced malaria, and the medico-legal aspects of malaria with reference to accidents. Professor Whitmore of Georgetown University contributes a full biochemical study of the blood in blackwater fever; he comes to no conclusions, but establishes valuable data.

After this section there follow a large series of papers of clinical importance. Tropical skin diseases, tropical ophthalmology, tropical surgery, and snake-bite are subjects dealt with in this series. Throughout, papers are admirably illustrated. In his covering letter to the report Dr. Deeks is able to write as follows:—"With the exception of six cases of leprosy among nationals, no quarantinable diseases have developed in any of our divisions during the year; nor has any infectious disease assumed serious epidemic proportions." It is a summary of very fine work carried out under tropical conditions, and of great interest from every aspect—epidemiological, medical, and clinical to other workers in tropical medicine.

As no price is mentioned, we take it that this annual report is only for official circulation, but the larger

medical libraries in India should certainly contain copies. The editor is Dr. W. E. Deeks, Medical Department, United Fruit Co., 17, Battery Place, New York.

A publication such as this leads one to wonder whether such industries as the Indian Tea, Jute Mills, and Mining Associations, or the Bengal Chamber of Commerce, could not publish a similar series of annual reports, for much valuable work is being done by the medical officers of these associations, and far too little of it is published in the journals. In India so far we have not attained anything like the wonderful standard of disease prevention and control that the United Fruit Co. have reached; still, progress must have a beginning some day, and such reports would be of great interest.

Perhaps what strikes the casual reader of the report most is that anti-mosquito screening is so commonplace a rule in the hospitals, schools, officials' houses, etc., of the United Fruit Co. that it is not worth mentioning; though the admirable photographs throughout the report show it in force everywhere. In India when a planter's bungalow is built, no one worries about whether it is or is not near a breeding site of malaria-carrying anophelines, and no one dreams of mosquito-proofing the house. In Central America the malaria expert is consulted before the house is built, and mosquito proofing of the house is a routine precaution.

Correspondence.

THE AGE OF CONSENT ACT.

To the Editor, THE INDIAN MEDICAL GAZETTE.

Capulet.

"My child is yet a stranger in the world,
She hath not seen the change of fourteen years
Let two more summers wither in their pride,
Ere we may think her ripe to be a bride."

Paris.

"Younger than she are happy mothers made."

Capulet.

"And too soon marred are those so early made."

SIR,—In Elizabethan times, as in India to-day, early marriage was the rule rather than the exception, but it is obvious that in the days of Romeo and Juliet the dangers thereof were well recognised.

There can be no question that from a sociological point of view, the Bill of Rai Sahib Harbilas Sarda is excellent, but it is open to criticism on its medical side.

The first appearance of menstruation, which in tropical countries roughly occurs between the ages of 12 and 13, coincides with certain general physiological changes which collectively constitute puberty. These changes affect the external genitalia, the internal genitalia, the mammary glands, and the psychical characteristics of the individual which differentiate the woman from the child.

Puberty, which the layman considers is complete on the appearance of menstruation, denotes the physiological co-ordination of the ovaries with other endocrine bodies, and therefore there is little doubt that from a natural point of view conception was intended to occur after its appearance, and should there be no great disparity in age between the contracting parties, there is little doubt that the process of nature can be fulfilled without disaster.

Recent research work has shown that the foetal head approximates in ratio in 80 per cent. of cases to the size and contour of that of the father, and that the uterus adapts the size of its contents in 80 per cent. of cases to that of the maternal pelvic inlet and outlet. Therefore the argument that difficult labour must occur as a result of early motherhood cannot be supported, for clinical experience has convinced us that if a primipara be of normal physical development, the process of labour is not accomplished with difficulty.

The Age of Consent Bill speaks of "the travails of maternity, and the high maternal and infantile mortality

as the result of premature co-habitation," but it should be borne in mind that such travail and such mortality are just as likely to remain high after the passing of the Bill as before it, for it would seem to be forgotten that "travails" have *per se* nothing whatever to do with the age of marriage, but are due to such preventable causes as eclampsia and sepsis. The Bill does not demonstrate how raising the age of consent is likely to ameliorate such diseases, for only intense propaganda and education can do that.

History and literature amply demonstrate that Europe had to face this same problem of early marriage with its frequent tragedies, until medical science proved that it was not so much the age of the primipara, as it was the ignorant dirtiness of midwives, and the lack of knowledge among physicians of the problems of maternity that caused the mortality. This dark age has passed, or is passing, not by virtue of legislation concerning the age of marriage, but because of education and ante-natal care.

As regards infantile mortality which the Bill attributes to early marriage, we must not confound cause with effect, for the appallingly high percentage of infant deaths in India cannot be attributed to this cause. Dr. Ubhaya, Director of Public Health in Madras, has shown that only 0.59 per cent. of first confinements occur under the age of 15, and that 24.7 and 31.2 per cent. respectively, occur between the ages of 15 and 24. These findings conclusively refute the argument of Sir H. S. Gour and, if we may say so, point the legal maxim that "hard cases make bad law," for the infantile mortality is due partly to avitaminosis during the ante- and post-natal periods, and partly to ignorance of the elementary laws of hygiene.

As regards the age limits which are definitely proposed in the Bill, it would seem to us infinitely hard to enforce them in rural India, for in a land where birth registration is unpopular and the age of maturity silently reached, who would be so bold as to give an affidavit on the correct age of a wife, or in the event of extra-marital connection to state truthfully whether Adam tempted Eve or Eve tempted Adam,—for the sex urge is a very vital question in the tropics.

The passing of laws is all very well, but who can bring them to the ears of the people unless there is a general raising of the standard of female education throughout the country. Without such education, preferably in the hands of women teachers, there is grave danger of such laws being used for the sport of blackmailers and those who bring false charges.

Anyhow let us say at once, that the Bill is a real step in the direction of social progress in India and we trust that it will bring into prominence the urgent necessity for intense propaganda on the subject of efficient ante- and post-natal care.—Yours, etc.,

V. B. GREEN-ARMYTAGE, M.R.C.S. (Eng.),
L.R.C.P. (Lond.), M.B., Ch.B. (Bristol),
M.D. (Bristol), M.R.C.P. (Lond.),
Lieutenant-Colonel, I.M.S.,
Professor of Midwifery, Medical College,
Calcutta.

Calcutta,
14th September, 1929.

(Note.—We have been urged by several correspondents to deal with the Age of Consent Bill in our editorial columns, and have hitherto refrained from doing so because the subject is admittedly a very controversial one, and involves deep seated religious and racial customs. At the same time, we are willing to admit correspondence by authoritative writers to our correspondence columns on the subject; although it must be clearly understood that the editor does not accept responsibility for the opinions of contributors.)

Colonel Green-Armytage is probably right in claiming that the average age of primiparae in India is not as low as is usually supposed to be the case. But we doubt whether the Madras statistics are applicable to Bengal. We understand that there is a passage in the Vedas which states that the healthiest first child is born when the father is 35 years of age and the mother 18. The

stricter Hindns of Madras possibly follow this rule, whereas we doubt whether the less strict Hindns of Bengal do so. In any case the evidence placed before the Committee appointed to report on the proposed Bill is overwhelming; and, in common with almost unanimous opinion, we are whole-heartedly in favour of the Bill. It cannot be right to force pregnancy on children of 12 and 13, whose internal genitalia have not yet fully developed. As the *Statesman* has recently observed, the Bill may be largely a dead letter if it is passed into law as an Act; but its real importance is its educational influence. One can mould public opinion by legal enactments no less than by propaganda. We cordially agree with our correspondent, however, that what is wanted—first, last, and all the time—is education in such matters; clean midwifery in place of filthy dais, and an awakening of a public health conscience.

We would welcome statistics from the large maternity hospitals in the different provinces of India as to the average age of Indian primiparae of different races and castes.—Editor, I. M. G.)

PERITONEAL FORCEPS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In this country where anaesthesia is so often far from perfect, the difficulties of the surgeon are increased many times.

One of the greatest of these difficulties is that of bringing the cut edges of the peritoneum together in sewing up the abdominal wall. Mouatts' three bladed peritoneal forceps, though useful when the anaesthesia is perfect, only damage the tissues when the patient strains.

To overcome this difficulty Messrs. Down Brothers, Ltd., have modified the forceps by making jaws similar to those of Duvals forceps, as illustrated. They are a great success.—Yours, etc.,

MISS M. V. WEBB, W.M.S.,
Principal, Women's Medical
School.

ACRA,
19th August, 1929.

THE TREATMENT OF MYIASIS IN LEPERS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—Dr. Rau's article on myiasis, which was published in the *Indian Medical Gazette* for July, 1929,

has prompted me to write briefly concerning my experiences.

In treating the condition, whether it be of the nasal mucosa or of the skin—I have found rectified turpentine quite successful. In the case of the nose, swabs dipped in turpentine have been inserted high into the nares and left there several minutes and then the nares irrigated with weak potassium permanganate lotion. This treatment has needed repetition for two or three days only. In the case of the skin, the ulcers have been dressed with cotton-wool containing a little turpentine and cleansed with a weak antiseptic lotion and the cleaning and dressing repeated once or twice a day as long as necessary.

The result of this treatment is both surprising and immediate. Soon after application the maggots begin falling or crawling out of the ulcers and continue their migration for two or three days until the patient is free: the inflammation and swelling rapidly subside; the foul discharge ceases and the ulcers begin to look healthy again.

I have found no need for surgical interference in cases treated as above, except where a deep sinus has become infested, in which case it has just been opened up in order to allow the drug to have free access to the maggots and to allow of a better exit for the latter.

The turpentine seems to act on the parasites as a stimulant and irritant and causes them to leave the tissues in order to escape the action of the drug. The irrigation with the weak antiseptic assists the larvæ in their efforts to leave the ulcers.

I believe that certain antiseptic lotions and chloroform, if used, kill some of the maggots in the tissues and lengthen the process of recovery, and I fear the use of the Volkmann's spoon or the opening up of burrows with the knife unnecessarily damages the tissues and tends to spread infection to surrounding parts.—Yours, etc.

E. LANDEMAN,

PURULIA LEPROSY ASYLUM,
22nd August, 1929.

THE INDIAN MEDICAL DEPARTMENT.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Since I entered the Indian Medical Department almost twenty-two years ago, I have noticed the puzzling and inconsistent tendency of officers of the Indian Medical Department, when contributing articles or correspondence to medical journals, to omit the letters "I.M.D." after their names. After all, it must be a curious type of mentality which leads men to despise or be ashamed of the service which provides their bread and butter. Some of the contributions are indeed very worthy and reflect credit on the writers, and it is a pity that such credit does not publicly accrue to the Department to which it is due.

This tendency of a man to despise his own service must bolster up the enmity of others against that service, and it is high time that men in the service woke up to the foolishness of this attitude.

The I.M.D. to-day is not the Department which it was twenty years ago, admittedly, but we are proud of many of our men. Let us then abandon this stupid policy and feel pride in our service. It is almost a truism nowadays that when one sees "Major, Captain, Lieutenant," or even "Doctor" signed to an article, without "I.M.D." the contributor is usually a member of that service.—Yours, etc.,

B. J. BOUCHÉ, I.M.D.,
Medical Officer.

JIND JUNCTION,
NORTH WESTERN RAILWAY,
23rd August, 1929.

(Note.—Speaking editorially, we would be the very last to decry the Indian Medical Department. The military assistant surgeons are the backbone of the British military station hospitals throughout India, the military sub-assistant surgeons of the Indian military station

hospitals. Both groups have carried out invaluable work in the Medical Research Department in India. The record of both in peace and war is alike admirable.—
EDITOR, J. M. G.

INTRAVENOUS IODINE IN ULCUS TROPICUM.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—We have been using iodine intravenously in all cases of sores which become septic from a slight injury. The patients are all coolie labourers working in manganese and iron mines and the site of the sore is generally on the foot, downwards. These sores are very similar to Naga sore as described in your *Gazette*. The result of iodine injections is quite admirable, but the patient complains of severe unbearable burning sensation after three or four injections. Though the dressings are changed with frequent change of lotions, this is of no avail.

Will you kindly or any of your readers inform us of the reason of this burning sensation?

We make our iodine solution as follows and give injections twice a week; the first dose being 1 c.c., gradually increased to 2½ c.c.

Iodine	gr. vi.
Potassium iodide	gr. vii.
Distilled water	oz. i.

Yours, etc.,

K. P. SARKAR, AND P. B. SARKAR,
Medical Officers.

C/o MESSRS. BIRD & Co.,
BARA JAMDA P. O.,
SINGBHUM DIST.,
B. N. R.

TROPICAL DIETARIES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I have the honour to address you on the subject of tropical dietaries. I have been making some investigations into this matter, and wish to gain as much information as possible with regard to the following points:—

- (i) What is considered an optimum caloric value for various classes of labour in the tropics?
- (ii) The proportion of proteins, carbohydrates and fats in such a dietary?
- (iii) The analysis of local food-stuffs.
- (iv) The vitamin content of dietaries in use, especially with regard to vitamins A and D.
- (v) The presence, if any, of diseases due to avitaminosis among the peoples on the dietaries named.

I should be grateful for any information you or your readers can give me on these lines, with regard to dietaries in use in the general population, or in hospitals and prisons in your territory.—Yours, etc.,

J. NEIL LEITCH,
Government Pathologist.

FREETOWN, SIERRA LEONE,
WEST AFRICA,
1st August, 1929.

FILARIAL LYMPHANGITIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Colonel Acton's and Dr. Sundar Rao's paper on secondary infections in filarial lymphangitis is certainly of very great interest; but the theory that attacks of lymphangitis are due to septic infection from "focal" sepsis does not appear to rest on convincing evidence. One wonders in what proportion of cases "focal" sepsis can be found in hospital patients before it is possible to attribute lymphangitis to this factor.

To one who has lived in endemic areas of filarial disease attacks of lymphangitis without any demonstrable cause are known to be quite common in comparatively healthy young people. Filarial fever has certainly definite characteristics which do not bring it into line with septic

fevers. To regard focal sepsis as the cause of these attacks is certainly bringing in a factor that has been attributed as causal to a host of conditions ranging from fibrositis to gastric ulcer. With equal justification one might incriminate constipation as a probable cause. It is recognised that these attacks are in the great majority of cases definitely due to damage of the lymphatics. It is possible that the damage may be caused by the parent worm, either by the secretion of a toxin or by lesions produced by the worm itself. It may be that the micro-filaria themselves cause injury to the lymphatics. Manson-Bahr has demonstrated that filarial orchitis is associated with the presence of a large number of micro-filaria in the tunica vaginalis. Nobody can question that attacks of lymphangitis give rise to thickening of the lymphatics and that chronic obstruction may supervene. Adult worms have even been found in filarial abscesses.

Secondary infections of the skin may possibly occur in filarial disease and are quite common in elephantiasis considering how often the skin is implicated. However, it seems to me that the real filarial fever is not in any way connected with these secondary infections, but is of the nature of an aseptic inflammation and that a distinction must be made between this and the secondary streptococcal and staphylococcal infections which are quite common in dermal lesions in the tropics.—Yours, etc.,

T. B. MENON, M.D., M.R.C.P.

44, HARRINGTON ROAD, CHETPET,

MADRAS,

15th August, 1929.

(Note.—We think that the answer to Dr. Menon's criticism will be found in the article by Lieut.-Col. H. W. Acton, I.M.S., and Dr. Sundar Rao on p. 601 of this issue, and in the editorial on p. 633.—Editor, I. M. G.)

STERILIZATION OF HYPODERMIC SYRINGE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—With reference to the query on p. 297 of your May issue, the method used by me for sterilizing syringes is described below:—

I carry a few "Soloid" examethylenetetramine (B. W. & Co.) and a spoon in my injection outfit. The needle is boiled in the spoon over the burning soloid which gives out a good heat. The boiling water is also drawn into the syringe several times. I have given a good many injections and so far have not seen any complications.

After injection the syringe and needle are cleaned with water and rectified spirit is drawn in and out twice or thrice. By this subsequent treatment with spirit I have never found a blocked needle and have therefore dispensed with the stilette.—Yours, etc.,

G. B. SINGH, L.S.M.F.,
Medical Officer,
Jaipur Lancers.

14th August, 1929.

A CASE OF INTOLERANCE TO QUININE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—The following case of intolerance to quinine may be of some interest to your readers.

A Mohammedan, aged 40, came to me complaining of fever, which used to appear in the evening, general weakness and a burning sensation in the eyes. Physical examination revealed the presence of an enlarged spleen, so I suspected malaria. I proposed to administer quinine orally, but he complained that as soon as he took quinine he vomited. So I thought it better to give an injection and I injected 10 grains of quinine bi-hydrochloride, intramuscularly. Within five minutes the patient perspired and his body became quite cold. The pulse was not felt at the wrist and the patient complained of intense itching of the whole of the body. He recovered soon after I had injected digitalis and strychnine.—Yours, etc.,

RATANLAL MAGANLAL GANDHI, M.B., B.S.
RAIPURA,
5th September, 1929.

Service Notes.

APPOINTMENTS AND TRANSFERS.

IN consequence of the grant of leave to Major-General J. W. D. Megaw, C.I.E., M.B., V.H.S., I.M.S., Lieutenant-Colonel C. A. F. Hingston, C.I.E., O.B.E., I.M.S., Principal and Professor of Midwifery, Medical College, Madras is appointed to officiate temporarily as Surgeon-General with the Government of Madras, with effect from the afternoon of the 22nd August, 1929.

Lieutenant-Colonel W. M. Houston, M.B., I.M.S., Port Health Officer, Bombay, is appointed Inspector-General of Civil Hospitals, Bihar and Orissa, with effect from the afternoon of 6th August, 1929.

Major F. J. Anderson, I.M.S., on return from leave, to rejoin his permanent appointment as Principal and Professor of Surgery, Medical College, Vizagapatam.

Major J. C. Bharucha, I.M.S., to act as Superintendent, Government Royapuram Hospital and Lecturer in Surgery, Medical School, Royapuram, Madras and Medical Inspector of Emigrants, in addition to his duties, during the absence of P. F. Mathias Avargal, O.B.E., M.B.C.N., on leave.

Major K. V. Ramana Rao, I.M.S., on return from leave to rejoin his permanent appointment as District Medical Officer, Kistna, and Superintendent, Government Headquarters Hospital, Masulipatam.

The services of the undermentioned officers are placed permanently at the disposal of the Government of Madras, with effect from the dates shown against their names:—

Major N. K. Bal, M.C., I.M.S. 12th December, 1923.

Major N. M. Mehta, I.M.S. 2nd January, 1924.

Major K. V. Ramana Rao, I.M.S. 27th July, 1925.

Major T. S. Shastri, M.B., I.M.S. 1st December, 1923.

Major P. H. S. Smith, M.B., I.M.S., D.A., D.M.S. (District and Embarkation), Bombay, has been appointed to act temporarily as Health Officer of the Port of Bombay in addition to his own duties, with effect from the forenoon of 5th June, 1929.

Captain R. T. Advani, I.M.S., to officiate as Superintendent of the Ahmedabad Central Prison, *vice* Mr. W. Laxton.

LEAVE.

Major-General J. W. D. Megaw, C.I.E., M.B., V.H.S., I.M.S., Surgeon-General with the Government of Madras, is granted leave on average pay for two months and six days combined with leave on half average pay for three months and twenty-five days, with effect from the afternoon of the 22nd August, 1929.

RETIREMENTS.

Lieutenant-Colonel V. H. S. Roberts, F.R.C.S.E., I.M.S., is permitted to retire from the service, with effect from the 20th July, 1929, subject to His Majesty's approval. Major M. Purvis, M.B., I.M.S., retires, with effect from the 6th August, 1929.

PROMOTIONS.

Major to be Lieutenant-Colonel.

Paul Knighton Gilroy, M.C., M.D., F.R.C.S. Dated 29th July, 1929.

Lieutenant (on probation) F. W. H. Coughy, I.M.S., to be Captain (provisional) (on probation), with effect from the 5th July, 1929.

Prizes at the Millbank Course.

We have been requested to publish the following list of the names of prize winners at the termination of the combined course of instruction at Aldershot and at the R. A. M. C. College, Millbank, in the last session. This batch of new recruits to both services sailed for India at the end of August, 1929. Senior officers of both services will be interested in the very considerable number of prizes now open to newly commissioned officers in both services.

Prizes.

- Herbert. Highest Aggregate Marks in all Subjects.
Lieutenant H. S. Waters, I.M.S.
- Parkes Memorial. Highest Marks in Hygiene.
Lieutenant D. C. Ettles, R.A.M.C.
- De Chaumont. Second Highest Marks in Hygiene.
Lieutenant D. Blewitt, R.A.M.C.
- Tulloch Memorial. Highest Marks in Pathology,
R. A. M. C. only.
Lieutenant F. Welsh, R.A.M.C.
- Fayrer Memorial. Highest Marks in Pathology, I. M. S.
only.
Lieutenant H. S. Waters, I.M.S.
- 1st Montefiore. Highest Marks in Military Surgery.
Lieutenant D. C. Ettles, R.A.M.C.
- Ranald Martin Memorial. Highest Marks in Tropical
Medicine.
Lieutenant H. S. Waters, I.M.S.
- 2nd Montefiore. Second Highest Marks in Military
Surgery.
Lieutenant H. S. Waters, I.M.S.
- Marshall Webb. Highest Marks in Military Medical
Administration.
Lieutenant D. Blewitt, R.A.M.C.

NOTES.**DIGIPAN.**

"DIGIPAN" is a digitalis preparation of the Temmler Chemical Works, Berlin-Johannisthal, Germany, for which it is claimed that it represents the full therapeutic activity of the leaves of *Digitalis purpurea*, and is free from the inert properties present in the crude extract. It is put up in solution for oral or hypodermic use, and in tablets for oral use. The composition is claimed to be uniform, also that there is no deterioration on keeping. The 1.1 c.c. ampoules of this preparation should interest the medical practitioner in India; it is well known that digitalis preparations are rather liable to deteriorate in the Indian climate; but in such a sealed ampoule there would appear to be no opportunity for such deterioration.

VIROL, LIMITED.**SUCCESSFUL YEAR'S WORKING.**

At the twenty-ninth annual general meeting of Virol, Ltd., Mr. Bertram S. Straus, J.P. (Chairman of the Company), presiding, the Secretary said: The gross profit is £269,707, the net profit, including the amount brought forward, is £124,096, and compares with £122,815 for the previous year. The directors recommend the payment of a dividend of 22½ per cent. on the Ordinary Shares.

The period under review has been one of continued depression in the basic industries of the country. The optimistic forecasts with regard to the revival of trade to which leading financial and industrial authorities from time to time give utterance, have not, so far, been realised, while the heavy losses arising out of the industrial upheaval in 1926 yet remain to be liquidated. In these circumstances I think we may congratulate ourselves on the satisfactory results disclosed in the balance-sheet, results which afford testimony to the popularity of our preparations and more especially to the public recognition of intrinsic merits of Virol.

In regard to the development of our new preparation Virol and Milk in powder form, you will see from the report that considerable progress has been made during the past year. The difficulty of dealing with increased trade, to which I referred at our last meeting, necessitated the erection of a new factory at Lapford, one of the richest milk districts in Devonshire.

Our Virolax preparation, one of the most valuable, from the general health point of view, that we handle, continues to meet with general support from the medical profession, as shown by the very favourable reports we

are continually receiving, especially in relation to its value in constipation and intestinal toxæmia. Virolax is a unique preparation inasmuch as it combines with its laxative qualities the recognised nutrient properties of Virol.

I should now like to direct your attention to some very important results published in the *British Medical Journal* last January. The investigations in question were concerned with the large number of cases of illness in children, which manifested itself mainly as debility associated with headache, constipation, nervousness, and recurrent sickness. These published results afford striking evidence of the necessity of maintaining a correct balance of food, especially in relation to digestion of fat, and confirm in a remarkable manner the great value of our Virol formula, which admittedly achieves the necessary physiological balance of vitamin foods. Hence its great utility as a food in all such cases. This important aspect of Virol has been discussed at length with experimental evidence in a pamphlet on debility, recently issued by us to the medical profession.

PACYL.

"PACYL" is claimed to be a derivative of cholin, a hormone normally present in the various tissues of the body, whose rôle is to maintain by stimulation of the parasympathetic the tone of such non-striated musculature as that of the gut. It is therefore especially indicated in conditions of vascular hypertension and arterio-sclerosis. Vasomotor disturbances, such as migraine, vertigo, formication, etc., are also indications for its use. The drug is manufactured by the Chemische Fabriken Dr. Joachim Wiernik & Co., Germany, and the British agents are Messrs. Coates & Cooper, 41, Great Tower Street, London, E.C. 3. It is put up in tablet form, and several reports in German medical journals speak very highly of its value; in the case of an elderly female patient of 50 years with high vascular tension, continuous administration of the drug led to a reduction of blood pressure from 210 mm. Hg. to 150 mm. in 48 days, although the dosage was steadily reduced.

This preparation may be of interest in cases of gout, arterio-sclerosis, and high blood pressure, whether of cardiac, renal or gastric origin.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers, relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India, Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

THE SIGNIFICANCE OF THE ANTIMONY TEST IN THE DIAGNOSIS OF KALA-AZAR.

PART I—SERUM TESTS.

By R. N. CHOPRA, M.A., M.D. (Cantab.),

LIEUTENANT-COLONEL, I.M.S.,

Professor of Pharmacology,

and

N. N. DE, M.B. (Cal.),

Research Assistant.

(From the Department of Pharmacology, Calcutta School of Tropical Medicine and Hygiene.)

DURING the course of an investigation on the pharmacological action of the antimony compounds, Chopra and his collaborators found that when a solution of an organic aromatic compound of antimony such as urea-stibamine was brought in contact with the serum from a kala-azar patient a heavy flocculent precipitate was produced. This precipitate was not, as a rule, produced by sera from non-kala-azar patients. This observation at once opened up the possibility of this reaction being developed into a test for the diagnosis of kala-azar. A large number of kala-azar and non-kala-azar sera were tested and three papers were published giving the results of this work. The first of these was merely a preliminary note recording the observation of the reaction on which the test was dependent. The second recorded results of the test as compared with the aldehyde test, and showed that the percentage of positive reactions with this test was somewhat higher than that with the aldehyde test. In the third paper standards of positivity were laid down, and it was shown that this test was more sensitive than the aldehyde test and appeared much earlier. The variations produced in the test during the course of treatment of the disease were also worked out in a small number of cases.

This new serum test held out a promise of being a useful adjuvant in the diagnosis of this disease. As time went on and more and more sera were tested it was found that the test was rarely positive in some non-kala-azar conditions, such as very big enlargement of spleen and liver produced by malaria, advanced tuberculosis, leucocythemia, and in a few cases of leprosy, etc. In the meantime Dr. Napier, in charge of the Kala-azar Research at the School of Tropical Medicine, returned from leave and further work on testing the practical utility of the test was taken over by him, though the senior author's laboratory carried out all the routine examinations of sera sent by the Carmichael Hospital as well as the Medical College Hospitals, Calcutta, in order to keep the standards of positivity uniform. During this period also Chopra and Choudhury worked out the changes in kala-azar serum which gave rise to this precipitation with antimony compounds.

The precipitate formed by the interaction of the serum and urea-stibamine was colloidal in character and consisted mainly of euglobulin, possibly contaminated with traces of albumin and pseudo-globulin. Moreover the precipitation of euglobulin, by any reagent, will be maximum at its iso-electric point, i.e., at a pH of 5.5. Since the iso-electric point of euglobulin in kala-azar serum does not differ from that of the euglobulin in normal serum, it follows that euglobulin from kala-azar serum will be precipitated most at a pH of 5.5. Consequently when we mix serum and a solution of urea-stibamine (4 per cent.), the final pH of the mixture, in addition to the concentration of euglobulin and buffer action of the serum, will control the formation of any precipitation. The nearer the final pH to 5.5, the greater will be the precipitation. The pH of a 4 per cent. urea-stibamine solution is 5.2 and, therefore, at the interface, the pH will be near about 5.5, the buffer action of kala-azar serum being very weak as compared to normal serum. The concentration of euglobulin is also high. All these factors contribute towards this characteristic reaction of kala-azar serum. By dilution of the serum, this reaction would be more unequivocal, as by dilution with water, the pH of the serum is lowered, the concentration of euglobulin still remaining sufficiently high (compared to other types of sera)—to be precipitated by a strong solution of urea-stibamine. These workers have also shown that it is better to dilute the serum and use a 4 per cent. solution of urea-stibamine instead of keeping the serum intact and diluting the urea-stibamine, i.e., using a solution of the compound, less than 4 per cent. as recommended by Napier (*J. M. G.*, Vol. 61, June 1927). In fact, by diluting the serum, it was found possible to differentiate kala-azar cases from a few of the conditions, e.g., advanced malaria, tuberculosis, etc., which sometimes give a positive antimony test.

The results of Dr. Napier's investigation on the value of this test were published in the December number of the *Indian Medical Gazette* (1928). His paper contains a number of valuable criticisms of the test and the senior author considered it necessary to develop the test further, improve the technique, and reconsider the standards of positivity if necessary. We have to express our gratitude to Dr. Napier for his whole-hearted co-operation in this work. He put all the resources of his department at our disposal, supplied us with sera, and gave us access not only to his patients but to all his records.

Although the series of cases recorded by the senior author and his collaborators on which the test was originally worked out was not large, Dr. Napier has been good enough to corroborate some of their observations during his critical examinations of the test. He says that there is no doubt that the antimony test gives a greater percentage of definitely negative reactions in leprosy than does the aldehyde test. He agrees that the test is more sensitive. He also agrees that there is no doubt whatsoever that a positive result is obtainable at a much earlier stage in the disease with the antimony test than with the aldehyde test, though he does not agree that a positive or even a doubtful result can be obtained during the first few weeks of the clinical manifestations of the disease. He has also remarked that the test is not positive in every case of the disease. The changes occurring in the serum of a kala-azar patient, producing the antimony test, also occur to a lesser extent in such conditions as chronic malaria, phthisis, leprosy, etc., and this delicacy of the reaction, according to him, is a distinct

disadvantage. For the test to be made of clinical value he says the standards of positivity should be readjusted and the condition of the patient taken into consideration. He has even suggested that a positive diagnosis should only be made in cases in which the spleen is less than six inches below the costal margin and in which there is a strongly positive reaction. A negative diagnosis should only be made by means of this test in cases in which the serum remains quite clear, or becomes cloudy but without showing definite flocculation. With these criticisms in view we started a large series of observations the results of which are discussed below.

It is also worthy of note that because a laboratory test does not give cent. per cent. positive results, it does not follow that it has no diagnostic utility. None of the laboratory tests can claim to give absolutely positive reactions in all cases. They should be merely considered as a guide to the clinician, who should read and judge their value after full consideration of the clinical signs and symptoms of the patients. The real value of a test is the extent to which it helps and guides the physician to reach to a correct diagnosis and the ease and rapidity with which it can be performed, and this we propose to bring out in this paper. We have compared our results with the aldehyde test not for the purpose of odious comparison, but because that is the only other accepted and standard test of this kind with which results of the antimony test are comparable. The senior author in collaboration with S. G. Choudhury (1928) showed that similar factors which are responsible for the antimony test also account for the aldehyde test.

Before analysing our data, we consider it advisable to record here for the reader the revised technique of the antimony test. We have no doubt that faults in technique and want of attention to the details is responsible for the discordant results in the majority of the instances.

Serum Test.—The serum separated from the patient's blood is transferred to a miniature test tube $2\frac{1}{2}$ inches to 3 inches long, made by sealing one end of a piece of glass tubing with an internal diameter of 4 to 5 mm. The transfer of serum can be easily affected by means of a capillary pipette with a rubber teat and if the serum is gradually poured along the side of the tube no air bubbles form. In a second tube serum diluted 1 in 10 with double distilled water is put in the same way. A 4 per cent. solution of urea-stibamine made up with distilled water is then slowly run down along the side of both the tubes with a capillary pipette, which must be thoroughly washed many times with distilled water. In positive cases a heavy flocculent precipitate appears almost immediately at the junction of the serum and the antimony solution in the case of whole serum, which being heavier, remains below. In case of 1 in 10 dilution of serum a heavy coarsely flocculent precipitate forms as the antimony solution permeates through the diluted serum.

From the physical character of the precipitate

formed various sera can be conveniently divided into 4 groups:—

1. Strongly positive (i.e., +++). Here the precipitate forms almost immediately, is thick, and shows coarse flocculation. It conglomerates into a thick coagulated mass at the junction of the two fluids and is difficult to break even on violent shaking.

2. Positive sera (i.e., ++ or +). The precipitate is coarsely flocculent, but is not so thick as in the first group. The signs ++ or + are allotted according to the amount of precipitation produced.

3. Doubtful (i.e., ±). Under this heading we include those sera which show a precipitate or a haziness which does not show any coarse flocculation.

4. Negative (i.e., —). Here no precipitate or haziness appears, and the tube remains perfectly clear. A non-flocculent precipitate may be produced by sera from other febrile conditions, such as enteric and diseases in which there is considerable disturbance of metabolism.

It will be noted that the precipitate formed by the 1 in 10 dilution of sera is naturally smaller in amount, and the thick conglomerated mass occurring in (1) is never produced here. There is a tendency here for the precipitate to appear as a thick white cloud as the antimony solution diffuses through the column of diluted serum. The coarsely flocculent character of the precipitate which is the chief criterion of positivity can be very clearly made out by holding the tubes against the light. When one has seen it a few times there can be no doubt about it.

The time of appearance of the precipitate after the addition of the urea-stibamine solution is another factor which is worthy of consideration. This factor is of paramount importance especially in connection with the test performed with 1 in 10 dilution of the serum. If this is not taken into consideration doubts and difficulties in the interpretation of the test might arise on this score alone. By doing a large series of both kala-azar and non-kala-azar sera and carefully noting the time of appearance of the precipitate and its maximum development, we found that although the precipitate in many cases appears immediately, the best time for the correct reading of the test was from 5 to 10 minutes after addition of the antimony solution. Readings taken within the first few minutes as well as those taken after about 20 to 30 minutes are both liable to error. In the former case a precipitate might not appear at all in a positive case, whereas in the latter case some form of haziness or even a granular looking precipitate giving the appearance of flocculation may form on standing. Incidentally this brings out the important fact that the test can be performed and the reading obtained in less than one quarter of an hour, as compared with the aldehyde test which may take as long as 24 hours.

We would like to direct the attention of readers to the above remarks as the correct interpretation

of the test depends on the correct reading of the character of the precipitate. With kala-azar sera the precipitate shows conglomeration into a thick mass or coarse white flocculation according as to whether the whole serum or 1 in 10 dilution is used. In the majority of cases errors and discrepancies in the interpretation of the test are due to want of attention to details of the technique. We have known many cases where a test was called positive because a precipitate or even a haziness appeared, no regard having been paid to the character of the flocculation. On questioning it was found that the test was being done merely on hearsay, with a very meagre knowledge of the technique, and in some cases even the papers written by the authors of the test had not been read. If the test is performed and read as detailed in this paper the results we trust will be uniform and reliable and the reaction will prove of utility to the physician in quickly diagnosing his case.

Technical Difficulties.—When a number of sera have to be tested there are certain difficulties to be contended with which we relate below in order to help those doing the test on a large scale.

1. The miniature test tubes and the capillary pipettes used should be scrupulously clean. Just before doing the test it is advisable to wash them several times with distilled water. If this is not done, precipitate or haziness may appear which might vitiate the results. We have on many occasions been shown a so-called positive test which on thorough cleaning of the tubes and pipettes did not even show a slight haziness and remained perfectly clear.

2. The tubes should be of standard bore and we recommend those of 4 to 5 mm. internal diameter. We have selected these because the flocculation is not so clearly seen if the tubes of larger bore are used. The small tubes also have the advantage that smaller quantities of serum and urea-stibamine solution are required.

3. Locking of air bubbles in the column of the fluid should be avoided. This can be easily done by gradually pouring the fluids along the side of the tube. If an air bubble is imprisoned a fresh tube should be taken. The presence of bubbles interferes with the appearance of the precipitate and flocculation.

4. The urea-stibamine solution should be allowed to run slowly along the side of the tube, and on no account should it be violently agitated. Too much shaking of the solution changes the character of the precipitate.

5. It is preferable to use double glass-distilled water for diluting the serum; the presence of a trace of heavy metal may cause finely granular precipitation.

6. Tap water should not be used for making urea-stibamine solution or for finally cleaning the miniature test tube and pipettes. The presence of calcium and other substances in it produces a finely flocculent precipitate.

7. The serum used for the test should be quite clear. Although traces of hæmoglobin giving it

a reddish tinge do not interfere with the accuracy of the results, when the serum is hazy the results cannot be depended on. Major Kernahan kept open tubes of sera for many weeks in Peshawar at room temperature during the hot weather without in any way altering the results, provided the serum was clear. He also found that the presence of traces of arsenic or mercury such as would occur in the sera of individuals receiving injections of arsenicals or mercurials in no way altered the reaction.

8. The solution of urea-stibamine required for the test should be preferably prepared in double distilled water, though ordinary distilled water gives quite good results. This solution should also be perfectly clear; if any haziness is present the solution should be discarded. A solution once prepared can be kept for a fortnight or even longer in a small bottle with a well fitting ground glass stopper.

If the test is done in a perfunctory and haphazard manner and attention is not paid to above mentioned points a certain amount of discrepancy in the reading of the tests is bound to arise. This has actually been the case. On more than one occasion it has been brought to the notice of the senior author that frank differences in the antimony test results on identical sera have occurred with two different workers, but curiously enough these differences are mostly in the domain of the "doubtful," when the physical characters of the precipitate are not clearly cut and well-defined.

SIGNIFICANCE AND VALUE OF THE TEST.

A. Undiluted Serum.

(1) *Significance of Positive Reactions.*—Kala-azar cases—early or late—generally give a positive reaction.

A perusal of Table I, horizontal columns (1) and (2) shows that of 201 definite cases of kala-azar, diagnosed by positive parasitic findings in peripheral blood culture or spleen puncture, the sera of only 5 patients gave negative results, thus indicating an error of 2.48 per cent. Strongly positive reactions indicated by +++ are usually definite cases of kala-azar, but this does not necessarily mean that ordinary positive reactions (++ or +) are not true cases of kala-azar provided typical coarse flocculation is present. In fact the majority of the early kala-azar cases give only a ++ or + reaction. We cannot, therefore, agree with the assertion that only a strongly positive reaction should be considered as indicating kala-azar. Moreover, we have noticed that there is a tendency in the minds of workers to interpret strongly positive results as "advanced cases" of the disease. Although this is true so far as the untreated cases are concerned, previous treatment with antimony compounds may modify the intensity of the reaction.

This series of patients were all from Dr. Napier's clinic and he was responsible for the parasite findings and readings of the aldehyde test. The antimony test was done in the senior

author's laboratory, and at the time the test was performed we had no knowledge of the clinical condition of the patient or as to whether leishmania had been detected or not. These results were obtained from Dr. Napier's records at a later date some time after the test was done, so that the factor of "natural bias" was excluded as far as possible.

TABLE I.

Comparative Results of the Aldehyde and Antimony Tests (Undiluted and Diluted Serum) in 201 cases in which diagnosis was made by finding leishmania.

	Strongly positive.	Positive.	Doubtful.	Negative.
1. Aldehyde Test.	128	40	23	10
Antimony Test.				
2. Undiluted Serum.	156	38	2	5
3. Diluted Serum (1 in 10)	109	66	13	13

A glance at this table will show that if doubtful reactions are excluded, the aldehyde test was positive in 168, or 83.58 per cent. of cases, and negative in 4.96 per cent. while the antimony test with undiluted serum shows positive results in 194, or 96.5 per cent. of cases, and negative results in 5, or 2.48 per cent. These figures bring out the value of the test in definitely positive cases of kala-azar. The percentage of doubtful and negative reactions among definite kala-azar cases is higher with the aldehyde test. We further carefully investigated the histories of those patients who gave a negative antimony test although they showed the presence of leishmania; most of them were apparently early cases of the disease. It is interesting to note here that most of these patients also gave a negative or doubtful aldehyde test. Probably similar factors were at work in both instances.

(2) *Significance of the Negative Reactions.*—A definitely negative reaction indicated by the serum remaining absolutely clear after the addition of the urea-stibamine solution is strong evidence that the serum is not from a case of kala-azar.

A group of 139 cases which were apparently not kala-azar has been analysed in Table II.

The cases in this series were admitted to the hospital during the same period as the 201 cases given in Table I. The aldehyde test in all cases was read by Dr. Napier himself and the antimony test was performed by the senior author's laboratory and in the majority of cases read by him.

TABLE II.

	Strongly positive.	Positive.	Doubtful.	Negative.
1. Aldehyde Test.	0	1*	30	108
Antimony Test.				
2. Undiluted Serum.	0	40	10	89
3. Diluted Serum (1 in 10)	0	7	7	125

* This was a treated case of kala-azar who was re-admitted for pneumonia one week after discharge.

In this table are included cases of filariasis, asthma, malaria, tuberculosis, rat-bite fever, etc., but no cultural examinations or spleen punctures were made definitely to exclude kala-azar by negative parasite findings unless there were clinical indications of the disease. It will be observed from horizontal columns (1) and (2) that in this group a large number of sera, though apparently non-kala-azar, gave a positive antimony test. As many as 35.9 per cent. of the apparently non-kala-azar sera gave a positive or doubtful reaction with the antimony test as compared with 22.3 per cent. with the aldehyde test. This is rather a high percentage and may be attributed to the greater sensitiveness of the test. We will show later how by the dilution method this source of error can be considerably minimised, but we would like to point out that this apparently high percentage may be a point in favour of the test and not against it. Napier has repeatedly drawn attention to it and the senior author realised very early in the course of this work that in an endemic area such as that in which we are working there may be cases of latent kala-azar, or even transient cases of the disease which may possibly give a positive or doubtful antimony test. In order to exclude this source of fallacy it was decided to do the test on a series of patients in a part of the country where kala-azar was not endemic. We are very grateful to Major Kernahan for doing a series in the Indian Military Hospital at Peshawar, the results of which are given in Table III. This officer came to Calcutta on one or two occasions before he undertook this work, thoroughly mastered the technique of the test, and became fully conversant with our standards.

TABLE III.

Antimony Test on 150 cases in a non-kala-azar endemic area.

	Strongly positive.	Positive.	Doubtful.	Negative.
1. Undiluted Serum.	1	6	19	124
2. Diluted Serum.	0	0	2	148

A study of horizontal column (1) of this table shows that out of a series of 150 cases, 124 gave definitely negative reactions, 19 were doubtful and 7 gave positive results. If the doubtful reactions are excluded, the error in negative diagnosis here works out at 4.6 per cent. All the sera which gave positive reactions had splenomegaly. The patient who gave a strongly positive reaction was a soldier who had served in Persia and who had an enlargement of both spleen and liver and was running a temperature. Major Kernahan thought it might be a true case of kala-azar but unfortunately the diagnosis could not be confirmed. He was the only one who gave a typical coarse flocculation such as is obtained with kala-azar sera. This shows that in a small percentage of cases in a non-endemic area where there is practically no possibility of kala-azar existing, 4.6 per cent. do give a positive antimony test with undiluted serum as compared with 28.7 per cent. in an endemic area. This might favour the suggestion of latent or fleeting kala-azar being the cause of the high incidence in an endemic area. It will be shown later how by the dilution method the percentage of positives in apparently non-kala-azar cases can be further reduced.

(3) *Significance of the Test in clinically diagnosed Kala-azar.*—We now return to another class of case which we collected from among the patients of the Medical College Hospitals. In this group, although the diagnosis could not be confirmed by positive parasitic findings, all the clinical symptoms as well as other laboratory findings such as leucocyte count, etc., left little room for doubt that they were cases of kala-azar. Besides, these cases reacted to the antimony treatment in the same way as the kala-azar patients do. This group may not be of importance to those who have all the facilities of well equipped laboratories which can carry out cultural and other examinations for the detection of the parasites, but as this is the usual standard of diagnosis which is attained by medical men in general practice and in the outpatient department of big hospitals, we have no hesitation in presenting the following table. Both the antimony test and the aldehyde test were performed by us and we tried to adhere to the rigid standards of positivity laid down by Dr. Napier.

TABLE IV.

Antimony and Aldehyde Test in 128 clinically diagnosed Cases of Kala-azar.

	Strongly positive.	Positive.	Doubtful.	Negative.
1. Aldehyde Test.	80	25	19	4
2. Antimony Test.				
3. Undiluted Serum	93	34	1	—
4. Diluted Serum (1 in 10)	43	62	15	8

Table IV, horizontal columns (1) and (2), gives the results of antimony and aldehyde tests in 128 patients collected from the Medical College Hospitals, where diagnosis was made from clinical symptoms and laboratory findings other than actual finding of the parasites. It will be observed that whereas with the aldehyde test 105, or 80.4 per cent., gave a positive reaction, with the antimony test 127, or 99.2 per cent., were positive. This series may not be important from the scientific point of view, but it brings out the utility of the test from the point of view of the general practitioner who wishes to confirm his clinical findings with such laboratory tests as are easily available to him. All these patients were treated as cases of kala-azar with antimony injections and progressed favourably.

Summary of Positive and Negative Findings in Kala-azar and Non-kala-azar.

Antimony Test (Undiluted Serum Method).

TABLE V.

Results.	Reading.	Definite kala-azar cases.	Non-kala-azar cases.
Positive ..	+++ } ++ +	194	40
Doubtful ..	±	2	10
Negative ..	—	5	89
		Kala-azar cases 201 diagnosed by finding parasites.	Control 139 non-kala-azar cases.

Correct diagnosis in $194 + 89 = 283$ cases out of 340, or 83.2 per cent.

Doubtful diagnosis in $2 + 10 = 12$ cases out of 340, or 3.6 per cent.

Wrong diagnosis in $40 + 5 = 45$ cases out of 340, or 13.2 per cent.

TABLE VI.
Aldehyde Test.

Results.	Reading.	Definite kala-azar cases.	Non kala-azar cases.
Positive ..	+++	168	1
Doubtful ..	(+) or ±	23	30
Negative ..	(-) or —	10	108
		201	139

Kala-azar diagnosed by
parasite findings.

Control non-
kala-azar
cases.

Correct diagnosis in $168 + 108 = 276$, or 81.2 per cent.
Doubtful diagnosis in $30 + 23 = 53$, or 15.6 per cent.
Wrong diagnosis in $10 + 1 = 11$, or 3.2 per cent.

Summarising the comparative results given by the two tests in the two groups of definitely kala-azar and apparently non-kala-azar cases, it will be seen that in case of the antimony test, a correct diagnosis can be made in 283 cases out of 340, i.e., in 83.2 per cent., a doubtful diagnosis in 12 cases, i.e., 3.6 per cent., and a wrong diagnosis in 45 cases, i.e., 13.2 per cent. In case of the aldehyde test a correct diagnosis can be in 276 cases,

or in 81.1 per cent., a doubtful diagnosis in 53 cases, or 15.6 per cent., and a wrong diagnosis in 11 cases, or 3.2 per cent. of cases. Wrong and doubtful diagnosis in the case of the antimony test works out at 16.8 per cent., as compared to 18.8 in cases of the aldehyde test.

DILUTED SERUM METHOD.

We have seen in Table II that 35.9 per cent. of apparently non-kala-azar cases in an endemic area gave a positive antimony test. Owing to the greater sensitiveness of the test a positive reaction is obtained in chronic malaria with enlargement of the spleen and a few other conditions. It was with a view to eliminating these that we introduced the 1 in 10 dilution method. We will see what bearing the application of this method has on the results.

We have to return to Table I, horizontal column (3), which shows that the diluted serum method gives 175, or 87.06 per cent., definitely positive results as compared with 194, or 96.5 per cent., with undiluted serum; the doubtful reactions were 6.4 per cent. as compared with 1.0 per cent., and negative results were obtained in 6.4 per cent. as compared with 2.5 per cent. The doubtful and negative reactions in this series where kala-azar was definitely proven by parasitic findings, is 3.3 in the case of the aldehyde test, 7 in the case of the undiluted serum test and 26 in case of diluted serum test. This shows that the value of the positive diluted serum test in kala-azar sera is not so great as the undiluted serum test, but even so is slightly higher than the aldehyde test. There are a larger number of doubtful and negative reactions owing to the fact that in all probability the proteins responsible for the reaction are not present in sufficiently large quantities to give a positive test in 1 in 10 dilutions in some of the early cases.

A perusal of Table II, horizontal column (3), shows the value of the dilution test in 139 patients who were not apparently kala-azar. It will be seen that whereas with the undiluted serum test only 89 negatives were obtained, with the diluted serum method a definite negative diagnosis could be made in 125, or nearly 89.9 per cent. The percentage of wrong and doubtful diagnosis in this series with the aldehyde test was 22.3 per cent.; with the undiluted antimony test it was 35.9 per cent.; and in case of the diluted serum test is only 10.0 per cent.

When the dilution test was performed in a non-endemic area even better results were obtained.

A perusal of Table II, horizontal column (2), shows that the dilution test was entirely negative in 148 cases out of 150, i.e., in 98.7 per cent., the error of positive diagnosis being only 1.3 per cent. in non-kala-azar cases in a non-endemic area.

Table IV, horizontal column (3), gives the results of 128 cases of kala-azar diagnosed by clinical and laboratory findings but in which no effort was made to find leishmania.

It will be observed that 105 cases, or 82 per cent. gave a positive result with the aldehyde test, 127 or 99.2 per cent., gave a positive result with the undiluted serum method, and 105, or 82 per cent., with the diluted serum method. In these cases the result of the dilution method runs parallel with the aldehyde test and if it can be claimed for the latter test that "for all practical purposes a positive reaction in an untreated case indicates kala-azar" the same claim can be put forward for the dilution method.

Summary of Antimony Test Result (Dilution Method).

TABLE VII.

Results.	Reading.	Definite kala-azar cases.	Non kala-azar cases.
Positive ..	+++ ++ +	175	7
Doubtful ..	±	13	7
Negative ..	—	13	125
		201	139

Aldehyde test from Table VI.

Correct diagnosis in 175 + 125 = 300 or 88.2 per cent.	..1	81.2 per cent
Doubtful diagnosis in 13 + 7 = 20, or 5.9 per cent	..	15.6 per cent.
Wrong diagnosis in 13 + 7 = 20, or 5.9 per cent.	..	3.2 per cent.

It will be observed that the percentage of correct diagnoses is greater than with the aldehyde test.

The Time of Appearance of the Antimony Test and its relation to Splenic Enlargement.

The time of appearance of the antimony test in the course of the disease is difficult to decide satisfactorily, as histories in most cases are unreliable and it is impossible to say at what stage of the disease patients come under treatment. Through the kindness of Dr. B. M. Das Gupta, Assistant Professor of Protozoology, we have been able to collect a series of 11 cases which were, according to him, very early cases of kala-azar. They were all his private cases, gave a history of fever of short duration, and the fact that the spleen in almost all these patients was only just palpable and well above the costal margin, showed that probably the duration of fever was not more than a month or two at the most. The final diagnosis in all these cases was made by finding the leishmania in cultures or by puncture.

A perusal of Table VIII shows that the antimony test was positive in all the eleven cases with the undiluted serum, and with 1 in 10 dilution was negative in 1 and doubtful in 2 cases. In such cases the aldehyde test is usually negative or doubtful. Although the series of cases is very small it does show that the antimony test appears at an early stage, probably within the first month or two. More work, however, is necessary on this point.

As regards the relationship between the antimony test and the size of the spleen, we have only been able to study its bearing on positive cases of kala-azar. Our experience is that the size of the spleen makes no difference to the diagnostic value of the test in these cases. The difficulty arises in differentiation of those cases of malaria with chronic enlargement of the spleen which give a positive antimony whole serum test. These can be usually differentiated by doing the 1 in 10 dilution test, but not infrequently there are border line cases in which nothing short of a spleen or liver puncture or blood culture will decide the diagnosis. Major Kernahan who did 50 cases of chronic malaria with enlargement of the spleen in Rawalpindi, which is a non-endemic area, informed us that the dilution test was practically never positive in chronic malaria. We are doing more work in this connection and we hope to bring out the relationship between the size of the spleen and the antimony test in non-kala-azar cases in an endemic and a non-endemic kala-azar area, and the results will be communicated in due course.

A perusal of the figures given in the tables incorporated in this paper will give the reader an idea of the diagnostic value of the antimony test. It is true that the series of cases given is not very large. This is due to the fact that we confined ourselves to patients who visited the out-patient department of the School or were actually admitted to the Carmichael Hospital for Tropical Diseases within a fixed period. These results are, however, typical of the test and our experience with a large number of patients shows that they are constant within reasonable limits.

SUMMARY AND CONCLUSIONS.

(1) The technique of the antimony test and the standards of positivity have been fully described. Although the precipitate in the majority of cases appears immediately, it has been shown that the best time for the reading of the test is from 5 to 10 minutes after the addition of antimony solution to the serum. This is especially the case

with the diluted serum test; readings taken within the first few minutes as well as those taken after 20 to 30 minutes are both liable to error. In the former case a precipitate may not appear at all in a positive case, whereas in the latter case some form of haziness or even a granular looking precipitate giving the appearance of flocculation may be formed on standing in a negative case.

(2) The correct interpretation of the test depends on the correct reading of the character of the precipitate. With kala-azar sera the precipitate usually shows conglomeration into a thick mass with the undiluted serum, and coarse white flocculation with the diluted serum.

(3) The miniature tubes and the pipette, etc., used for performing the test should be scrupulously clean, and before the test is done it is advisable to wash them with distilled water. The tubes should be of standard size and we recommend those with 4 to 5 mm. internal diameter. The urea-stibamine solution should be prepared in distilled water. If these precautions are not taken a haziness or even a precipitate may appear with non-kala-azar sera.

(4) It is advisable to do the test with both the undiluted and diluted serum (1 in 10) in all cases. With a little practice the dilution can be easily made and the test can be performed by the patient's bed-side.

(5) Strongly positive reactions (i.e., +++) are usually definite cases of kala-azar, but this does not mean that ordinary positives (i.e., ++ and +) are not true cases of the disease. In fact the majority of the early cases of kala-azar give a ++ or + reaction.

(6) In 201 cases of kala-azar in which a diagnosis was made by the finding of leishmania a positive reaction was obtained in 96.5 per cent. of cases with the undiluted serum, as compared with 83.5 per cent. of aldehyde test. With the diluted serum this percentage was reduced to 87.0 because proteins responsible for producing the reaction were insufficient in some of the early cases.

(7) In a series of 139 non-kala-azar cases in which, however, the diagnosis was made clinically in the majority of cases without looking for leishmania, the antimony test was definitely negative in 64.1 per cent. as compared with 77.7 per cent. of the aldehyde test. The high percentage of positives in apparently non-kala-azar cases is due to the greater sensitiveness of the test. It is admitted that in a kala-azar endemic area from which these cases were obtained, there may be patients suffering from fleeting or latent kala-azar which have been missed by the aldehyde test and were caught by the antimony test. This is borne out by the fact that in a series of 150 cases done in a non-endemic kala-azar area (Peshawar) the percentage of definitely negative reactions with undiluted serum was increased to 86.6 per cent.

(8) With the diluted serum the source of error in non-kala-azar cases can be greatly reduced. Owing to the greater sensitiveness of the test, a positive reaction is sometimes obtained in very chronic cases of malaria with enlargement of spleen, advanced tuberculosis, leucocythæmia, etc.; such cases do not as a rule give a precipitate in 1 in 10 dilution. With the dilution method 89.9 per cent. of cases gave a definitely negative reaction in the above mentioned series of 139 non-kala-azar cases from an endemic area. When the dilution method was done in 150 cases in a non-endemic area the percentage of negatives went up to 98.7.

(9) In a series of 128 cases of kala-azar diagnosed by clinical symptoms, leucocyte counts and the therapeutic test of recovery after treatment with antimony compounds, etc., the antimony test was positive in 99.2 per cent. as compared with 80.4 per cent. by the aldehyde test.

(10) Taking kala-azar and non-kala-azar cases together in a series of 340 cases, correct diagnosis could be obtained with the aldehyde test in 81.2 per cent. of cases, with the undiluted antimony test in 83.2 per cent. and with the dilution method in 88.2 per cent. This brings out the advantage of doing the test both with undiluted and diluted serum.

(11) The size of the spleen does not in any way affect the diagnostic value of the test in definite kala-azar cases. The antimony test has been shown to be positive in early cases of kala-azar with a hardly palpable spleen when the aldehyde test is negative, as well as in those with a spleen over 6 inches below the costal margin.

(12) By means of the antimony test a diagnosis can be made in the majority of cases of kala-azar met with in the outpatient departments of dispensaries and hospitals in the same way as with the aldehyde test.

(13) The test is somewhat more sensitive than the aldehyde test and appears earlier in the course of the disease. The dilution method enables us to exclude a large majority of non-kala-azar cases and therefore it is possible to make a negative diagnosis in a large number of cases.

(14) The antimony test can be performed and read in less than one quarter of an hour. For the completion of the aldehyde test it may be necessary to wait for 24 hours.

In conclusion it may be said that the antimony test is a rapid and efficient method of diagnosing kala-azar. A positive reaction is as a rule obtained with undiluted sera of almost all cases of the disease. If the serum is diluted ten times, kala-azar sera give a characteristic coarse flocculent white precipitate; non-kala-azar sera rarely give a similar precipitate. With undiluted sera almost all the early and advanced kala-azar cases will give a positive reaction, but a few of the chronic malaras, advanced tuberculosis, leucocythæmia, etc., may also come in. When 1 in 10 dilutions are used some of the very early cases of kala-azar may be negative, but the non-kala-azar conditions named (which give a positive test with whole serum) will be excluded. If the test is done with both the undiluted and diluted sera a more or less certain diagnosis can be obtained in a very large majority of cases, especially if the results are interpreted with due regard to the clinical condition of the patient. A very small class of difficult and border line cases will be left, in which a definite diagnosis cannot be made except by spleen or liver puncture or cultural examinations.

NOTES ON "THE SIGNIFICANCE OF THE ANTIMONY TEST IN THE DIAGNOSIS OF KALA-AZAR."

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P.,
Kala-azar Research Worker (Indian Tea Association),
Calcutta School of Tropical Medicine and Hygiene.

A YEAR ago the writer of these notes published a paper entitled "A Critical Examination of the Antimony Test for Kala-azar." This paper was an analysis of the results of the antimony tests and the aldehyde test in 165 cases in which a definite diagnosis had been made by demonstrating the presence, or the absence, of the parasite by means of a spleen or liver puncture. One hundred were cases of kala-azar and 65 were patients who had come under suspicion as cases of kala-azar, but who had subsequently been shown not to be suffering from the disease. Thus the 65 non-leishmania patients were not a true sample of the "hospital population," nor even of the "fever population," but were selected controls who were suffering from a condition clinically identical with kala-azar, or whose blood had undergone some of the protein changes associated with that disease (i.e., their aldehyde reaction was "doubtful"). It is not surprising therefore that the results of all the serum tests did not appear to be altogether satisfactory: they are summarized in the table below:—

	Aldehyde.	Antimony, undiluted serum.	Antimony, diluted serum.
Correct ..	49.4	62.8	63.4
Incorrect ..	5.5	23.8	14.0
Doubtful ..	45.1	13.4	22.6
Proportion of correct to in- correct (to nearest whole figure).	9 to 1	3 to 1	5 to 1

To take just one figure in the table of the first series, it will be seen that for the antimony test with undiluted serum the proportion of correct to incorrect results was 3 to 1; this figure is so low that it suggests that the test is not of much practical value. By taking into consideration the size of the spleen and readjusting the standards of positivity it was found possible to raise the proportion to 12 to 1, i.e., 28.6 correct to 2.4 incorrect diagnosis, but this meant a considerable curtailment of the utility of the test, as there remained a very large group of "doubtful" results. Anyone who knew the extreme difficulty of making a diagnosis in this class of cases, except by the finding of the parasite, would realise that this is a comparatively satisfactory result, but judged by ordinary standards it does not appear satisfactory, and it seems possible that this paper may have prejudiced the inexperienced against the test. For this reason the writer promised Col. Chopra his assistance in carrying

out another series of tests on definitely diagnosed cases of kala-azar with the general hospital population as the controls. The results of this series have been reported above by Col. Chopra and Dr. De; at their suggestion these notes have been written by way of comment on their interpretation of the results.

In the previous series all the results were read by Col. Chopra, but in this series the whole test was carried out in his laboratory. Previous experience had shown that some slight modification in the technique—mainly with reference to the time after addition of the serum at which the results should be read—was advisable. The modifications undoubtedly improve the tests—especially the test with diluted serum—but the very marked apparent improvement is due mainly to the fact that the controls were an entirely different class of patient in this series.

The figures for the present series can be summarized as follows:—

	Aldehyde.	Antimony, undiluted serum.	Antimony, diluted serum.
Correct ..	81.2	83.2	88.2
Incorrect ..	3.2	13.2	5.9
Doubtful ..	15.6	3.6	5.9
Proportion of correct to in- correct (to nearest whole figure).	25 to 1	6 to 1	15 to 1

The ideal test would be one in which there were no "doubtful" results and in which all the results were correct. The shortcomings of a test can be measured in two ways, by the number of "doubtful" results and by the proportion between the correct and incorrect results. Though figures can be given for these two factors they are not comparable; in certain circumstances it may be advantageous to obtain a diagnosis in only 50 per cent. of cases provided the diagnosis is accurate, whereas in others it may be better to make a definite diagnosis in 100 per cent. of cases, even if this diagnosis is correct only four out of five times. In hospital practice where other methods of diagnosis are available—e.g., spleen puncture and blood culture—it is not a serious matter if, as in the case of the aldehyde test in this series, there are 15.6 per cent. "doubtful" results, provided 25 out of 26 of the definite (i.e., positive or negative) results are correct; whereas in mofussil dispensary practice, when other means of diagnosis are not available, in order to obtain a definite diagnosis in a higher proportion of cases it is possibly better to make some sacrifice of accuracy and to use the antimony test with diluted serum with which a definite diagnosis can be made in 93.5 per cent. of cases, but in which the number of correct definite results is reduced to 15 in each 16 cases. It is, however, doubtful if under any circumstances it would be justifiable to use the

undiluted serum antimony test and reduce the proportion of correct to incorrect results to 6 to 1 for the purpose of obtaining a further slight increase in the number of definite results.

Col. Chopra has shown that in a non-endemic area the antimony test is seldom positive. This is also true of the aldehyde test. Gaté and Papacosta (1920) tested the serum of some 400 persons in Europe by the same technique and in no case did they report that opacity of the serum occurred; also Lal (1923) after testing a number of cases of chronic malaria in the Punjab concluded that "The aldehyde test as used by Napier is not positive in malaria if the standards of this author be taken."

Col. Chopra has argued that the rarity of these false positives in non-endemic areas suggests that many of the controls in this series may have been cases of "latent or transient" kala-azar. This, in the writer's opinion, is extremely unlikely. They were all patients in the Carmichael Hospital for Tropical Diseases and whenever there was a suggestion that they might be suffering from kala-azar the present writer was asked to see them; a spleen or liver puncture was done in most instances and in 17 cases a spleen puncture culture was done and was "negative"; the serum test results in these 17 cases can be summarized as follows:—

	Positive.	Doubtful.	Negative.
Aldehyde test ..	0	12	5
Antimony test, undiluted serum	13	2	2
Antimony test, diluted serum.	4	3	10

Furthermore, in the writer's experience the serum tests are always entirely negative in the transient case; when the serum changes develop, the disease becomes progressive until checked by treatment, or by some severe disturbance, such as an attack of pneumonia.

On the other hand, the presence of a disproportionately large number of "false positives" in the endemic area requires accounting for and a possible explanation is that many of the patients in which these occur have at some time or another had kala-azar. The practical point, however, is that at the time they are not suffering from a generalized leishmania infection and from experience with such cases one knows that the clinical condition is not improved by antimony treatment.

The observations with the test in cases of kala-azar diagnosed by other methods than finding the parasite do not add any evidence in favour of the test, because probably in most instances the diagnosis was made on the result of the test itself.

CONCLUSIONS.

It is difficult to compare the two tests, the antimony and the aldehyde, as each shows individual qualities and individual defects. The aldehyde test's main defect lies in the fact that it gives a large number of "doubtful" reactions, 53 (or 15.6 per cent.) in this series, and that the reaction is negative in many early cases, in 10 in this series. Its advantage lies in the fact that for all practical purposes a positive result means that the patient is suffering from kala-azar—of the 169 positive results of this series 168 were in patients actually with kala-azar and the other was in a patient who had completed a course of treatment and had only been discharged one week before he was readmitted with pneumonia, that is, he was a convalescent kala-azar case.

The antimony test with undiluted serum has the advantage of being positive more frequently than the aldehyde test in early cases, but nevertheless it was entirely negative in 5 cases of kala-azar in this series. A strongly positive result appears to be diagnostic of kala-azar, but a positive, i.e., ++ or +, result has little significance as more than half the cases in this series in which it occurred were not kala-azar.

The antimony test with diluted serum has the advantage of giving a definite result in a large number of cases, 93.5 per cent. in this series, but at the same time the results are less satisfactory than the aldehyde test results at both ends of the scale; 7 of the negative controls gave a positive, i.e., ++ or +, result, and 13 of the kala-azar cases gave a negative result, whereas for the aldehyde test the figures were 1 and 10, respectively.

As a final conclusion, the present writer considers that Col. Chopra and Dr. De's figures show that the aldehyde test and the antimony test with diluted serum are tests of almost equal and very considerable practical value in the diagnosis of kala-azar, but that the antimony test with undiluted serum falls short of both these tests in this respect.

My thanks are due to Col. Chopra and Dr. De for permitting me to see, not only the text of their paper, but all their laboratory records, and for allowing me this opportunity of submitting these conclusions on their observations.

T. A. B. VACCINE IN RELATION TO AN OUTBREAK OF ENTERIC FEVERS.

By M. K. AFRIDI, M.B., Ch.B. (St. And.),
D.T.M. & H. (Lond.),
CAPTAIN, I.M.S.,

Quetta.

THE introduction of T. A. B. inoculation in the Army, while its undoubted value is

recognized, has produced two definite complicating effects in that it has made the study of diagnosis and epidemics decidedly more difficult. The uncertainties of a diagnostician are too well known to elaborate, and it is now becoming clear that the isolation of the causative organism is the only definite and early laboratory help in diagnosis.

milk. In addition, the food handlers were reclassified according to their arrival in the station and association with cases. Two bhisties, recently enrolled and related to five cases, were each examined on six consecutive days and found "non-carriers." The possibility of a "carrier" or "carriers" amongst the men themselves was

* Worked in a cook house. Used water from tap No 4 while on duty.

SPOT MAP of Barracks showing (I) Distribution of cases.
(II) Water supply.

The Widal reaction, which used to be such an effective factor, has ceased to hold its former position; the agglutinin curve takes at least two weeks to work out and requires repeated samples of blood which may be justifiably objected to by the patient. A certain officer had *B. paratyphosus* A infection and his wife was aghast at the number of times her husband was "bled." I am sure she laid the usual charge of callousness at the door of the medical profession.

To illustrate the rôle of T. A. B. vaccine in altering the course of an epidemic I will describe an outbreak of the enteric group of fevers in a protected community.

Commencing from February 1928, a number of cases occurred in a training battalion. Neither the situation of the affected barracks, nor the order of occurrence of the disease pointed to any of the classical vehicles of infection. The cases kept on appearing in a sporadic manner and made the problem of their source of origin a very puzzling one indeed.

The investigations carried out, with negative results, included repeated examination of the food handlers and the bacteriological analysis of

kept in mind, but no relationship was traceable to any individual. The outbreak was not influenced by the "fly seasons."

At no time was water ignored as a possible source of infection, and in the early stage all the available evidence was against its involvement. Thus the rest of the garrison remained unaffected throughout this period, and in the training battalion itself no cases occurred in 11 out of 17 barracks; also, the routine examination of the water supply from a tap in the British Military Hospital had been giving constantly satisfactory results.

On reviewing the situation in November 1928 when the cases had totalled 10, the fact that the affected individuals belonged to different castes, different religions, and different cookhouses; and secondly, that one man contracted the disease whilst in the Indian Military Hospital for a surgical condition, made the further detailed investigation of water supply essential.

Water Supply.—Water is centrally chlorinated in a tank situated about two miles to the north of the affected lines. Distribution is by pipe line. The main pipe runs by the British Military Hospital, through the British infantry and artillery

lines, along the training battalion barracks and terminates in the Indian Military Hospital, the most southerly situated unit in the station. The supply to the training battalion comes from four stand pipes on the main line.

Prior to August 1928 the main pipe terminated at the furthestmost tap marked 4 in the diagram and the hospital was supplied by a branch line taking off above tap No. 1. Owing to incessant demands for increased water supply the main pipe was extended to the hospital, thus giving it

Diagram Representing Station Water Distribution System.

a double supply, viz., from the branch as well as the main pipe. This recent extension has a special importance in view of the "hospital infected" case, as it served to crystallize the growing suspicions against the main pipe water as a source of infection.

Samples of water from the four taps in the training battalion lines were then examined, and it was found that taps Nos. 3 and 4 yielded definitely contaminated water; tap No. 2 was slightly contaminated; while a sample from tap No. 1 was sterile. These tests were repeated, and although the results did not wholly corroborate the first findings, it was evident that the taps Nos. 4 and 3 yielded definitely contaminated water, and that the water from taps Nos. 2 and 1 had slight contamination only. The conclusion drawn was that there was a leakage in main line somewhere below tap No. 1.

The reluctance of the M. E. S. to agree to expose the line on such evidence had an element of justification. It was, however, ultimately agreed to, and the pipe was found to have a freely leaking joint below tap No. 3, and a smaller leakage below and close to tap No. 2. The Garrison Engineer was of opinion that this condition of the pipe was of old standing.

The proximity of the urinals to the points of leakage has special significance in this connection (*vide* diagram).

The water supply is intermittent, and the flow of water influencing the spread of contamination up and down the pipe would account for the discrepancy shown in the results of the analysis from taps Nos. 1 and 2. It would, however, be expected that the contamination would tend to concentrate more in taps Nos. 3 and 4 which supply

the southern barracks and the segregation camp where most of the cases occurred.

The repairs were completed in the first week of December, and after case No. 11—presumably infected before the repairs—no more cases occurred for a month and a half. The water samples from the taps gave satisfactory results, and we thought we had seen the last of the disease. This, however, was not to be, and to our intense disappointment seven further cases occurred in the next two months.

Of these seven cases, No. 1 deserves a passing note. He was originally admitted for hepatitis with jaundice, and a rise of temperature (100°F.) lasting two days. He had no symptoms of typhoid fever. On routine examination of the faeces and urine, *B. typhosus* was isolated from both. The agglutinin curve did not show a diagnostic rise and fall. He continued to pass *B. typhosus* in the urine for three months, all the while keeping excellent health. These considerations and the course of his illness pointed to his being a typhoid carrier with localization of infection in the gall bladder and possibly common bile duct.

Case No. 2 was admitted as a convalescent, having contracted the illness at his home when on leave. *B. typhosus* was isolated from his stools and urine.

Cases Nos. 3, 5 and 6 were undoubtedly out-station infections. Case No. 3 had recently returned from his home and had there attended on his father and brother who had died from typhoid fever.

On the other hand, Cases Nos. 4 and 7 were infected in the station. They belonged to the same company and barrack room, and in their case the infection was traceable to their cook, who was found to be a "carrier" of *B. typhosus*. This cook had attended the hospital for two days in December 1928 for colic and slight temperature. It is probable that he had then a very mild form of typhoid fever, as a recent carrier examination in September 1928 had given negative results.

Water was thus found to be free from being a source of infection in the second series of cases.

There have been no further cases to date.

General Remarks.—This investigation has been given in full to bring out the fact that although the source of infection was a commonly recognized one, the tendency for the outbreak was to lose its classical features. The explosive character and the uniform distribution of a water-borne infection were conspicuously absent. The immunity factor which is always an "unknown quantity" in the study of an epidemic, is rendered still more "unknown" by prophylactic inoculation. This results in an irregular and

wider dispersal of the "susceptibles" who eventually develop the disease, when they receive a massive dose of infection. That in my opinion can be one explanation of the peculiar behaviour of the outbreak.

Another point worthy of notice is the degree of protection afforded by the T. A. B. inoculation. Excluding the barracks supplied by tap No. 1, there were roughly 500 men exposed to infection for a period of one year, and if allowance is made for the fact that a training battalion has a complete "turn over" of personnel every nine months, this figure would come to be nearer 1,000. Out of these 11 men contracted the disease with a case incidence ratio of only 2.2 per cent.

It is also apparent that the protection is not absolute, and it is only in the combination of T. A. B. inoculation and good sanitation that we possess a powerful and effective weapon against the onslaught of this disease.

A SIMPLE METHOD OF STANDARDIZING THE RED CELL SUSPENSION IN CONNECTION WITH THE WASSERMANN REACTION.

By S. D. S. GREVAL, B.Sc., M.D., D.P.H.,

CAPTAIN, I.M.S.,

Assistant Director, Pasteur Institute of Burma, Rangoon.

Red cells collected and washed apparently under identical conditions may not yield a deposit of the same density. A 5 per cent. or 3 per cent. suspension made from the deposit will consequently differ from day to day. The minimum hæmolytic dose of the complement obtained therefore is not comparable on different days. Besides, with a suspension thicker than usual an M. H. D. is obtained which is in excess of what is normally destroyed by an anticomplementary antigen.

Attention appears to have drawn to this important adjustment of the hæmolytic system long ago(1). In the usual works of reference and publications in English, however, one does not find any details.

The writer finds that the density of the suspension, for the requirements of method IV of the British Medical Research Council(2), is optimum when 7 drops of a 6 per cent. suspension delivered from a Wright's pipette, with the point fitting hole No. 58 of the standard wire gauge, giving a direct reading of 51 on Sahli's scale. Such drops measure 0.02 c.c. each.

A suspension giving a higher reading can be adjusted to give the required figure by dilution.

Example:—A suspension gives a reading of 62, total volume is 100 c.c.

$$51 : 62 :: 100 : X \therefore X = \frac{62 \times 100}{51} = 121.56$$

An increase of volume to 121.6 c.c. will reduce the reading to 51.

A suspension giving a lower reading can be made to give a higher reading by the addition

of more of the deposit and then adjusted as detailed above.

Since adopting this method of standardizing the red cell suspension, the writer has always found a perfect correspondence between the two rows of tubes used in determining the M. H. D. of the complement, when titrated with and without the presence of antigen. This fact, incidentally, emphasizes the importance of determining the M. H. D. of the complement in presence of the antigen. Any lack of adjustment is made visible by a lack of correspondence between the tubes of the two rows.

AN INQUIRY INTO THE PHYSICAL CONDITIONS OF INDIAN LABOUR.

(A PRELIMINARY COMMUNICATION.)

By DR. P. V. GHARPURÉ, M.D. (Bom.),
Grant Medical College, Bombay,

and

S. G. LATEY, B.com. (Bom.).

THIS inquiry was undertaken with the object of making preliminary observations on the conditions of Indian labour. All the equipment required was purchased with a view to ascertaining the total cost of such a preliminary investigation carried out outside the laboratory over a fixed period. A suitable place to carry out such an inquiry was found by us at Khandala* where a large labour camp was situated. The favourable conditions that made us select this place may be summarized as follows:—

The labourers were paid on a daily wage system (payments being made once a fortnight), and purchased their provisions (food and clothing) once a fortnight. They were better paid than the labour available in Khandala village proper. The wage normally existing was about 8 annas per day, as compared with the wage paid in the camp which was one rupee or more.

(a) A large sized camp (average population over 5,000) was situated at this place in connection with the "Bhoreghat Realignment Scheme" undertaken by Messrs. Tata Construction Co., Ltd., for the G. I. P. Railway.

(b) The camp consisted of a large number of specially erected huts built on a uniform plan.

(c) The labour was imported practically from all parts of India.

(d) The camp had its own shops, hospital, electric supply and sanitary arrangements.

* Khandala is a place situated 70 miles from Bombay in the Poona District, a well known health resort and once a military station under the Southern Command, situated at a height of 1,900 feet above sea-level. The rainfall was on an average 200 inches. The village called Khandala proper is a small one with a population of about 2,000. It has a government dispensary.

(e) The hours of work were fixed, either by day or night.

(f) The camp was well organized and we were promised all facilities by the authorities concerned.

The following general observations regarding the labour may be made. The labourers had their own boarding houses. Often a group of labourers employed one from amongst themselves to cook for all and paid his daily wage in return for his services. Many of them lived with their families. They were poor and had no reserve fund to start with. They had on the whole very poor ideas of personal hygiene, but were willing to change their habits on being told, and shown the importance of cleanliness, e.g., bathing, the use of soap, etc.: they had no prejudice against western methods of treatment. They were on the whole congenial and helped us in our inquiry. They had their own prejudice about working inside the tunnels, but most of them were willing and capable of picking up new work which naturally increased their income. The composition of the camp varied.

The inquiry was restricted to such of the labour as had a semi-permanent residence, the floating population of the labour force being eliminated as far as possible.

The inquiry was carried out by the interview system, and the details were directly written down on a card specially printed for that purpose.

As will be seen from the card the findings were grouped under three main headings:—

- (1) Medical,
- (2) Social, and
- (3) Economic.

Inquiry into family budgets of labourers living with their families was not undertaken.

The findings under different heads have been tabulated and may be taken for what they are worth, especially considering the preliminary nature of the work taken up, with an idea to give us experience to carry out further similar investigations on more elaborate lines.

For purposes of the inquiry we have chosen to group the labour force from a geographical point of view and divide them according to the places they came from. The divisions are as follows:— (1) Frontier (referred to as Pathans in the table and text that follows); (2) from the Punjab, United Provinces and Central India (referred to as Northern Indians); (3) from the Bombay Presidency (referred to as Marathas); (4) from Madras Presidency and Mysore (referred to as Southern Indians); and (5) from Baluchistan and the surrounding areas of Hyderabad, Sind, (referred to as Makranis). It has not been possible for us to study the comparative conditions of vegetarians and non-vegetarians respectively or from any other point of view, owing to various difficulties.

The total number of labourers examined was over 800, but some persons had to be omitted on account of some omissions in the notes. The actual figures obtained by us are approximately representative of the ratio of the actual population to the respective groups made by us.

Medical.

The first section relates to findings in which medical men will be interested, and under this heading are included comparative tables of height, weight, and chest measurement of different classes as an index of physical development in different parts of India.

These tables give a general idea of the development of inhabitants of different parts of India. In the South an average adult male is comparatively thinner and shorter than one from the North. Amongst the groups made by us in this

inquiry we have noted that the average Pathan possessed the best physique. Some excellent examples were seen of young males of age between 18 and 20, having lbs. 120 weight, and over 6 feet height. It was a pity we were not able to persuade such men to allow us to take their photographs. Some of the poorest specimens were seen amongst the inhabitants of the Bombay Presidency. Whether this is to be explained by the diet or otherwise we have no data in our possession to conclude. In general it may be stated that the height, weight and chest measurement proportionately increase as age advances up to a limit of 30 years, beyond which there is a disparity in the proportions, especially in the fullness of chest, owing to frequency of chest troubles of some kind being common. It also appears that there is either bending of the vertebral column or absorption of cartilages rather early, explaining the diminution in the height noted above the age 30 years.

near, and colour blindness. The object of the questions was later found very difficult to explain to our subjects, and to understand ourselves their description of the colour, etc., and this detail had to be omitted from the subsequent inquiry. The findings about colour blindness would have been very useful. The only thing possible to do was to note down the reaction of the pupil to light, and evident diseases such as trachoma, corneal opacities, congenital defects, cataract, etc. All these have been grouped under the one title "eye diseases." The malaria incidence was based on splenic enlargement and blood examination. The rest of the diseased conditions have been diagnosed from symptoms complained of or the results of physical examination. Under "tumours" are included only such as were visible externally. This figure cannot be taken as an absolute index of incidence of tumours. In the deeper organs it is not at all uncommon to see tumours in the post-mortem room in India.

spleen. It was noted that except for one all sera gave a negative reaction. The blood showing a positive reaction was sent to the laboratory for culture but unfortunately this was not carried out.

The cost of medical aid given to all inmates of the camp was only about Rs. 2,000 per mensem, including the salary of two doctors, a compounder, and two hospital servants, etc., and drugs and dressings.

TABLE III.

Table showing Disease Incidence in Percentages in Different Classes.

A FURTHER NOTE ON THE TREATMENT OF VESICO-VAGINAL FISTULA BY RECTAL TRANSPLANTATION OF THE URETERS.

By F. C. FRASER,

LIEUTENANT-COLONEL, I.M.S.,

District Medical Officer, Malabar.

IN a previous paper published in this journal (*Indian Medical Gazette*, Vol. LXIV, June 1929), I touched upon most of the difficulties that might militate against a successful operation. Since then I have operated upon more cases and as a result of the experience gained I am able to add two more very important points to the list of eight previously given (*loc. cit.*).

The presence of a torn perineum or atonic sphincter ani.—In one of our recent cases, after the completion of the two abdominal operations, I was greatly mortified to find that the patient could not retain urine in her rectum and on coming to examine the cause, I discovered that she had had an old tear in the perineum which had involved the sphincter. A third operation had to be undertaken to repair the perineum; this was successful and the patient left the hospital dry and happy.

Wise after the event, it seemed surprising that such a possibility had not suggested itself to us before, for patients badly torn about the vagina are more than likely to be torn about the perineum. Now every patient is carefully examined to see if the sphincter is in a condition to bottle up urine, and secondly to see if any recto-vaginal fistula is present before we commit

her to any severe abdominal operation. If the perineum is found to be incomplete, a radical cure is first carried out, as this is more likely to be successful when the rectum is comparatively dry than when full of a mixture of fæces and urine. In the case mentioned above, the operation was quite successful in spite of the rectal contents being liquid.

The danger of giving enemata after the operation.—Recently we lost the first and only case in our long series of operations, and this was due to an Indian nurse giving a copious enema to the patient without having received instructions to do so. The danger of such a proceeding is so obvious that I had not thought it at all necessary to issue instructions against such a possibility. The nurse appears to have given the enema as part of the usual routine after abdominal operations if the bowels are not open on the third day. In this case there was even less necessity as the patient was passing urine by the rectum. A copious soap and water enema was given and the patient exhibited signs of collapse within twenty minutes. She died three hours later exhibiting all the signs of peritonitis and very profound shock. No post-mortem was allowed but there can be no doubt but that the rectum was distended until the transplantation site was burst open and the rectal contents escaped into the peritoneal cavity. Similar accidents have been reported after appendectomy, the stump being burst open by giving a high enema. Personally I always issue a warning that no enema is to be given after the latter operation; it now seems to be none the less necessary to issue a similar warning after transplantation of the ureters.

A NOTE ON MUSEUM MAKING.*

By DR. P. V. GHARPURÉ, M.D. (Bom.),

Grant Medical College, Bombay.

THE main object in exhibiting objects in a museum is to give prominence to essential parts of the material in its natural position and appearance as far as possible.

In the preparations required for an Anatomy Museum of the Pathology Department I experienced certain difficulties and I have used certain methods which I propose to describe here.

The main steps in the preparation of museum preparations from wet material may be summarized as follows:—

1. The object must be obtained fresh as possible.

2. No time should be lost before it is dealt with.

3. No agent which will produce hæmolysis should be allowed to come in contact with it, but it should be washed in normal strength of salt solution.

4. The fixing of the object should be carried out immediately.

5. The fluid used for fixing must be at least ten times the volume of the preparation, but not much more.

6. In the case of a bulky preparation its interior should be injected with the same fluid.

7. The preparation when put in "fixing fluid" must be kept away from light and at room temperature. Fixing at lower temperature fails.

8. The preparation must not be allowed to come in contact with the container.

9. Heavier objects must be suspended and lighter ones weighted down.

10. The container must not be sealed but ample ventilation must be allowed. An unglazed earthenware container should serve admirably or a wooden cask.

11. The preparation must not be allowed to remain too long in the fixing fluid. The moment it is observed to change the colour of the fluid to turbid red, it must be transferred to another quantity of fixative. Such repeated baths must be used, sometimes every 12 hours, if one expects excellent results.

12. As soon as one comes to a condition when no further colour is given to the fixing fluid the preparation should be transferred to running water and kept under the tap for a few hours and then transferred to the preserving fluid.

13. I have never found it necessary to use spirit or alcohol to recover colours.

14. The preparation is allowed to remain in this second or preserving fluid for at least six months before it is mounted as a museum object.

15. If these details are followed one gets reasonably good results.

16. Fresh sections as a rule should not be made after these stages are gone through. The

best stage to do sectioning is during the preliminary fixing after the first 24 hours.

The composition of the fluid described by the International Association of Medical Museums was not found by me to be satisfactory.

I made the following alterations:—

(1) *Fixing*.—Double the amount of formalin, common salt and chloral hydrate.

(2) *Preserving*.—Double the amount of common salt.

My own experience is that glassware is not required at all except for mounting the exhibits; wooden casks are cheaper and serve best for stocking, fixing, preserving, etc.

The second method of preparing museum mountings is more attractive and useful for teaching purposes.

It consists of embedding a thin slice of any organ in a glycerine-gelatine mixture of such a consistency that it remains solid at room temperature at all times.

In the publication of the International Association of Medical Museums a composition of such a mixture is given which may be best suited for climates which are different from that of Bombay. I could not succeed in getting a solid block with that composition in Bombay.

On investigating the causes I found that the glycerine of the mixture abstracted a large amount of moisture from the atmosphere. I worked up the total amount of moisture abstracted by every 100 c.c. of the mixture and obtained in this way an altered composition of the mixture. The original formula and the one now in use with me are shown in the following table.

TABLE.

The following table shows the difference in the compositions.

Fixing Fluid.

		Original.	Revised.
Sod. Sulph.	..	11 grams	11 grams.
Sod. Bicarb.	..	10 "	10 "
Sod. Chloride	..	9 "	18 "
Potass. Nitrate	..	19 "	19 "
Potass. Sulphate	..	1 "	1 "
Chloral Hydrate	..	50 "	100 "
Formalin	..	50 c.c.	100 c.c.
Water	..	1,000 "	1,000 "

Glycerine-Gelatine Mixture.

		Original.	Revised.
Gelatine	..	80 grams	140 grams.
Sat. Soln. of Arsenious Acid.	..	200 c.c.	200 c.c.
Glycerine	..	800 "	1,000 "

It will be observed that the proportionate quantity of arsenious water had to be reduced and the gelatine percentage proportionately increased.

This mixture keeps indefinitely and solidifies and remains solid throughout the year.

I have some preparations made in 1926 which are still in perfect condition.

Such preparations are of great use in sending round in a class room while one is lecturing.

* Read before the British Medical Association, Bombay Branch, on 19th July, 1929.

DYSENTERY IN THE CENTRAL JAIL, RAJAMANDRY, MADRAS PRESIDENCY.

By SUB-ASST. SURGN. CH. KRISHNAMURTY, L.M.P.,
Central Jail, Rajamandry.

DYSENTERY is one of the most prevalent diseases in this jail. A careful investigation was made in 1928, and measures taken to reduce its incidence with some success. The fresh stool of every case was microscopically examined, and a diagnosis of the type of dysentery present arrived at. The following are the figures:—

Year.	Amœbic.	Percentages Bacillary.	Mixed.	Case mortality. per cent.
1927 ..	5.5	94.5	..	8
1928 ...	10.0	88.4	1.6	2

The disease is chiefly spread here by flies, and its incidence is directly proportional to the fly prevalence. January is the month of heaviest incidence, and the disease then gradually abates until it is almost absent in April. It again commences about July, and again wanes in November. There are thus two periods of the year when the disease is prevalent, with a quiescent period in between. That the disease is very prevalent in January probably throws some light on its epidemiology; January is an extremely cold month in Rajamandry, and the moisture does not dry up quickly. Flies are very numerous and active at this time. There is no rainfall during January, as a rule.

A fly-proof ward was constructed and almost all cases of dysentery segregated in it. Stringent measures were taken to prevent infection of food supplies and water, and all latrines were fly-proofed. General sanitary control was tightened up in 1928, and all possible breeding places of flies searched for and cleaned. Fly killers and fly papers were freely used inside the jail.

After the type of disease present has been diagnosed microscopically, appropriate treatment is given. Experiments were carried out in 1928 to try and determine the best line of treatment, with due regard to expense and efficiency. In 1927 all acute bacillary cases were treated with salines; but in 1928 a new departure was made, and polyvalent anti-dysentery serum of the Lister Institute was used for all acute cases in a dosage of 20 c.c. The effect of this measure on the temperature chart, the number of stools, and the abdominal pain is very marked. The earlier the serum is administered, the more marked is its effect. If the case is seen late, two doses, each of 20 c.c., may be required; we have had no occasion to give a third dose; and if the disease is of more than 48 hours' duration the serum is of no value.

On admission every patient received immediately a dose of Mist Olei Ricini (B. P.). As a rule, with the preliminary dose of castor oil mixture and serum treatment, the patients became convalescent in three to four days, and were discharged to duty a week after admission.

After discharge from hospital all cases were kept under control, segregated from the other prisoners, for one month in a separate dysentery block. During this period intestinal antiseptics such as hydrarg. perchloride, bismuth and salol, or a mixture containing thymol, dilute hydrochloric acid, and liquor arsenicalis was given. This last prescription appeared to have especially good results. Diet during this period was restricted to buttermilk and rice for a period of from 15 to 30 days according to the initial severity of the disease. There were no relapses.

The attached temperature charts illustrate the value of treatment by the castor oil mixture and anti-dysenteric serum.

CASE 1.

Name. V. pathi. Dis. B. Dysentery. C.No. 5988.

CASE 2.

Name. K. Kotadu. Dis. B. Dysentery. C.No. 7136.

CASE: 3.

Name. R. Kudu. Dis. B. Dysentery. C.No. 7367.

CASE 4.

Name. J. Narne. Dis. Dysentery. C.No. 3929.

The *Bacillus dysenteriae* (whether of Shiga or Flexner type) appears to be present here throughout the year. It becomes virulent for some reason only at certain periods of the year, and appears to be least virulent in summer. Strict segregation and anti-fly measures appeared to have been very successful in 1928. In barracks not protected from flies the infection appears to be able to secure a firm hold in spite of use of the usual disinfectants. This was repeatedly seen when, for disciplinary or other reasons, the patients could not be segregated in the dysentery ward.

CASE 5.

Name. V. Dhom. Dis. B. Dysentery. C.No. 889.

CASE 6.

Name. M. Narayya. Dis. Dysentery. C.No. 7383.

In about 100 cases treated with anti-dysenteric serum, serum anaphylaxis was never seen. We have used rather smaller doses of the serum than are recommended by Manson-Bahr, as the dysentery was most of less virulent type, and usually due to the bacillus of Flexner.

A comparative study of the cases treated in 1927 by salines and those treated in 1928 by castor oil mixture and anti-dysenteric serum shows the much superior value of the second method. In 1927 the average stay in hospital was 13 days as against 7 days in 1928. Though salines remove toxins as rapidly as they are formed, there is often a prejudice among the majority of patients against taking purgatives when they are already being purged.

My thanks are due to Dr. C. R. Kameth, M.B., C.M., Medical Officer, Rajamandry Jail, for kind permission to publish these notes.

NOTES ON MALARIA IN THE SIBSAGAR DISTRICT, ASSAM.

By ASSISTANT SURGEON J. M. SEN GUPTA, M.B., D.T.M. (Bengal),

Assam Medical Service (Senior), Sibsagar.

THE very word "Assam" at one time used to fill the minds of people of other provinces in India with a sense of fear and awe, as it was considered to be a province saturated with both malaria and kala-azar. This idea is to-day passing away gradually, as it has been found that certain portions of Bengal are no less infested with both diseases, and as bad as the worst districts in Assam. Not only was such an idea prevalent among laymen at one time, however; it also prevailed among the medical profession.

Such a belief is to be attributed chiefly to lack of accurate information on the subject. This year, Lieut.-Col. R. Knowles, I.M.S., in the closing lecture of his course on medical protozoology at the Calcutta School of Tropical Medicine, deplored that information on the subject of the parasitology of malaria in India was so meagre that workers on the subject had to depend on utterly insufficient data and out of date information. If I am not mistaken* the figures given by him for Assam were roughly as follows:—

P. vivax infections; not seen.

P. malariae infections, 2 per cent.

P. falciparum infections, 98 per cent.

In my experience, however, this percentage seems to indicate much too high a figure for *P. falciparum*, whilst *P. vivax* infections are so common here that one would give them an equally high percentage with those due to *P. falciparum*. In 1923 I kept a record of all blood examinations which I carried out during the year, and the results are shown in the accompanying chart.

In this chart *P. vivax* and *P. falciparum* infections alone are shown, and are seen to divide the malaria in Assam fairly evenly between them. *P. malariae* infections show a small percentage—perhaps about 2 per cent.—but are excluded from consideration. It must be remarked, however, that in some years the percentage of malignant tertian infections rises very abruptly—so much so that almost every case encountered appears to be due to this parasite, and 1928 was such a year.

The present position with regard to the diagnosis of malaria, its various clinical manifestations and complications, and their treatment is very much clearer and more satisfactory than

was the case a few years ago. For the treatment of malaria medical men have to fall back upon the drug of old—cinchona febrifuge, and its derivatives—and have to depend on its efficacy, in spite of the fact that innumerable attempts have been made by practitioners and pharmacologists

Seasonal incidence of Malaria in Sibsagar.

M.T. Thick line. B.T. Thin line.

alike to invent some new remedy for malaria which would excel quinine in its efficacy. Many such remedies have been proposed, but one by one their gradual disappearance has attested their worthlessness. There is no denying the fact that when quinine is administered in the proper method and in the proper dosage, an uncomplicated case of malaria can be treated very effectively, and that the drug is a specific in the cure of malaria under such circumstances.

On the other hand, notwithstanding the extreme value of quinine in straightforward cases of malaria, there is a group of about an equal number of cases of malaria where it seems to have but little effect. It is in connection with these cases that medical men are driven to variously advocated drugs, to other preparations of cinchona febrifuge, or to pushing dosage to a high degree in the hope of destroying the parasites. Even with so drastic a method as that last referred to, it is not known how high a percentage of cures would be reached. The types of malaria cases which present especial difficulty may be classified as:—

(i) Relapses in cases of benign tertian infection.

(ii) Malignant tertian malaria with cerebral complications—cerebral malaria.

(i) *Benign Tertian Malaria with Relapses.*—Nowadays these cases are treated with cinchona febrifuge—preferably the Indian variety—by oral administration, and the results are on the whole satisfactory. There is another school, however, who prefer intramuscular injections of quinine acid hydrobromide or hydrochloride, and consider this method to be far superior to oral administration of either quinine or cinchona febrifuge. Six injections are given, each of

* Not correct, and, one believes, not correctly quoted. The figures, on some 4,000 films examined at all seasons of the year by several different workers in Assam, are:—
P. vivax .. 1,086 cases—36.3 per cent.
P. malariae .. 298 cases—9.9 per cent.
P. falciparum .. 1,610 cases—53.9 per cent.
P. falciparum predominates.—R. K.

8 grs., on six consecutive days. How such a procedure should have a beneficial action it is very difficult to understand in view of the facts that (i) the total quantity of quinine injected is only 48 grains, and the medicinal efficacy of such a small quantity of the drug in curing relapsing malaria is impossible to understand; whilst (ii) when quinine is injected intramuscularly it is absorbed only slowly, and does not attain a higher concentration in the blood than is the case when quinine is administered orally; (iii) the view that a slow, gradual, and long-continued absorption will act more efficaciously on the malaria parasites is not borne out by biochemical findings.

These facts, together with the markedly necrotic action of the salts of quinine on the tissues, have led a certain group of medical men—especially those connected with research and experimental medicine—to consider this mode of treatment a most unscientific and harmful one. But another—and, I should think, a much larger group—of practising physicians have found the intramuscular method efficacious, and do not hesitate to inject salts of quinine in every case of malaria. The difference of opinion between these two groups of medical men is so divergent and striking that one does not know what to do; whether to abandon intramuscular administration entirely, or to continue with it until some harmful result is evident.

I was faced with this problem when attending the D. T. M. class at the Calcutta School of Tropical Medicine. The harmful results of intramuscular quinine were put before us so vividly by the professors at the School that it disturbed some of one's most fundamental beliefs. I had been accustomed to giving quinine intramuscularly to a large percentage of my cases of chronic malaria, and had used the method in at least one hundred patients, without seeing any harmful results. I had had no occasion to repent using this mode of administration. I enquired of a number of doctors who were attending the D. T. M. class, and was informed that none of them had seen any untoward consequences—on the other hand their experience was that the method was most satisfactory. What, then is the solution to this difficulty? Sir Leonard Rogers prefers cinchonine bihydrochloride intramuscularly, and reports very favourably on it, (*Recent Advances in Tropical Medicine*, 2nd edition, p. 81). I have found that results are better when grain $\frac{1}{2}$ of emetine hydrochloride is combined with the quinine acid hydrobromide, grains 8 to 10. The emetine is added with the idea that the liver function is very much upset in malaria, and that emetine may overcome this.

Anyhow, the question of intramuscular quinine is an important one, and should be investigated. Neither school of opinion can be ignored, but each should receive the views of the other with due consideration, and a decisive opinion be arrived at. I have not mentioned here the beneficial effects of adding intramuscular injections of

quinine to its oral administration in acute cases of malarial fever, where the dual mode of administration very much enhances the efficacy of the drug.

(ii) *Cerebral Malaria*.—This is responsible for a very high percentage of the deaths caused by malaria. The treatment of these cases is not only difficult, but is also very uncertain, and the physician is often faced with many hours of anxiety in connection with them. The routine method of treatment is the intravenous injection of quinine, given as frequently as one can safely introduce it into the system. By this I mean what a learned professor expressed by saying "It is better to allow the patient to die of quinine poisoning rather than to die of malaria." I have had occasion to treat a large number of cases of cerebral malaria, and have treated them by intravenous quinine, combined with quinine intramuscularly, or given by the oral route wherever possible. I kept one man alive for about ten days by intravenous injections of glucose, with intravenous injections of grains 10 of quinine morning and evening. The parasites (and even the crescents) gradually disappeared from the peripheral circulation, but he made no progress and eventually died. In my series prior to 1928 results were uniformly unsatisfactory, especially amongst the cases which were not brought for treatment until twelve hours or later after the onset of cerebral symptoms.

In 1928, as previously mentioned, there was a very high incidence of malignant tertian and cerebral malaria, and this afforded me a unique opportunity of studying the treatment of this condition. The first patient in whom results were satisfactory was a man who had become maniacal, was considered by his relatives to have become possessed of a ghost, and treated as such for not less than twenty-four hours. When I first saw him he was completely unconscious, the temperature a little over 100°F., the conjunctivae intensely congested, and frothy saliva dribbling from the mouth. At times he would become so violent that it took three or four persons to keep him under control with some difficulty. Blood examination showed a very heavy infection with *P. falciparum*. I gave him an injection of morphine and hyoscine hydrobromide, and the usual intravenous quinine. Next day I repeated the intravenous quinine, but omitted the morphine and hyoscine. The treatment proved extremely successful; it kept the patient quiet, and controlled the fever, though it was eight days before he was out of danger.

My second case was a similar one, the servant of a villager, who became suddenly unconscious one afternoon, and was supposed to have become possessed by a ghost. He was not brought to me until the next afternoon. On admission he was comatose, and blood examination showed a very heavy infection with *P. falciparum*. He was also given hyoscine hydrobromide and intravenous quinine; also a daily enema, as he was very constipated. On the third day of treatment

he became fully conscious, and in a week's time had recovered.

Since then, myself and my Sub-Assistant Surgeon Romesh Chandra Choudhury have used hyoscine hydrobromide as a routine injection for such cases, in addition to intravenous quinine, adding morphia only when the patient shows signs of being violent. Quinine is given in 8 to 10 grain doses twice a day, either intravenously or intramuscularly. We have not had a single death since adopting this procedure.

The contrast between the two groups of cases, with and without hyoscine and morphia in addition to the quinine, is so striking that one naturally seeks for some explanation. The efficacy of the hyoscine treatment is probably due to the antispasmodic action of the drug, which by relieving vascular constriction of blood vessels relieves the tendency towards choking of the internal visceral capillaries with red corpuscles loaded with parasites, keeps the circulation active, and exposes the parasites to the full action of the quinine.

(Since the above was written, a further case of malignant tertian malaria has come under my treatment. The clinical symptoms were such that the patient was admitted to the isolation wards as a case of cholera. Examination of his blood, however, revealed the true diagnosis. Under treatment the intestinal symptoms began to abate, but cerebral symptoms supervened; he became almost unconscious, his eyes became intensely congested, whilst at times he was almost violent—the whole picture rather suggesting uræmia, had one not known what the true diagnosis was. This patient was also treated by hyoscine and quinine, and made a sound recovery, being discharged from hospital cured within a fortnight from admission.)

NOTES ON THE USE OF CARBON TETRACHLORIDE.

By S. C. NAG,

*Barbheel Tea Estate Hospital, Bargang P. O.,
Tezpur, Assam.*

ALTHOUGH the result of carbon tetrachloride treatment in hookworm disease is very satisfactory, and the great majority of physicians consider it to be without danger, it has been reported by several that toxic symptoms ensue in some cases, and that some of these cases end fatally.

In the course of administration of this drug I have noticed the following cases where toxic symptoms ensued.

Series 1.—The drug was administered for hookworm infection to 342 adults of both sexes, all of them tea garden coolies. Of these, 5 patients exhibited toxic symptoms two to four hours after taking the drug, the symptoms roughly simulating a mild type of hæmoglobinuric fever, with a slight rise of temperature, vomiting, restlessness, very high coloured and scanty urine, a coated tongue, jaundice, giddiness, and sometimes slight delirium. Some

of these patients were very anæmic before the drug was administered; others were only slightly anæmic. The patients were all females. One of them passed roundworms, and had incessant vomiting; so irritable was her stomach that she could not even keep down a cup of water; she was in this condition for four days, and then a dose of oil of chenopodium, followed by a purgative, removed all toxic symptoms and she recovered completely. The four other patients were treated with magnesium sulphate and diaphoretics. There was no death in this series. The series included twenty women who were at various periods of pregnancy, but who exhibited no toxic symptoms.

Series 2.—A total of 289 (non-working) children, aged between 3 and 11 years, was treated with carbon tetrachloride, and out of these 4 exhibited symptoms roughly simulating those of hæmoglobinuric fever. Suppression of urine was present in two. The symptoms in these cases came on earlier than in Series 1—within 24 hours. Three of the patients died, and one recovered. (No post-mortem examinations were permitted.) Ten other children in this series had mild febrile symptoms with slight giddiness, but all recovered.

Dose and Mode of Administration.—In Series 1 the drug was given in 60 minim doses in water once on an empty stomach, followed by 1½ to 1 oz. of sulphate of magnesia in 1½ to 1 hour. In Series 2 the drug was given in accordance with the instructions in the *British Medical Journal* of 1st July, 1922, by Nicholls and Hampton (10 minims for a child 1 year old, increased by 2 minims for each year of age), and magnesium sulphate was given 1½ to 1 hour later. Alcohol was not taken by any of the patients who fell ill.

The drug used in both series was that made by Messrs. Merck & Co., of Germany, and was supplied by a reliable firm of chemists in Calcutta in the original bottles. (The use of only chemically pure carbon tetrachloride is advocated by all authorities, but it is not possible for a large number of practitioners in the rural districts to determine whether a given preparation is chemically pure or not. It is very desirable that some of your readers would kindly give in the *Indian Medical Gazette* some simple test for determining whether a given supply of the drug is chemically pure or not. A drug supplied by Messrs. Merck & Co. must presumably be unimpeachable.)

Discussion.—It is impossible to say whether the above symptoms were due to any trace of impurity in the drug due to the effect of a hot climate, or occurred in spite of the drug being chemically pure. The jaundice in some of the cases observed may have been due to obstruction of the common bile duct by roundworms, since *Ascaris* infection is exceedingly common here. The other symptoms may have been secondary to absorption of bile after such an event. Whatever the cause, it seems to me desirable to publish this record, with a view to discussion and to elicit the opinions of authorities.

MALARIA THERAPY IN TABES DORSALIS.

By B. G. VAD, M.D.,

and

N. W. KULKARNI, M.D.,

Sir J. J. Hospital, Bombay.

UNTIL the brilliant discovery of Wagner von Jareggs, the treatment of neuro-syphilis has always eluded a satisfactory solution. Tabes dorsalis and general paralysis of the insane being very resistant, even to the prolonged treatment by the usual anti-syphilitic measures, various new lines were tried from time to time, but none of the new treatments could be said to have even touched the fringe of the problem. In 1912 Swift and Ellis introduced intrathecal administration of salvarsanized serum, but the results fell short of expectations. Sicord in Paris injected minute doses of neosalvarsan directly into the spinal canal after dilution with aspirated cerebro-spinal fluid. Byrnes tried horse serum mercurialized *in vitro*. Ravaut, Arbeit and Rabean injected intraspinaly a hypertonic solution of neosalvarsan mixed with the patient's own serum. Swift, Waller, Haller and others from time to time reported some good results by the intrathecal administration of these anti-syphilitic drugs, but a reliable solution could not be said to have been achieved. Therefore remedies on altogether new lines were introduced. Thus Hilgermann tried spirochætal vaccines and recorded some good results. Jacobs and Heidelberger of the Rockefeller Institute introduced tryparsamide, and though Wolfohn of San Francisco, Solman and Viet of Boston, and others recorded cases showing marked improvement after treatment with tryparsamide, the problem of tabes and general paralysis remained materially unsolved. Then came the discovery of Wagner von Jareggs introducing malarial therapy, which time has proved to be a reliable remedy for general paralysis and to a great extent also for tabes dorsalis.

Observations were carried on by us on 16 cases, 10 of which were treated with the common anti-syphilitic measures only, 5 were treated with malarial therapy and one case by injection of hydrarg. perchloride lotion into the cisterna magna. For a summary of these 16 cases we may refer to Table I. The 6 cases treated by malarial therapy and injection of hydrarg. perchloride lotion into the cisterna magna are given below in some detail.

Case 1.—J. D., aged 50, seaman, was admitted to the hospital on 31st October, 1927, for lightning pains in the right side of the neck and face for the last ten months. He had been infected with syphilis 20 years before. The present complaint first attracted his attention two years ago, when one morning he felt a sudden giddiness and pain while washing his face. Attacks of pain in the lower extremities started suddenly about 18 months previously.

On examination, patches of anæsthesia were noticed on the nose, chest and medial side of the legs and in the urethra. The testicular sensation was markedly diminished, practically absent on the right side. The vibration sense was absent in the lower extremities.

Hypotonia, tabetic gait, and Romberg's sign were present. The knee-jerks were very sluggish, ankle jerks lost on the left side, extremely sluggish on the right. Fundi oculi normal. Vision 6/12 in both eyes. Hypermetropic astigmatism present.

The Wassermann reaction of the blood and cerebro-spinal fluid was negative on first examination, but positive after a provocative dose. Lange's colloidal gold reaction shows a tabetic curve. Sugar present, 0.112 per cent. Albumen present, globulin not increased.

For three weeks the patient was treated with drachm doses of potassium iodide and mercury inunctions every day, and a neosalvarsan injection once a week, but no improvement was seen. On 22nd November, 1927, 10 c.c. of blood, containing benign tertian and malignant tertian malarial parasites from a donor was injected intramuscularly. The patient had fever the next day but no parasites were found in his blood. From 30th November, 1927, the patient got fever with rigors, but *P. vivax* was found for the first time on 3rd December, 1927, and *P. falciparum* on 5th December, 1927. On 7th December, 1927, the patient, having shown alarming symptoms, was treated by adequate doses of quinine both parenterally and orally on that day only. Though the symptoms were controlled, the parasites persisted in the blood. From 12th February, 1928, the patient was again given weekly injections of neosalvarsan for six weeks.

Three weeks after the injection of malarial blood, the patient began to show definite signs of improvement. The knee-jerks returned first, then the deep sensation in the testes and the tendo Achillis. The patches of anæsthesia disappeared first on the legs, then on the chest and last on the nose and urethra. The vibration sense was the last to recover; and by the 7th of February, 1928, i.e., in about a week's time after the malarial injection, the patient was clinically cured, though the serological tests remained positive. The patient has been examined from time to time and has not yet shown to this day any return of the signs or symptoms.

Case 2.—Patient S. D. B., aged 40, complained of inability to walk, and a sensation of treading on soft ground. Sensation to deep pressure and pain was lost. Patches of anæsthesia present on the chest and legs. Argyll-Robertson phenomenon in the pupils. Knee-jerks lost. Vision 6/9 dots both eyes, cannot see small objects properly. Optic atrophy present. Romberg's sign present. Cerebro-spinal fluid—12 cells per c.mm., globulin increased. Wassermann reaction on the blood and cerebro-spinal fluid negative.

For one month the patient was given the usual anti-syphilitic treatment, but no improvement was noticed.

On 27th July, 1924, 5 c.c. of blood, containing malignant tertian malarial parasites from a donor was injected and the patient used to get fever with rigors from 28th July, 1924 to 19th August, 1924. The vision in the right eye improved from 6/9 to 6/6, and the gait was better. Patient was again injected with 4 c.c. of blood with *P. falciparum* on 3rd September, 1924, and he got fever with rigors from 6th September, 1924 to 13th September, 1924. From 14th September, 1924, onwards the temperature was normal. The patches of anæsthesia on the legs disappeared, and there was no longer any sensation of treading on soft ground. Romberg's sign was now absent, the patient being able to stand with eyes closed and feet together. The patient having markedly improved, desired to go home and was discharged on 22nd September, 1924.

Case 3.—Patient, P. A., aged 35, admitted to the hospital for ataxia and gradual dimness of vision. Pupils showed the Argyll-Robertson phenomena. Patches of anæsthesia on the face, chest and feet. Romberg's sign present. Tabetic gait. Knee-jerks and ankle jerks lost. Fundi oculi showed primary optic atrophy. Vision—only moving objects seen. Wassermann reaction on the blood and cerebro-spinal fluid positive.

On 11th April, 1924, the patient was injected with citrated blood containing *P. vivax*, but this had no effect. From 1st August, 1924 to 3rd January, 1925, the patient was put through vigorous anti-syphilitic treatment with potassium iodide mercury, and neosalvarsan injections. He was also given strychnine injections in the temporal

regions. From 13th October, 1925, he began to show some improvement in vision, which gradually improved first for light, then for white and other colours, then for figures, etc. When improved as regards his vision, he was discharged at his own request on 25th March, 1926.

On 30th November, 1926, the patient was admitted again, when he was stone blind and unable to walk. All jerks were absent. Testicular and deep sensations were completely lost. The muscular power in both right extremities was more diminished than in the left. He

was gradually getting worse. On 11th December, 1926, he showed sudden signs of effusion in the chest, with distension of veins, and the glands on the right side hard and discrete. On 14th December, 1926, two pints of clear fluid were aspirated from the pleural cavity. On 15th December, 1926, the patient suddenly developed hemiplegia with aphasia. Every fortnight 2 to 3 pints of fluid had to be aspirated from the pleural cavity. On 15th March, 1927, the patient showed signs of effusion in the peritoneum and pericardium, and died on 1st April, 1927.

Case 4.—Patient, J. M., aged 40, admitted for ataxia and dimness of vision. Romberg's sign present. Gait tabetic. Sensations slightly impaired on the legs. Knee-jerks and ankle jerks absent. Fundi oculi showed primary optic atrophy. Wassermann reaction in blood and cerebro-spinal fluid, positive.

No improvement noticed after treatment by neoarsenobillon and bismuth injections. On 20th May, 1929, 10 c.c. of blood containing *P. vivax* from a patient injected intramuscularly, but without any result. On 31st May, 1929, a culture of 48 hours old benign tertian malarial parasites was injected intramuscularly, and on 19th July, 1929, a culture of 72 hours old malignant tertian malarial parasites was also injected, but absolutely without any effect. Even after six weeks the patient has as yet shown no improvement.

tion of pins and needles in the feet. Gradual diminution of vision. Argyll-Robertson pupils seen in both eyes. Cutaneous sensations diminished on the inner side of the feet and legs. Deep sensations lost in the calf muscles, eyeballs and testicles. Romberg's sign present. Gait tabetic. Knee-jerks and ankle jerks absent. Hypotonia and incoordination present. Wassermann reaction on blood and cerebro-spinal fluid, positive. Lange's colloidal gold reactions shows a tabetic curve.

The patient was given six neoarsenobillon and two silver salvarsan injections, mercury inunctions and potassium iodide orally, but no improvement was seen. On 2nd September, 1927, he had a slight rise of temperature but no malarial parasites were found in blood. On 4th September, 1927, 1/40 gr. of hydrarg. perchloride in 5 per cent. solution was injected into the cisterna magna,

Case 5.—Patient, B. M., aged 35, was admitted for ataxia and dimness of vision. Patches of anæsthesia and hypotonia present, also Romberg's sign and commencing optic atrophy. Wassermann reaction on the blood and cerebro-spinal fluid negative. Gives a history of syphilis, for which, he says, he was formerly treated. Increase of cell content in the cerebro-spinal fluid.

The patient was treated by injections of neoarsenobillon and of bismuth preparations and also by intrathecal injections of salvarsanized serum but no improvement ensued. No benefit resulted from injections of benign tertian and malignant tertian malarial parasites cultured *in vitro*.

This patient is still under observation.

Case 6.—Patient, A. A., aged 45, a Chinese carpenter sought admission to hospital for ataxia of one year's duration with gradual onset. He had occasional setisa-

and the patient had a severe reaction. On 6th September, 1927, the patient had a sharp rise of temperature to 105°F. when benign and malignant tertian malarial parasites were found in his blood. This naturally-developed malaria was not immediately checked, hoping that it would be beneficial to him. But quinine having shown rather severe symptoms of malaria that day. This malaria did not give any relief to his tabetic signs or symptoms. On 25th September, 1927, again, 1/40 gr. of hydrarg. perchloride in 5 per cent. solution was injected into the cisterna magna, and the patient again had a reaction. Examinations on 1st October, 1927, and also on 18th October, 1927, did not reveal any improvement in vision. Examination on 7th November, 1927, showed no improvement in any of the patient's clinical signs or symptoms.

SUMMARY.

(1) Patients in Bombay appear to have acquired a certain amount of resistance to malaria infection, and hence cannot be infected by injections of blood from persons containing *P. vivax*.

(2) In our cases, injections of malarial parasites cultured *in vitro* produced no improvement of any kind.

(3) Malaria acquired in the natural way, while in the hospital, did not improve one patient's condition.

(4) In order to induce malaria and secure its therapeutic advantage, the patients had to be injected with fresh blood containing *P. falciparum*.

(5) Treatment by the usual anti-syphilitic measures did not result in any clinical improvement.

(6) Lange's colloidal gold reaction was not materially influenced either by the anti-syphilitic measures or other malaria therapy (*vide* graphs 1 and 2).

(7) Injections of hydrarg. perchloride lotion into the cisterna magna in one case did not improve the patient's vision or any other symptom.

(8) Effusion into the pleural cavity in case 3, developed suddenly without the patient showing any symptoms at all.

CONCLUSIONS.

Malaria therapy is beneficial in cases of tabes dorsalis, particularly the early ones. But in malaria-infected countries like India, where the patients have to be infected with *P. falciparum*, the problem becomes a difficult one. As some of these cases are likely to show severe signs of cerebral malaria, necessitating a constant and alert watch, and prompt treatment, the importance and responsibility of this line of treatment, can never be over-emphasized. As the malaria therapy does not influence the positive serological findings, it seems imperative that it should be supplemented by the usual anti-syphilitic measures.

We are very much obliged to Lieut.-Colonel S. S. Vazifdar, M.R.C.S., I.M.S., Superintendent and Senior Physician, Sir J. J. Hospital, for giving us facilities to carry out these observations.

THE INDICATIONS FOR SUPRAPUBIC CYSTOTOMY.

By A. N. GHOSE,

Officiating Civil Surgeon, Tippera.

SINCE the introduction of litholapaxy by Bigelow, and its modifications in India by Freyer, the suprapubic operation has fallen largely into disuse. Litholapaxy in hands accustomed to it is no doubt an excellent operation. But in *mofussil* towns of Bengal where one comes across stone cases only occasionally it is not always a safe and desirable operation even in expert hands. The instruments too are likely to deteriorate. I have seen a case of perforation of bladder in the hands of a very capable operator when he was operating with an old lithotrite. Of course

immediate suprapubic lithotomy was done and the patient made an uninterrupted recovery. On the other hand, suprapubic cystotomy is very easy to do, requires no special instruments, can be done in ordinary *mofussil* towns by surgeons of ordinary skill, complete removal of stone or any other foreign body is ensured, and the condition of the bladder wall can be definitely ascertained. Of course the convalescence is a little prolonged. The operation can also be undertaken with less danger in debilitated patients with cystitis, the type of cases we meet with in the *mofussil*.

The following case will illustrate this:—

Case 1.—A Hindu male, aged about 46, came to the outdoor department of the Comilla Hospital with the distinctive gait of pain in the lower abdomen. He was very emaciated, weak and anæmic. He gave a history of gonorrhœa. He said that about seven months before he had retention of urine for which a soft catheter was passed by a private medical practitioner, but as it was an old catheter a fragment of it was left behind. A few days after, he said, the broken fragment came out with the flow of urine. Burning during micturition and frequency of urination began shortly after that. On examination of the chest rales and ronchi were present on both sides of chest. The suspicion of stone was confirmed by the sound. But the patient was so very weak that it was not thought advisable to operate on him immediately. He was treated with urotropine, laxatives and a milk diet. But as there was no definite improvement of general health, it was decided to operate. As there was stricture of the urethra, the urethra was dilated by Lister's bougies. About 6 ounces of sterilized saline was then put in by means of a metal catheter. After the usual median incision the recti muscles were separated and the posterior layer of fascia was carefully incised. The subperitoneal fat was then pushed up, and with it the reflection of peritoneum; the bladder, recognized by its muscular fibres and bluish grey colour, was then fixed by two sutures high up, and was incised. Two horse-shoe shaped stones were removed by stone forceps and the bladder was drained by a syphon arrangement.

The patient was much relieved, but the bronchitis was definitely increased and he began to expectorate large quantities of purulent sputum. A mixture of oil of eucalyptus, tinct. benzoini com., tinct. belladonna and rum, and an inhalation of eucosote and eucalyptus oil were then prescribed. In a week's time he was much better and there was no further trouble.

It will perhaps be not out of place to give a brief summary of two other cases in which suprapubic cystotomy was found to be of great service to me.

Case 2.—I was called in to see a respectable retired pleader of the local Bar, aged about 70 years, for retention of urine. I found the case to be one of enlarged prostate and relieved the bladder. A month later (13th August, 1928), I was again called in and was told that instruments had been passed before my arrival without any success. As there was much bleeding on the slightest attempt to pass a prostatic catheter I advised him to come into hospital for suprapubic cystotomy, which I carried out immediately. Drainage of the bladder was continued for about one month. As the abdominal wound was healing up he began to pass small quantities of urine through the natural passage and by the fourth week of September 1928, he had no difficulty in passing urine.

Case 3.—A Hindu, head constable, aged about 40 years, attended the Sadar Hospital with retention of urine on 17th March, 1928. He had been suffering from stricture of the urethra for about seven years. He gave a history of retention of urine on one occasion two years previously. On the present occasion instruments were tried by several private practitioners without any success. I found on examination that several false passages had

been made. I, therefore, thought it better to drain the bladder after suprapubic cystotomy in preference to the Wheelhouse operation. After two weeks the urethra was gradually dilated and the patient made an uneventful recovery.

I may here mention that I always drain the bladder after the suprapubic operation by stitching the walls of the bladder to the abdominal wall and in my opinion this procedure leads to better results than the so-called ideal operation of closing the bladder wall.

A NOTE ON THE ACTION OF SYNTHETIC ADRENALINE.

By A. S. PARANJPE, M.B., Ch.B. (Edin.),
M.D. (Heidelberg), D.T.M. (Lond.),

Professor of Pharmacology and Materia Medica;
Seth G. S. Medical College and King Edward Memorial
Hospital, Bombay.

ADRENALINE was the first of the "hormones" to be separated in a state of purity and it is the only one included in the current edition of the British Pharmacopœia. It was first isolated from the suprarenal gland by Abel and Crawford (1897) and Takamine first obtained it in a crystalline form. Adrenaline was also the first of the hormones to be synthesised; the synthesis has been attempted in many ways but the method of Scholtz patented by the Farbwerke vorm. Meister, Lucius and Bruning (1904) gives the best results (Linnel, 1928). The synthesis of the racemic compound was first accomplished, but now the same firm has put on the market the synthetic L-rotatory adrenaline under the name of "Suprarenin Synth." along with their natural "Suprarenin."

Recently there was a complaint in our hospital about the efficiency of certain brands or samples of adrenaline in use and so all of them, "good" and "bad," were sent to this department to be tested. The ordinary method biological standardization was used, but, instead of a standard, fresh samples of adrenaline of certain reputed manufacturers were obtained from the local agents and used for the comparison. The method is based on the fact that if in an animal the same quantity of adrenaline is injected several times in succession the rise in blood pressure caused by each injection is about the same (Storm van Leeuwen, 1923). Burn (1928) recommends the cat as a suitable animal, but Pittenger (1928) prefers dogs; the latter were used here being the most easily available animals. Several tracings were taken, after the injection (into the femoral vein) or each sample in every animal, and compared. Since the "Suprarenin Synth." was one of the samples referred to us from the hospital, it was also tested along with others and found to be equal to the best samples of natural adrenaline of the same and other manufacturers. A few of the carotid blood pressure tracings are given below:—

No. 1.—Dog's carotid blood pressure after intravenous injection of equal doses of synthetic and natural adrenaline or "suprarenin." (Time marking: 10 secs.)

No. 2.—Comparative effects after intravenous injection of equal doses of different brands of adrenaline on carotid blood pressure of dog. (Time marking: 10 secs.)

The original synthetic (racemic) D-L-isomer was found to be nearly half as strongly vaso-constrictor as the natural by Cushny (1926). Hence, certain statements like the following:—"Natural adrenaline is L-rotatory, synthetic adrenaline is optically inactive and has only about half the toxicity of the natural variety because it is a mixture of stereo-isomers" (Dixon, 1925), have created the impression among the students and practitioners that a L-rotatory adrenaline, identical with the natural base, has not yet been synthetically prepared, or, at least, is not on the market, and they hesitate to use it, if such a preparation is offered to them. The results of the tests at this laboratory have therefore been published. They show only the hæmodynamic action due to its action on blood vessels after intravenous injection, but there are reports of its efficiency as a vaso-constrictor when applied to mucous membranes (Kraupa, 1928) and used with anaesthetics (Fuler).

It is claimed that the synthetic L-adrenaline possesses certain advantages over its natural isomer. It is said to be more uniform and free from impurities, therefore it can keep longer. All this is obvious from its method of preparation and source; and it is hoped that the next edition of the B. P. will include also the synthetic product (Bennet, 1928).

WERTHEIM SCHANTA'S INTERPOSITION OPERATION FOR COMPLETE PROLAPSE OF THE UTERUS.

By CAPTAIN D. H. VARIAVA,
Acting Chief Medical Officer, Nawanganar State,
Jamnagar.

THE interposition operation for complete prolapse of the uterus consists in bringing out the uterus through the anterior vaginal colectomy incision and placing it between the base of the bladder and the anterior vaginal wall. This paper is based on five operations that have been performed for complete prolapse of the uterus by the author at Jamnagar State Hospital, during the last three months. Of these, four were interposition operations, and one was a complete vaginal hysterectomy, as there was incipient cancer of the cervix. All the five operations have proved quite successful and the conditions have been cured. The author has seen very gratifying results from these operations in Vienna hospitals and especially at the clinic of Professor Kermanner, the successor of Wertheim.

Before describing the technique of the operation, certain anatomical and aetiological factors in prolapse of the uterus will be described.

Normally the uterus is held in position by a suspensory mechanism and supporting mechanism. The former consists of endopelvic fascia, sacro-uterine ligaments, round ligaments and broad ligaments, and is chiefly concerned in the normal anteverted position of the uterus in relation to the rectum and bladder. The fibrous portion of the endopelvic fascia round the cervix and running from it to the back and front of the pelvis is designated by E. Martin as the retinaculum uteri, and according to him anomalies of the suspensory mechanism are chiefly concerned in prolapse of the uterus. On the other hand, Halban and Tandler maintain that the anomalies of the supporting apparatus are all-important in the production of prolapse. The chief supporting mechanism consists of the diaphragma pelvis-rectal (levator ani) and diaphragma urogenital. The levator ani forms the chief part of the former and is the main support of the uterus. Its anterior fibres, arising from the back of the pubis, run backward along the sides of the urethra, the base of the bladder and vagina, and passing behind the latter, some of the fibres are inserted in the anterior surface of the rectum just above the upper end of the anal canal and into the central tendon; the rest, passing by the sides of the rectum, are inserted into the median raphe and some into the anterior surface of the sacrum. This anterior portion of the muscle is designated the pubo-rectalis. The opening in the muscle, through which the vagina traverses, is compared by Halban and Tandler to a hernial ring; as long as the ring is small and well contracted, the uterus will remain inside the pelvis in spite of increased intra-abdominal pressure, but if this ring gets enlarged and lax from any cause, then the uterus will tend to come down, and prolapse will eventually occur. Again, if the uterus is abnormally small, as in

senile atrophy, it may prolapse through a normal ring. According to Reifferscheid,—Wertheim, Jascike, and Sellhaun think that both the suspensory and supporting mechanisms are concerned in the production of prolapse. Lately even Hallan has stated that "without retroversion there is no descent, and without descent no prolapse."

Aetiology.—From the above considerations it is clear that increased intra-abdominal pressure with enlargement and laxity of the genital ring will cause prolapse of the uterus. The chief causes of prolapse are:—(1) Injury during childbirth due to a large head stretching and tearing the muscles of the pelvic diaphragm and ligaments. (2) Instrumental delivery causing trauma. (3) Infection causing inflammation of muscles and ligaments and destroying their elasticity and leading to atrophy. (4) Want of proper rest after delivery may lead to laxity of ligaments and muscles. (5) General asthenia after childbirth, or due to other diseases. (6) General visceroptosis may be accompanied by uteroptosis. (7) Spina bifida by causing destruction of the 3rd and 4th sacral nerves may lead to paralysis of the levator ani. (8) According to Hirsch certain work requiring constant sitting may cause disuse atrophy of the levator ani. (9) Increased intra-abdominal pressure, due to tumours or ascites. (10) Atrophy of the uterus at the climacteric or senile atrophy. The largest number of prolapses occur between the ages of 40 and 45, which coincides with the climacteric.

It is not necessary to describe the different degrees of prolapse, for the operation in question is most suitable for complete prolapse. Generally all the cases of prolapse seen in India are of long standing and there are one or more ulcers on the prolapsed mucous membrane of the vagina. By complete rest in bed in hospital and keeping the part clean and occasional touching with silver nitrate and pure carbolic acid, these ulcers heal completely, or if they do not heal completely, the granulations become quite healthy and clean, all discharge stops and in these cases the ulcer is excised completely at the time of operation.

The Technique of the Operation.—The bladder is completely emptied with a catheter just before the operation. The patient is put in the lithotomy position. Spirit biniodide and tincture of iodine are applied to the whole perineum and the prolapse; the anterior lip of the cervix is held with a vulsellum. A bladder sound is introduced into the bladder to ascertain the lower limit of the organ. A vertical incision is made in the middle of the anterior vaginal wall starting $\frac{1}{2}$ inch below the opening of the urethra and running down to $\frac{3}{4}$ inch above the anterior lip of the cervix. The vaginal mucous membrane of the anterior vaginal wall is now dissected off from the wall of the prolapsed bladder on either side with a pair of flat curved scissors. Then the lower pole of the prolapsed bladder is dissected off from the elongated anterior surface of the body of the uterus, till the vesico-uterine fold of peritoneum is reached; this dissection is greatly facilitated by

pushing up the bladder with the index finger covered over with a piece of gauze. The fold of peritoneum is held with a forceps and is divided transversely; the anterior fold of the peritoneum is secured with a pair of artery forceps. This opens up the abdominal cavity through the vagina. Now a sharp hook or a toothed forceps is introduced into the abdominal cavity and the body of the uterus is hooked just above the peritoneal wound and is pulled downwards; a second hook is now introduced a little higher up till the fundus comes in sight. Thus hooked, the whole uterus is brought out through the peritoneal opening.

The anterior fold of the peritoneum is stitched to the posterior surface of the body of the uterus just above the internal os with interrupted catgut sutures, thus shutting off the peritoneal cavity from outside. Catgut sutures are now passed through the round ligament and the tubes near their origin and are secured on both sides to the levator ani muscle by the side of the base of the bladder. The vaginal mucous membrane of the anterior wall is now stitched over the uterus, which lies under the base of the prolapsed bladder and pushes it up. For this interrupted catgut sutures are used, care being taken to include a part of the anterior surface of the uterine wall in the sutures to secure the uterus firmly in its new position. Generally the uterus is atrophied and small, and to make the vaginal wall fit over it tightly long strips of the vaginal mucous membrane are cut off from both the flaps, the breadth of the cut strips depending upon the size of the uterus. After this the cervix automatically goes inside the vagina. If the posterior vaginal wall is still lax, then similar strips are removed from it and the cut borders are sutured together.

A 12 inches long strip of iodoform gauze is introduced into the vagina so as to cover the sutured surface and then the whole vagina is packed with sterile roller gauze so as to prevent any oozing in the new uterine bed. This is kept in for 24 to 48 hours. Subsequently only a small strip of iodoform gauze is introduced into the vagina and a pad applied outside. Throughout the operation only catgut is used. The patient is generally allowed to sit up on the 8th day and can walk about on the 15th day and can be discharged after that.

It is evident that the most important step in the operation is the anterior vaginal coleotomy. If the plane of the vesico-uterine fascia is not entered while separating the bladder from the body of the uterus, the vesico-uterine peritoneal fold will not be found. If the dissection is too superficial then the bladder may be punctured or cut into, which will be a tragedy; if too deep the uterine muscles will be cut and there will be bleeding. If the proper plane is entered then the two organs will be very easily separated without any loss of blood, and the peritoneal fold will be very quickly and easily reached.

Later Wertheim further modified the operation by fixing the anterior portion of the cervix

to the sacro-uterine ligaments through a posterior colpo-coleotomy. But according to Doderlein this step is not essential, except in very rare cases.

In women of child bearing age, sterilization should be performed by cutting off a piece of tube on both sides and closing up the cut ends. Wertheim had 93 per cent. of permanent cures and others had between 70 and 80 per cent. According to Reifferschied, the operation mortality is between 3.4 to 7.5 per cent. and due generally to secondary hæmorrhage in the extensive wound surface, suppuration or thrombosis.

As far as is known, this operation is very rarely performed in India, and in view of its good permanent results and safety, it is pleaded that this method of operation should be more extensively practised in the treatment of prolapse of the uterus. Incidentally it may be urged that vaginal coleotomy should more extensively be practised in gynæcology as entailing less shock, whilst in a country like India where abdominal laparotomy is still dreaded, more patients will submit to operations if this route is used.

Short Case Histories.

Case I.—Mrs. K. N., Mahommedan. Admitted on 14th April, 1929. Age 70 years. Complete prolapse with extensive ulceration on the right side of vaginal wall. Ulcers took a long time to heal. Interposition operation performed on 13th June, 1929. Also posterior colporrhaphy performed. Discharged cured 3rd July, 1929.

Case II.—Mrs. J. K., Hindu. Admitted on 8th July, 1929. Age 60. Complete prolapse. Slight inflammation of cervix. Interposition operation performed on 16th July, 1929. Discharged cured 7th August, 1929.

Case III.—Mrs. F. D., Mahommedan. Admitted on 24th July, 1929. Age 50 years. Complete prolapse with cancerous ulcer on the posterior lip of the cervix. Total vaginal hysterectomy performed on 30th July, 1929. Discharged cured 20th August, 1929.

Case IV.—Mrs. M. T., Hindu. Admitted on 28th June, 1929. Age 60. Complete prolapse and extensive

Case IV. Complete prolapse of uterus. The ulcer on vaginal wall is very well seen. It was excised completely at operation.

ulceration of the cervix and vaginal wall. Ulcers took a long time to heal; one ulcer $\frac{1}{2}$ inch diameter did not heal. Interposition operation done on 17th August, 1929. Ulcer completely excised. Posterior colporrhaphy performed. Complete recovery. Patient will shortly be discharged.

Case P.—Mrs. A. N., Mahommedan. Admitted on 7th August, 1929. Age 50. Complete prolapse with ulcer on the posterior lip of the cervix. Interposition operation done on 24th August, 1929. Ulcer completely excised. Complete recovery. Patient will be discharged shortly.

The common feature of all the cases are ages between 50 and 70. All had ulcerations which generally cleared up rather quickly. In all, the recovery was complete and uneventful.

CONCLUSIONS.

(1) The cause of prolapse is due to anomalies of both suspensory and supporting mechanisms.

(2) The interposition operation, based on anatomical findings, cures the condition permanently in more than 90 per cent. of cases.

(3) Cystocele is very effectively cured.

(4) The vagina is restored and the cervix lies almost in its normal position.

(5) If the patient is still menstruating then the discharge can come out by the normal route.

(6) The risk of sepsis and the operative mortality are very low.

(Note.—We have shown the above article to Lieut.-Col. V. B. Green-Armstrong, M.D., F.R.C.P., I.M.S., Professor of Midwifery and Gynaecology, Calcutta Medical College, who writes as follows:—

This article is a very welcome contribution on a condition which is present in almost 50 per cent. of Indian multiparae. The operation described is the one that has been regularly performed in the Eden Hospital, Calcutta, for the last five years with excellent results. The only difference is the name that has been attached to the operation, for there has been much discussion in the gynaecological press as to priority of description. Twenty-five years ago Duhressen wrote up an operation which was very similar, but we think that the first independent illustrated account of the technique used was given by Watkins of Chicago, and therefore to him the credit is given as a rule, though, of course, Wertheim may have independently evolved it on the Continent about the same time. Anyhow, among English-speaking gynaecologists, the American is given the palm of priority.

We are convinced that it is the ideal operation for India, as it is not accompanied by shock or great bleeding, as is the Fothergill or Manchester school operation; and our experience of over one hundred operations amply confirms that of Dr. Variava. There is, however, just one small criticism to make, and that is that as the operation is described, the posterior vaginal wall and the vaginal outlet must be left gaping, with or without a rectocele, as occurs in 75 per cent. of patients on this side of India. Therefore we always finish off the Watkins' technique by doing a high posterior colporrhaphy as a routine.—EDITOR, I. M. G.).

THE SUCCESSFUL USE OF A TUBERCULOUS METHYLIC ANTIGEN IN EXTERNAL TUBERCULOSIS.

By MAJOR V. LABERNADIE, M.D., M.S.P.E. (Paris),
and

MEDICAL OFFICER ANDRÉ ZEGANADIN,
M.S.M.H.T. (Paris),

Chief and Assistant of the Research Laboratory of
Researches, Pondicherry (French India).

FOR numerous practitioners, the question of the cure of tuberculosis by specific agents is not yet solved. There were too many deceptions with the use of tuberculin, and many doctors have come back to the older and more prudent methods which reinforced the means of defence of the organism by chemical or physical agents. Research workers, however, have never lost the hope of curing tuberculosis by the corresponding bacilli or by their more or less modified extracts.

Among the recent methods of treatment, it may be useful to point out the good effects of the methyl antigen prepared by Boquet and Negre, at the Pasteur Institute of Paris.* This method is very simple and can be easily controlled; it deserves to be adopted as a routine, in hospitals as well as in general practice—at least in external tuberculosis.

The product is obtained by the maceration of tubercle bacilli in methyl alcohol and filtration. (1) This extract is used at first diluted at 1 : 10, by subcutaneous injection, at a dose of 0.25 c.c. The rectal temperature must be taken carefully twice a day. A little feverish reaction is common, and the following injection should be given only when this reaction is over. In general, two injections may be made weekly. In case of a strong reaction, the dose should not be increased, if the reaction has been weak, the dose is increased by 0.25 c.c. (that is to say 0.50, to 0.75 c.c.). One arrives in this way after 4, 6, or 8 injections at a dose of 1 c.c., which is then repeated several times.

Pure antigen (not methyl) must then be used. The doses are given in a similar way of progression, say from 0.25 to 1 c.c. But here, the temperature and the general condition must be very carefully observed. A stronger dose should be given only if the feverish reaction has been very slight. On the contrary, if the reaction has been marked, the same dose should be repeated till the patient keeps a normal temperature.

It is according to this method that we have treated the following patients:—

Case 1.—Tang, male, aged 30. Cervical cold abscess (on the right side) of the size of a pigeon's egg. Received 19 injections of methyl antigen from 15th December, 1927 to 19th November, 1928. Practically cured.

Case 2.—Ant, male, aged 20. Cervical cold abscess (right side). Received 14 injections of methyl antigen from the 1st November, 1928 to 26th March, 1928. Practically cured.

Case 3.—R. And, male, aged 31. Sterno-clavicular arthritis (left side) with fistula. Received 19 injections

* The Pasteur Institute supplies 1 c.c. phials of methyl antigen, pure or diluted.

of methyl antigen from 12th November, 1928 to 1st May, 1928. Fistula closed up, arthritis practically cured.

Case 4.—Mar., male, aged 46. Sterno-clavicular arthritis (right side). Received 15 injections of methyl antigen from 23rd March, 1928 to 18th May, 1928. Practically cured.

Case 5.—Can., female, aged 27. Submaxillary lymphadenitis (right side). Received 23 injections from 18th May, 1928 to 15th August, 1928, on which date she left us of her own accord, the volume of the lymph-nodes having come back almost to the normal.

Case 6.—P. Laz., male, aged 17. Coxo-femoral arthritis (right side) with impossibility of walking, patient bed-ridden for one month. Received 30 injections of methyl antigen from 16th June, 1928 to 21st September, 1928. The patient left us of his own accord, not cured, but very much improved, walking with a stick.

Case 7.—Ratt., female, aged 9. Cervical lymphadenitis (left side). Received 15 injections of methyl antigen from 15th July, 1928 to 13th August, 1928. Practically cured.

Case 8.—Vall., female, aged 30. Submaxillary lymphadenitis (right side). Received 17 injections of methyl antigen from 30th July, 1928 to 10th October, 1928. She left us of her own accord, the volume of the lymph-nodes having come back almost to the normal.

Case 9.—Rang., male, aged 45. Sterno-clavicular arthritis (left side). Received 23 injections of methyl antigen from 31st July, 1928 to 1st November, 1928. Practically cured.

Case 10.—Ratt., male, aged 40. Cervical cold abscess (right side) with fistula and sterno-clavicular arthritis. Received 22 injections of methyl antigen from 7th August, 1928 to 1st November, 1928. Abscess and fistula closed up, arthritis practically cured.

Case 11.—Sey. Al., male, aged 16. Tumor albus of the left knee joint. Received 24 injections of methyl antigen from 24th September, 1928 to 29th December, 1928. At that date the patient walked easily and could be considered as practically cured.

Case 12.—Gov., male, aged 50. Cold abscess of the left axilla with fistula. Received 14 injections of methyl antigen from 2nd August, 1928. On the 1st October he is continuing the treatment and he is already much better.

A Mirror of Hospital Practice.

A CASE OF IRREDUCIBLE HERNIA RELIEVED BY ATROPINE SULPHATE.

By D. V. PRADHAN, M.B., B.S.,

Shahapur, District Thana.

I WAS called to a neighbouring village to see a patient with severe abdominal pain and vomiting. On examination I found it was a case of strangulated inguinal hernia (left side). The patient had lifted a heavy stone ball that morning in order to give an exhibition of his strength. The swelling in the scrotum was very tense. I tried taxis without success. The patient was too poor to go anywhere for surgical relief. I immediately remembered having read in the *Indian Medical Gazette* about the successful employment of atropine sulphate in a similar case, so at once I gave 1/100 gr. atropine sulphate subcutaneously. Within 15 minutes the whole descended gut suddenly returned to the abdominal cavity without any external manipulation. The patient felt prompt relief. The same man again

had a similar trouble. This time he had carried two big tins of water from a well. I tried taxis, but it was not successful. So I gave 1/100 gr. atropine sulphate. This time it took nearly 30 minutes to act, but the gut returned to the general peritoneal cavity without any external manipulation.

I think atropine sulphate should be given a trial in every case of the above mentioned type in the early stage before sending the patient for operation.

A CASE OF URTICARIA.

By S. M. HUSAIN, B.Sc., M.B., B.S.,

Tibbyia College, Muslim University, Aligarh.

A FEMALE patient, aged 20 years, consulted me about the urticarial attacks from which she had been suffering for the last three months. She had tried other treatment, but with no relief. I started to find the cause which was responsible for her condition. Her diet, habits, clothing, all received careful consideration. She was put on milk diet, and then on dal, rice and curd, but with no change in her condition. After a few experiments of this nature it became obvious that no article of diet was responsible for it. There was nothing wrong with her habits, dress, or environment. Failing to find a cause, palliative measures were resorted to with only temporary and incomplete relief, among which was a daily warm saline bath. This last seemed to do her good. The wheals decreased in number and size as well as in duration. But every third or fourth day a fresh crop would appear which coincided with the use of soap. The use of the soap was discontinued, and then she was asked to change her soap. When after two weeks' complete freedom she was asked, as an experiment, to use her original soap, she again got an attack. It is now over six months after the change of soap and she has remained perfectly healthy. It was a mere chance that led to the discovery of the cause.

In this particular case it was that excellent soap "Life-buoy," which is said to contain 1 per cent. carbolic acid, to which the patient was sensitive.

A CASE OF RAYNAUD'S DISEASE.

By A. P. BAJPAYEE, M.B., B.S.,

MacLaren Leper Hospital, Dehra Dun, United Provinces.

RAYNAUD'S disease is so rarely met with in the tropics that it will be of interest to record the following case for the benefit of general practitioners and those medical men who are working in leprosy.

The case was sent to Dehra Dun from Etawah as a suspected case of leprosy, which it simulated on account of the dropped-off toes. But for that solitary sign there was no other sign or symptom of leprosy. The illustrations (Figs. 1 and 2) show the condition of the patient.

R. K., æt. 38 years, came over from Etawah to the MacLaren Leper Hospital, Dehra Dun, on the 16th July, 1929, complaining of severe burning pain in the ulcerating toes, the soles of the feet and legs for the last eight months.

History of present illness: At the end of October 1928, the patient had a rise of temperature associated with slight shivering and pains in his feet; the temperature became normal in a day without treatment. Four or five days later he got drenched in the rains and he continued wearing the shoes which remained wet and cold for four or five days. At the end of this period he

noticed a dull pain in both the feet; this pain got worse one day; so he consulted a hakim who gave him purgatives to be taken thrice on alternate days. He felt relief after the first two doses, but the pain again grew worse on taking the third dose of the purgative on the fifth day. The pain was so intense that he could not get any sleep for twenty-four days. Local applications of lead lotion with opium and hypodermic injections of morphia gave him only a little relief. Then hot fomentations with a heated mixture of cow's urine and nux vomica seeds were applied as advised by a vaid to the satisfactory relief of the patient; but after twenty-two days he found his toes were hard and black. Some local application gave rise to blister formation, resulting later in ulcerations.

of the feet where there are numerous ecchymotic patches. There is no patch of anæsthesia, erythema or depigmentation; no thickening of the great auricular, ulnar or external peroneal nerves; nasal swab "negative" to *Mycobacterium lepræ*; Wassermann reaction "negative" in all dilutions. The urine showed an appreciable quantity of albumen (2 grammes per litre), granular casts and pus cells, as well as diminished excretion of chlorides. The parts where the patient gets the burning sensation are cold to touch. Temperature, 102°F.

Discussion.—Raynaud's disease is a local arterial ischæmia, generally followed by asphyxia, occurring at the periphery of the circulation and

Fig. 1.

The toes were dressed daily till, at the end of three months, the distal halves of all the toes except the left great toe fell off. This dropping off of the toes gave rise to anxiety and he consulted all classes of medical men who all suspected the condition to be leprotic. A vaid applied leeches to his heels and to his index and middle fingers of the right hand, where there was severe pain and swelling, in the month of April 1929. This treatment gave relief to the pain, but the ulceration did not improve; at last on the advice of the civil surgeon, he came over to Dehra Dun.

Present condition: All the toes except the left great toe have ulcerated stumps which are hyperæsthesic. Left foot swollen. Burning pains in the soles and heels

producing symmetrically distributed gangrene of the skin and other tissues in the affected region. Symptoms usually appear after exposure to cold, often without any other symptoms except sleepiness. The most frequently attacked parts are the fingers, toes, tip of nose and ears. The phenomena is explainable by the spasm of arterioles due to central or peripheral influence on the sympathetic nervous system by the toxins absorbed most probably by the large bowel. The diagnostic features of the disease are coldness, lividity,

spasmodic pains in the affected area, and symmetrical distribution, the last named being a significant and pathognomonic feature of the disease, as pointed out by Raynaud in 1862.

Diagnosis.—Excluding syphilitic endarteritis, diabetic gangrene and leprosy, the case was diagnosed as one of Raynaud's disease.

Treatment adopted.—On the hypothesis that very likely the toxin comes from the alimentary canal, Einhorn has succeeded in abolishing the symptoms of Raynaud's disease by administering large quantities of sterile normal saline (0.85 per cent.) sufficient to produce fluid motions. A light breakfast on waking followed two hours later by twenty-four ounces of the sterile saline daily was enough to produce four fluid motions in this case.

For the pain Atophan grs. xv twice a day for three days in a week was administered. The ulcers were aseptically dressed and almost all had

Fig. 2.

healed, except those in the three left toes, at the time he was transferred from here to Lucknow.

Hot dry fomentations were given to the soles and the heels, and the consumption of salt in the diet was controlled by the excretion of chlorides in the urine.

The following note on this case has been made by Lieut.-Col. G. T. Burke, I.M.S., Professor of Medicine, King George's Medical College, Lucknow.

"The condition of Raynaud's disease is so rare in a climate where severe cold is not usually experienced that it is necessary to be very sure of the diagnosis. In this case there does not seem to be any doubt. There is no history of hæmoglobinuria, which is sometimes associated, and only the toes are involved. There is the history of one attack, not going beyond the stage of asphyxia, affecting the index and middle finger of one hand. The lesions have now almost healed, and he has lost most of his pain under treatment by radiant heat. He may require some surgical

trimming of the stumps eventually to do away with tender scars."

TWO CASES OF LEPROSY SUCCESSFULLY TREATED.

By L. N. MOHANTY,

Civil Sub-Assistant Surgeon, In-Charge Rajkumari Leper Asylum, Deoghar, Behar (India).

P. N., a young man of 32, a resident of Singhbhum district, was admitted on 26th July, 1928, for the treatment of leprosy. His condition before treatment was as follows:—

The case was one of the mixed variety; he had crooked fingers, a little thickening of the lobes of the ears in which leprosy bacilli were found, superficial anæsthesia of the legs almost up to the knees and of the forearms and hands all round, and swelling of the ankles. General health—poor, almost emaciated, and unable to do any work. No family history of contact, but he had been in prolonged contact with a leper in his village. Kahn's reaction was "doubtful."

He had suffered from no other diseases except leprosy, the duration of which was two years before treatment. Not unlike other lepers he was a sufferer from constipation and other bowel troubles. Purgatives were given for the removal of constipation and other bowel troubles. One tube of neosalvarsan was injected in the course of treatment to make the "doubtful" Kahn reaction negative. The anti-leprosy treatment was potassium iodide orally and hydnocreol subcutaneously twice a week, doses 5 grs. to 240 grs., and 2 c.c. to 10 c.c., respectively, in gradation. Besides, chaulmoogra oil was given for inunction and trichloroacetic acid was applied on the affected lesions. The two former medicines were administered alternately or in combination with each other as his general health allowed. When necessary rest from the treatment was given; tonic mixtures were also prescribed for the maintenance of his good health. Sufficient good food including meat twice a month was his diet. The quantity of potassium iodide taken by him up till now is about 10 ozs. (240 grs. dose taken sixteen times) and the quantity of hydnocreol is 150 c.c. All the while, except during the first weeks, he was given some physical work to do, gradually increasing the labour hour. The length of treatment yet is only one year, during which he has suffered from a few moderate reactions. Almost from the beginning he showed marked improvement; the swelling at the ankles disappeared, the anæsthesia came down and is now practically nil, the crooked fingers became straight and the general health improved. On 22nd June, 1929, he was bacteriologically examined and found negative, both skin and mucous membrane. He is now almost cured as he still sustains no perceptible signs of leprosy and is fairly able to do any physical work, yet he is undergoing treatment for another period of six months before he will be finally discharged as cured.

Case 2.—Another youth of Manbhum district, S. P., aged 18, came here on 16th September, 1928, for the same purpose. He was purely of nerve variety, three small fingers of his left hand were contracted, peroneal nerves deeply affected, consequently he had drop foot and anæsthesia up to the knees, anæsthesia up to the elbow of his left hand, some depigmented and anæsthetic patches on upper arms and thighs, and septic ulcers on the right swollen foot. His general health was fair. He had contracted the disease from his own brother who is an infectious leper and with whom he had mixed intimately. The disease was of four years' duration; the contraction of the fingers appeared one year later. Malaria and constipation were his two main predisposing causes. The treatment was similar to that of the above. The first few months brought him little improvement, excepting the healing of the ulcers and the disappearance of the swelling of the right foot. Afterwards patches began to disappear and the anæsthesia lessened. A few weeks

ago he showed me his fingers straight. The length of treatment up till now is only 10 months during which he has not suffered from any severe reactions. The amount of hydnocreol taken is 140 c.c., and potassium iodide is only 4 ozs. He is a regular physical worker, specially a carrier of water hanging from his fingers in buckets. This I think considerably helped the restoration of his crooked fingers. His diet was good, including milk, meat, vegetables, etc. Although he is now free from any active signs of leprosy yet he will do better for being treated for another period of six months, or more.

A CASE OF ENTERIC IN WHICH THE WIDAL REACTION BECAME POSITIVE ON THE 49TH DAY.

By RABINDRANATH CHATTERJEE, M.B.,

House-Physician, Medical College Hospitals, Calcutta.

J. L. B., Hindu, male, aged 30, was admitted into the Medical College Hospital on the 27th August last, as a case of enteric fever.

He came with a high continuous temperature which had continued for twenty-five days, and he gave a history of having passed two hæmorrhagic stools about four days before his admission into the hospital.

Condition on admission.—Temperature, 102°F.; pulse rate, 112; respirations, 26 per minute. The pulse was of fairly good volume and did not give any indication of internal hæmorrhage at the time. Tongue, coated and moist. Abdomen, slightly tympanitic, resonant all over, and not rigid. No enlargement of spleen and liver. Bowels constipated for about four days after the last two hæmorrhagic stools.

The case was clinically diagnosed as a case of enteric and the treatment was carried for this disease.

Just after his admission he was given a simple enema and as a result of which black (? altered blood) fluid was returned. The stool contained occult blood.

The Widal test was positive (1 in 25) to *B. typhosus* on the 2nd day after admission, negative on the 7th and 13th day, and again positive (1 in 500) to *B. typhosus* on the 24th day after admission (49th day of the disease). The blood culture was sterile on the 7th, 13th and 24th days and the urine culture on the 9th, 19th, and 23rd. No enteric group organisms were found in the stool examined on the 9th day after admission.

The first Widal test, which was positive to *B. typhosus*, 1/25 only, was of no importance. The Widal being negative on the 38th day, we grew anxious as to the real causative factor of the temperature which now became more or less of an intermittent type. Still a negative Widal could only be explained by low body resistance, but we had to keep our minds open to other possible causes for the temperature. Mainly amongst others we thought of three things:—

- (1) *B. coli* infection
- (2) Kala-azar.
- (3) Tuberculous affection.

Repeatedly negative results obtained with urine culture and a maintained alkalinity of urine, together with the failure of heavy doses of alkalis to control the temperature gave us some justification to exclude *B. coli* infection.

Next came the question of kala-azar. There was no progressive leucopenia, nor any enlargement of the spleen; and moreover Napier's and Chopra's tests were absolutely negative.

Thirdly, as to tuberculous affection of the lung. The chest was x-rayed, and a perfectly normal

skiagram was received. Von Pirquet's cutaneous tuberculin test was done on the 14th September, 1929. The test showed a negative result. This negative result, as we know, has more distinct value, from a diagnostic point of view, over the positive result, which is often obtained in normal healthy individuals.

CONCLUSION.

The chief object of my publishing this case note is to record that that a positive Widal test, for the first time, was obtained as late as the 49th day of illness. It is little wonder that we were misled as to the diagnosis when the Widal was not positive until the 49th day. The patient became convalescent soon after the positive Widal reaction was found.

My thanks are due to Dr. B. L. Majumdar, Additional Physician, Medical College Hospitals, for kindly permitting me to publish these notes.

A CASE OF APHASIA DURING SPINAL ANÆSTHESIA.

By K. S. APPU MUDALIYAR AVL, M.B., B.S.,

Assistant District Medical Officer, East Godavari.

A HINDU male, aged 60, was admitted on 9th July, 1929, in the hospital as an in-patient.

History.—Noticed small cyst-like growths here and there on the face round the mouth which gradually increased in size and spread to the under-surface of chin. He was operated upon at

Vizagapatam 3 years back. The condition recurred.

Physical Examination.—Small tumours, cystic to feel, adherent to skin and deeper tissues, highly

vascular. A specimen was sent to the pathologist. The pathologist's report was "endotheloma of the face."

I have given spinal anæsthesia a number of times, both here and at other places where I have worked. The method I have adopted is making a puncture at the 3rd or 4th lumbar space in the sitting posture, putting into the subdural space 2 c.c. of 2 per cent. glucose stovaine, and then making the patient lie flat on the table and breathe well. In about 10 minutes time complete anæsthesia up to the umbilicus can be obtained by holding the head down very carefully. As soon as anæsthesia of the required level was reached the patient was put in an inclining posture with head high. A screen was put in front of his face and during the operation some one engaged him in conversation. The last patient to whom I gave spinal anæsthesia was an adult man on whom radical hydrocele operation was done. This patient during operation suddenly developed a stammer in his speech, and later was not able to speak at all. His pulse and respiration were normal. For two hours after the operation he was still unable to articulate in spite of his attempts to do so. After two hours he suddenly developed the power of speech.

I have to thank the Superintendent of the hospital for allowing me to publish these records.

NAGA SORES IN GWALIOR.

By K. G. KHANDEHAR, M.B., B.S.,
Civil Hospital, Guna, Gwalior State.

PRIOR to reading Dr. Roy's article on Naga sore in the *Indian Medical Gazette* of December 1928, my attention was drawn to two patients of this place by their having ulcers of unusual character on their legs. On reading the article I had no difficulty in settling the identity of the ulcers.

I am herewith appending photos of three cases. On microscopical examination of the exudate from these ulcers no spirochaetes, fusiform bacilli, or diplococci could be found.

These ulcers are called "Gala" owing to the tissue-lysis that is produced, and are not entirely new to this part of the country, but have become common during the last two years, the years of bad harvests, and have evoked enquiries in the local paper. About 75 cases were treated in the Bhilsa Hospital and 15 in the Guna Hospital. Almost all the patients were in poor physical condition and about 50 per cent. had their spleen enlarged.

Excepting one poor clerk living in a village, all were villagers working in the fields.

The one thing noted was that even when the ulcers healed, leaving a good scar, the surrounding induration did not subside for a long time, (see photo C), and the affected limb was too painful to be used.

DECEMBER.

A NEW SUGGESTION IN MALARIA CONTROL.

THE rôle of Plasmochin in the treatment of malaria has been the subject of innumerable papers in the literature on tropical medicine during the last few years, and we do not propose to attempt here to summarise the findings with regard to it. Certain generally accepted facts, however, emerge from a study of this literature; (a) that plasmochin has a definitely destructive action on all phases of *P. vivax* infection; (b) that it has no destructive action on the schizogony cycle of *P. falciparum*, but has a markedly destructive action on the crescentic gametocytes of this species; (c) that the drug is not entirely safe for general use in outpatient departments, since its administration may be followed by abdominal colic, respiratory embarrassment and cyanosis,—whilst a few deaths have followed its use; it is therefore regarded in general as a drug for use only in well-controlled hospitals where patients are under continued and skilled observation. The position, in brief, may be summarised by saying that whilst plasmochin is an undoubted triumph for German synthetic chemistry, it is only a half-way house towards the ideal of a synthetic drug for the extirpation of malarial parasites in the human body, with no possibility of causing toxic symptoms in man, than the ideal cure itself. In this remedy we have rather a glimpse of future possibilities than a certain present-day utterly reliable and universal cure, such as the salvarsan derivatives present in the case of syphilis.

Yet there are possibilities with regard to plasmochin which, we believe, the medical profession in this country has as yet scarcely grasped. A recently published paper which may well become a classic in malariology is that by Barber, Komp, and Newman (1929). These authors began with the generally accepted view that plasmochin has a specially destructive action on the crescentic gametocytes of *P. falciparum*. Their special objective was to determine the minimal dose of plasmochin which would render these gametocytes incapable of developing in the mosquito, using *A. albimanus* as the test mosquito on account of its susceptibility to infection with the malaria parasites, and its eagerness to bite man. Laboratory-bred mosquitoes were used, were kept at room temperature under tropical conditions, and were dissected in general three days after the feed on the malaria carrier which served as donor of the infection.

A detailed description of the cases observed follows. These may be summarised as follows:—

Case 1.—European male, adult, aged 24, infected with *P. falciparum*. Received during three days after admission to hospital 54 grains of quinine sulphate in solution. Then showed 97 crescents per 1,000 leucocytes. Five mosquitoes fed at this stage on the patient gave 100 per cent. of oöcysts present.

This patient was now given 4 cgms. = $\frac{3}{4}$ grain of plasmochin on the fourth day in two equally divided doses. During the next three days crescents were abundantly present; 46 mosquitoes were fed on him during these three days, and not one became infected.

Case 2.—Negro-Spanish adult, male, infected with *P. falciparum*. Received 15 grains of quinine during the first three days after admission to hospital. During this period 16 out of 29 mosquitoes fed on him showed oöcysts on dissection. On the fourth day 1.5 cgms., or $\frac{1}{4}$ grain, of plasmochin was administered, and the 5 grains of quinine a day was continued. From the fourth to the seventh day 57 mosquitoes were fed on him, but none became infected. In the meantime crescents were always abundantly present.

Case 3.—West Indian negro with malignant tertian malaria. On admission there were 130 crescents per 1,000 leucocytes. A dose of 0.5 cgm., or $\frac{1}{10}$ grain, of plasmochin was now administered. The next day no crescents were found in the films. Four out of 14 mosquitoes fed on the first day became infected, but none out of 13 fed on the second day.

Case 4.—A West Indian negress with malignant tertian malaria. On admission 196 crescents were present per 1,000 leucocytes. Of 14 mosquitoes fed on this day, 10 were found to contain oöcysts three days later. The patient was now given 10 grains of quinine daily plus 3 cgms. = $\frac{1}{2}$ grain of plasmochin. On the third day of this treatment 16 mosquitoes were fed on her; none became infected.

Case 5.—West Indian negress, aged 14, admitted with malignant tertian malaria. On admission showed 26 crescents per 1,000 leucocytes. Of 13 mosquitoes fed at this stage on the patient, 10 became infected. Was treated with 11½ grs. of quinine a day plus 6 cgms. = 1 grain of plasmochin. Two days later 6 mosquitoes were fed on her, but no infections resulted.

Two further cases are cited, where, however, the blood was not examined or mosquito feeds made prior to plasmochin administration, but which gave similar results. The authors go on to write as follows:—"The results of these experiments seem to be clean-cut. In no case did mosquitoes become infected after plasmochin treatment. It appears that single doses of as small as 0.2 mgm. per kg. of body weight may affect the viability of crescents, even though they have increased in numbers, and are still capable of living and capable of ex-flagellation."

The number of patients tested was but small; and it must be admitted that the West African negro in the southern United States often carries a surprisingly large number of parasites without showing symptoms. On the other hand, two conclusions stand out pre-eminently from these experiments; first that quinine has no destructive action on the crescentic gametocytes of *P. falciparum*—this observation confirming what has long ago been proved; secondly, that plasmochin in minute and safe doses has a destructive action on these forms of the malaria parasites.

To summarise, the position reached by the authors is that in cases of malaria one should always prescribe a quinine mixture, in order to destroy the schizogony forms of the malaria parasites, but also at the same time doses of from 3 to 5 cgms., or $\frac{1}{2}$ to $\frac{3}{4}$ grain, of plasmochin in order to destroy the gametocytes. The dual

combination may well be ideal; for it destroys not only the asexual schizogony cycle which is causing malarial fever in the human host, but also the gametocytes which will carry on the infection, via. the transmitting anopheles mosquito, to the next human host; and that—be it noted—with a minimal dose of plasmochin which cannot possibly prove toxic on administration, and which is especially suitable for mass administration on a large scale to coolies on tea gardens and mines, troops in cantonments, prisoners in jails, and all mass collections of labour forces.

There appears to be here an approximation to what we may regard as the ideal in the therapy of malaria. Quinine is utilized to destroy the infection in the patient, plus minute and safe doses of plasmochin to destroy the gametocytes and thereby render him non-infective to the transmitting anopheline mosquito. Further, the combined dosage of both drugs is guaranteed to be safe to the patient, and free from all possibilities of toxic symptoms developing. The authors of this most interesting memoir are men who are very well known in the world of tropical medicine investigators who have made the study of malaria in Central America for several years their special duty, and whose work is entirely reliable. Their conclusions are (wisely) restrained; but the inferences are of immense importance. We are here on the verge of a true *therapia sterilisans magna* with regard to malaria; a therapeutic combination which will not only cure malaria in the human subject, but also prevent its transmission from the human subject to the mosquito, and that without any toxic symptoms in the human patient concerned—a treatment suitable for mass treatment of out-patients of all classes.

The authors are wise to insist that their report is only of a preliminary character; yet its importance in the practice of medicine in the tropics appears to be very great.

CORRIGENDA.

In our November issue on page 603, in the last line of the first column and the first line of the second column the words "microfilaria" and "microfilarie" should read "larva" and "immature filarie," respectively, as they appeared in the authors' typescript.

The word "microfilaria" is not a generic term, and is frequently used by writers to indicate any microscopic stage of the worm. This careless use of the word is not desirable. Yorke and Maplestone (1926), and Baylis and Daubney (1926) agree that the word should be used more specifically to indicate "immature Filariidæ occurring in the blood stream of vertebrates." The word "agamofilaria" would have covered both terms in the particular context; this, according to the above-quoted authorities, is a collective name applicable to all larval filariæ.

H. A. Baylis, and R. Daubney (1926). *Families and genera of Nematoda*. British Museum, London.

W. Yorke, and P. A. Maplestone (1926). *The Nematode Parasites of Vertebrates*. J. A. Churchill, London.

On page 631, in the 17th line from the bottom of the first column, for the word "sensitive" read "positive." Microfilaria were found in the peripheral blood in this case; an editorial correction was made under a misapprehension.

Barium Chloride in Typhoid Fever.

(Abstracted from *The Prescriber*, June 1929, Vol. XXIII, p. 224.)

K. ROURKEVITCH, of Krasnodar, U. S. S. R. (*Presse med.*, 1928, Aug. 18, 1046—1048), states that in 1908 he demonstrated that barium salts produce vasoconstriction, with consequent rise in blood-pressure, and stimulate the vagus and the myocardium. On the basis of these observations he gave barium chloride to thirty-five typhoid patients whose myocardium was in good functional condition. The salt was given by mouth in doses of 0.06 to 0.1 gm. (1 to 1½ grain), increased progressively to 0.5 gm. (7½ grains), three times daily for 6 to 7 days, with intervals of 3 to 5 days. Intravenous medication was not tried, on account of uncertainty regarding the absolute purity of the salt. Results were good, the striking feature being the very satisfactory general condition of the patient: the toxæmic phenomena disappeared, the appetite returned, and it was difficult to believe that the patients had typhoid. Of the thirty-five patients, two died; one from a profuse intestinal hæmorrhage and one after pneumonia. In the other patients the administration of barium chloride was followed after one or two days by a decrease in temperature, then a slight elevation, and a progressive drop by lysis or by crisis. The action of the barium chloride was several times verified by interruption of its administration; this was always followed by a rise in temperature, which fell again when the administration of barium chloride was resumed.

Remarks on the Gall-Bladder in Relation to Focal Infection.

By D. P. D. WILKIE, M.Ch., F.R.C.S.

(Abstracted from *The Brit. Med. Journ.*, July 13th, 1929, No. 3575, p. 37.)

GALL-BLADDER disease commands our attention from three aspects—namely: (1) As a cause of recurrent attacks of acute abdominal pain. (2) As a cause of persistent reflex flatulent dyspepsia. (3) As a focus from which infection spreads to various organs and tissues throughout the body.

With biliary colic and with gall-bladder dyspepsia we are all thoroughly familiar, and I do not propose to touch on these subjects, nor will I refer to complications such as obstructive jaundice and pancreatitis. Our concern to-day will be entirely with the infective aspect of gall-bladder disease and its relation to certain common ailments of obscure ætiology.

The importance of the study of the "pathology of the living," which Moynihan has done so much to emphasize, is seen nowhere to such advantage as in the investigation of biliary disease. Post-mortem pathology taught us practically nothing in regard to the essential features of infection of the biliary passages. The gall-bladder is the organ above all others which suffers from early post-mortem changes which mask all the finer pathological features. Indeed, the frequency with which gallstones were found at post-mortem examination tended

to obscure the significance of gall-bladder disease and its relation to other morbid changes.

To surgery belongs the credit of disclosing the frequency of gall-bladder infection and of defining its essential characters. The study of the early stages of cholecystitis in the operating theatre and clinical laboratory has proved a fruitful field of observation during recent years, and the correlation of this study with experimental research has led to results which are fundamental in their bearing on pathology. The practice of extirpating the gall-bladder when it has shown clear evidence of disease has provided an experiment the results of which have been illuminating, and we are now in a position to speak with some assurance regarding the rôle which this organ plays as a seat of focal infection. We now know that gall-bladder infection, far from being merely the result of the straying of bacteria into its lumen by way of the bile, as was so long believed and taught, is a very definite specific blood-borne infection of the wall of the organ by a streptococcus which has a specific affinity for this tissue. This idea, which sprang from the pioneer work of Rosenow, has received ample confirmation in the Surgical Research Laboratory in Edinburgh, from the work of Illingworth, and of A. L. Wilkie. The latter was able to isolate a streptococcus from 84 out of 100 gall-bladders removed at operation for biliary disease. He showed that, whilst the bile was usually sterile, there could be isolated from the wall of the viscus, and still more readily from the cystic lymph gland, a streptococcus which had this peculiarity—that it was killed or its growth inhibited by the presence of bile. The customary method of making cultures from a snipping of the whole thickness of the gall-bladder wall had failed to obtain a growth because the mucous membrane, included in the section, had bile adhering to it.

Wilkie showed that intravenous injections of an emulsion of this streptococcus into rabbits produced with great regularity a chronic cholecystitis with gall-stone formation, in every way similar to that found in the human subject. The *Streptococcus viridans*, which was isolated in these cases, resembled closely that found so frequently in pyorrhœa, in infected dead teeth, in chronic tonsillitis, in chronic gastric ulcer, in chronic appendicitis, and in the nodules in chronic muscular rheumatism. In a few cases, three or four in all, we have isolated *B. welchii* from the wall of the gall-bladder, and, although rare, this form of infection is peculiarly toxic, and in its acute phase may prove fatal. The *B. coli*, although not infrequently found in acute obstructive cholecystitis, has proved in our experience to be a rare type of infection in chronic gall-bladder disease.

The conception of chronic cholecystitis as a blood-borne streptococcal infection situated within the wall of the gall-bladder, indolent, slow, tenacious, causing at first little interference with the bile storage and concentrating functions of the organ, but permitting of streptococcal invasion of the lymph stream, as evidenced by the frequent presence of the organism in the cystic lymph gland and thence possibly infection of the blood stream—this conception, now a proven reality, establishes the important rôle which the gall-bladder may play as a focus of infection. There is now a considerable body of proof that a chronic streptococcal infection may have an intimate ætiological relationship to many of the so-called chronic rheumatic conditions of joints and of fascial planes, to myocardial degeneration, to certain renal conditions, and to some affections of the central nervous system.

Possessed of the knowledge that the gall-bladder is very frequently the seat of a chronic streptococcal infection, it would seem to be only natural that we should search for evidence of gall-bladder disease when casting about for a focus of infection in our investigation of cases of any of the above-mentioned maladies. I propose to refer to some cases in which such an ætiological relationship appeared to be possible, and in which the removal of an infected gall-bladder was followed by a notable amelioration in the secondary lesion.

Chronic Arthritis.

Miss S., aged 32, had suffered for almost two years from a chronic rheumatic affection of both knees which did not yield to local treatment or anti-rheumatic remedies, and which incapacitated her from all forms of active exercise. She also suffered from a mild flatulent dyspepsia, and on two occasions during the past six months had had an attack of severe pain in the upper abdomen, accompanied by vomiting and diarrhœa, and by marked tenderness under the right costal margin.

On examination she looked healthy and was well nourished. Her knees were slightly swollen and were painful on movement. Definite tenderness was elicited over the gall-bladder. A cholecystogram showed a fairly well-defined gall-bladder shadow.

At operation, in January, 1928, the gall-bladder was found to be small, was slightly opaque, but not appreciably thickened. There were no gall-stones; the other abdominal organs showed no abnormality. The gall-bladder was removed and cultures were taken from the bile, from the gall-bladder wall, and from the cystic lymph gland. Those from the bile and gland were negative, that from the wall of the gall-bladder gave a pure growth of a streptococcus which, on injection into rabbits, produced cholecystitis.

Progress.—One year after operation the patient reported that within a few months of the operation the rheumatic condition of the knees had cleared up completely, and that she could skate and play badminton for hours on end without ill effect.

Comment.—The above case is one of a number in which so-called rheumatoid joint conditions have shown lasting improvement following cholecystectomy.

Toxic Myocarditis.

Mrs. A., aged 45, complained that for two and a half years she had suffered from increasing breathlessness and palpitation on slight exertion. She had been subject to persistent flatulence after meals for at least seven years, and on several occasions had been laid up with attacks of severe pain in the epigastric region and the right side of the chest, and had been treated for "congestion of the lungs" in two of these attacks. Owing to her inability to take exercise without distressing breathlessness she had got much stouter during the past year.

On examination the patient was rather stout, pale, and of poor muscular tone. Moderate exercise induced breathlessness and rapid heart action. There were no cardiac murmurs, but the heart sounds were feeble. There was very definite tenderness on pressure below the right costal margin. A cholecystogram showed a definite gall-bladder shadow with a few negative areas indicating calculi.

A diagnosis of cholecystitis with gall-stones and myocarditis was made and operation was recommended.

Operation (June, 1926).—A greatly thickened gall-bladder, containing numerous calculi, was removed. A pure growth of a streptococcus was obtained from the wall of the gall-bladder; the bile was sterile.

Result.—Complete recovery.

Comment.—The "cholecystitic heart," as it has been termed, is, in my experience, a very common condition. It would appear to result from chronic toxæmia, probably first a slight myocardial degeneration, later complicated by fatty infiltration owing to the patient's inability to take exercise without distress, and the consequent obesity so common in these cases. It is the myocardial change which presents the chief risk of operation in old-standing and neglected cases, and which makes acute infective complications, when they supervene, so dangerous.

Facial Neuralgias.

By PHILIP A. HARRY, M.D., D.P.H.

(Abstracted from *The Prescriber*, June, 1929, Vol. XXIII, p. 209.)

A MINOR form of trigeminal neuralgia is frequently complained of and causes a good deal of inconvenience and incapacity. At first the condition may be diagnosed,

according to the position, as eye strain, sinus disease, or dental infection, until it is discovered that local treatment is insufficient. It is important that a correct diagnosis should be established, as major operations on the Gasserian ganglion are of no value in this type of facial neuralgia. Trigeminal neuralgia is most common after the third decade of life and is associated with arteriosclerosis, general and cerebral, whereas facial neuralgia is found in younger patients, chiefly females, and is associated with foci of infection and a less chronic aetiology than in the other condition. As age advances it is possible for the milder to develop into the more severe type. The pain is less acute in the former, but more constant; in trigeminal neuralgia the pain is described as sudden, severe, sharp, shooting, lancinating, and excruciating, and is usually of short duration. Pain due to sinus infection is more or less constant and may be accompanied by local tenderness, while in dental caries the pain persists after the patient retires.

The type of facial neuralgia under discussion is similar to that described by Sluder as spheno-palatine neuralgia. The pain is constant, dull, and boring in character, and is situated usually in the superior maxilla but may radiate towards the malar bone and temple to the gums and hard palate, and towards the sphenoid and back of the neck. The pain is moderately severe, and in neurotic subjects will be sufficient to incapacitate them from work. Unlike the major neuralgia, the pain is referred more to the periphery than to the course of a particular branch of the nerve. The condition is associated with hysteria and other mental states; in women it occurs more frequently on the right side of the face. It is fairly common during pregnancy and may be secondary to malaria, syphilis, alcohol, lead poisoning, or other toxic states. General states of the body have an important bearing on the condition.

The pain is usually worse during hunger, fatigue, or excitement, and when the patient is debilitated. Vaso-motor changes are frequently noticed, the face showing pallor or flushing, together with a certain amount of swelling. Lachrymation, salivation, or sweating may be present. A draught of cold air, a sudden change of temperature, or the act of stooping may be sufficient to accentuate an attack and increase the already distressing symptoms.

Besides the spheno-palatine type of facial neuralgia a similar group of symptoms is produced secondary to zoster. It can be differentiated by the character of the pain, which is persistent and burning; there is no tendency, however, for it to spread into the territory of the other divisions of the trigeminal. The presence of the cutaneous scars will also assist in the diagnosis. Genuiculate neuralgia is essentially an otalgia; the pain radiating downwards into the neck and forwards into the face.

Another type of facial neuralgia is that associated with convulsive tic. It is characterized by spasmodic contraction accompanied by severe facial pain. The facial contortions resemble chewing or masticatory movements. Tumours involving the fifth nerve will give rise to facial neuralgia. These may be classified as inflammatory or neoplastic growths compressing the sensory root, and lesions of the brain stem such as cerebello-pontine tumours, syringobulbia, and softening following arterial thrombosis. Neuralgias with no definite organic basis, occurring in patients with unstable mentality, may be diagnosed as hysterical. The pain has a bizarre distribution, is constant and often bursting in type, and is accompanied by no objective signs. The pain of migraine may be felt in a limited area in the region of the fifth nerve, but this is chiefly supra-orbital.

With regard to the aetiology of facial neuralgia, it is important to ascertain if there is a dental cause of the trouble. The examination, which must be thorough, must include an x-ray as well as an individual investigation of each tooth. A case has been reported where a hidden cavity containing a portion of a bristle was the cause of the facial neuralgia. Teeth with large amalgam

fillings are especially liable to pulp irritation and other changes.

In a consideration of pain phenomena of the face, the importance of the sympathetic must be remembered. Throughout the region supplied by the fifth nerve there is abundant provision for sympathetic control and association. At one time operations on the cervical ganglia were strongly advocated for neuralgic conditions of the face, chiefly on account of these significant connections, as well as of the fact that electrical stimulation of the cervical sympathetic or the periarterial sympathetic plexus of the common carotid artery will produce pain within the zone of the trigeminal distribution. In these cases the patient, in relating his history, often gives a confused and indefinite picture of the character and location of the pain. Dissociation of sensation is not marked and there is not the clear distinction between the types of pain, or the thermal and pressure sensations giving rise to burning and smarting, boring and grinding, or stabbing and pricking. In some cases facial neuralgia is a symptom of peripheral neuritis due to an inclusion of the terminal filaments of the fifth nerve in an inflammatory process. The pain, originating with the infection, is more or less constant, often throbbing in character and subsiding with the cessation of the inflammation. The pain is not paroxysmal. Many responsible authorities hold that trigeminal neuralgia is secondary to an ascending neuritis, although treatment of oral sepsis and extraction of teeth will not cure this type of neuralgia.

Sinus disease is frequently a cause of facial neuralgia and recurrent headaches. Antral abscess may be secondary to dental caries, but like infection of the other sinuses it is produced more often than not by infection from the nasal passages. There is marked periodicity in the pain from this disease; commencing at 10 or 11 a.m. it may last until 5 p.m. The diagnosis is confirmed by eliciting tenderness on pressure over the affected sinus. Antral pain is at first referred to the upper jaw below the orbit, but it may spread over the whole trigeminal area, extending down the neck and arm. Besides lavage of the antrum and transillumination, an x-ray investigation should be made. In one case pressure on a certain spot below and above the inferior turbinate was sufficient to produce an attack of facial neuralgia; in this case also Dalrymple's sign and Stellwag's symptoms were present on the affected side, and there was a noticeable increase in the dilatation of the right pupil. In this connection reference should be made to the following case; a female patient, suffering from pulmonary abscess, complained of facial neuralgia with severe stabbing pain in the region of the inner canthus, the side of nose and cheek below the eye on the same side as the abscess of the lung. Lachrymation is mentioned, although there is no note with regard to the size of the pupil. The occurrence of the referred facial pain is explained by recounting three possibilities: (1) Impulses might reach the central nervous system by way of the phrenic nerve (a portion of the nerve had been excised to relieve the troublesome cough); (2) there might be an accessory phrenic nerve, joining the phrenic distally to the excised portion, having central connections with the caudal portion of the trigeminal; (3) newly formed fibres might extend from the abscess to the distal end of the phrenic. The pain was always relieved after free expectoration.

In the treatment of facial neuralgia it must be remembered that infection plays a greater part, primarily, than in the cases of true trigeminal neuralgia, and the focus must be sought out and removed if possible. The administration of the constant current of as high an intensity as the patient can tolerate has proved successful in a few cases. No difficulty attends the administration of the treatment, and the improvement is more lasting than with x-ray treatment. The benefit is said to be obtained from the reflex stimulation and its consecutive effects set up by the current. Sluder has reported relief in many of his cases from the administration of alcohol and phenol in the form of injections into the spheno-palatine ganglion, as well as by the application of silver nitrate externally to the mucous membrane of the region.

Modern Surgery in the Treatment of Empyema.

By FRANK J. HATHAWAY, M.D.

(Abstracted from *The Practitioner*, August 1929.
Vol. CXXIII, No. 2, p. 103.)

SURGERY has advanced with such tremendous strides, especially as the outcome of our experience during the Great War, that now a surgeon is not satisfied with mere palliative treatment, but aims at a much higher ideal, namely, "restoration of function" of the diseased organ or part of the body.

In every branch of surgery there is, with increased knowledge, this very definite and recognizable aim at a higher ideal, and it is in chest surgery that greater advances have taken place in our time than in any other branch of surgery. Before the war, the surgeon who dealt with major thoracic surgery dared not deal with the lung as is now done. He used some method to maintain the pressure in the lung for fear of its collapse. It is now known that we can open the pleura, produce a pneumothorax, handle and operate on the lung with impunity, and with the certainty that the lung will re-expand and that restoration of function will be re-established.

At one time it was considered sufficient to evacuate the pus with or without rib resection, insert a drainage tube, and leave the question of re-expansion of the lung as a minor point. It is now realized that, given the suitable case, re-expansion of the lung and restoration of its function is much more important than the mere evacuation of pus from the pleural cavity.

This is aiming at the ideal treatment, but before discussing this the surgical treatment of empyema must be considered from all its aspects. First, a distinction must be drawn between the treatment of empyema in infants and older children and adults. Among infants the mortality is so high and the operation of rib resection so dangerous that in them we must be satisfied either with aspiration, repeated frequently, or simple and rapid incision with drainage—or with the excellent closed method of drainage and aspiration advocated and brought forward by Poynton and Reynolds.

Secondly, after the age of infancy more elaborate methods of treatment can and should be considered. But now any method of treatment must depend on the organism which is the cause of the disease—i.e., pneumococcal, streptococcal, staphylococcal, influenzal or other causes, such as tubercle or actinomycosis. It is of great interest to notice how organisms which have their normal habitat in any one part of the human body increase in virulence when they get into any strange part of the body. For instance, the *Bacillus coli* is a normal inhabitant of the intestinal canal and we know that should it invade the peritoneum this membrane can—provided we can deal with the paralytic ileus of general peritonitis—destroy it much more readily than some years ago we believed it possible. In other words, the peritoneum is naturally highly resistant to infection from *Bacillus coli*; on the other hand, *Bacillus coli* infection of the bladder or kidney and the resulting pyelitis and cystitis may be of a very serious character.

Again, the pneumococcus in the lung or pleura sets up pneumonia or empyema, and we get as a result a recognized severe infection with which, given ordinary strength in our patient, the lung or pleura can deal. But when the pneumococcus gets into the peritoneum or into a joint we know how devastating and malignant the disease and the infection caused by it can be and it can cause far more toxæmia than it would in its normal habitat. A streptococcal or staphylococcal empyema is a much more serious and fatal disease than a pneumococcal empyema.

A pneumococcal empyema can be treated with far more confidence than an infection caused by any other organism. Therefore the treatment of any but a pneumococcal empyema must be free incision and drainage—the object of treatment now being the saving of life rather than restoration of function. But in pneumococcal empyemas, which, after all, are the commonest, the ideal

of treatment is higher, the object being early re-expansion of the lung rather than the mere evacuation of pneumococcal pus. When, therefore, the presence of pus in the pleural cavity has been definitely determined by aspiration, the first thing to do is to find out the bacteriological nature of the causal organism. The previous history of the case will of course give much help in the diagnosis.

If it is streptococcal, influenzal, or any infection other than pneumococcal, the treatment is either continued aspiration—which is frequently the best treatment in severe streptococcal cases—or free incision, rib resection and drainage. Should the lung not re-expand, some form of plastic operation, which will be discussed later, must be carried out at a subsequent date.

In a pneumococcal empyema the pleura can deal with this infection much more readily because it is naturally resistant to the pneumococcus.

The object in treatment then is not mere evacuation of pus, but restoration of function and early re-expansion of the lung.

In these cases wonderful results can be obtained by correct technique and immediate closure with healing by first intention.

Naturally the ideal result is not obtained in every case. Cases in which, despite the length of the illness, there are no adhesions between the visceral and parietal pleura do best. But cases with many adhesions are not so favourable.

Long-standing compression of the lung, owing to delay in diagnosis, is not so important, because if there are no adhesions then, given favourable conditions, although the lung has been compressed for many weeks, it will quickly re-expand. What are the favourable conditions for restoration of function of the lung? First and foremost, I put immediate closure of the wound and by this means the abolition of a "sucking wound." Atmospheric pressure plays a large part in the problem because the atmospheric pressure of air with a sucking wound is greater than the pressure of air in the lung, and the frequent dressing of such an open wound, with an open drainage tube, does not give the lung as good a chance to re-expand as a closed method. A closed method of drainage, in those cases in which there is the least doubt of a successful result by first intention, should be carried out, and in any doubtful case I use a glove drain, i.e., a soft colotomy tube turned inside out; this allows pus to escape without allowing the ingress of air.

The technique of the immediate closure of pneumococcal empyemata is as follows:—

(1) Sufficient resection of rib must be made to allow the whole hand to be introduced into the pleural cavity. The object of this is threefold. First, to evacuate all the big fibrinous clots which are present; secondly, to separate as many adhesions as possible; and, thirdly, to decorticate the lung if necessary. These last two objects are attended with much bleeding, and one can only be guided by experience as to how far one should go in this separation of adhesions and decortication. But the free bleeding will soon cease once the chest cavity is closed.

(2) After this treatment, the pleural cavity is washed out freely with a solution of 1-5,000 perchloride of mercury, because the pneumococcus is particularly susceptible to this fluid. I leave a large amount of this fluid in the pleural cavity and have never seen any signs of mercurial poisoning. The chest wall is then sewn up in successive layers, pleura and muscles with catgut with interrupted sutures, and the skin with silkworm gut.

The after-treatment is very important, and is that of continued aspiration of the fluid left in the pleural cavity. This is quite painless; an exploring syringe is inserted daily between the edges of the wound and evacuates the contained fluid. This fluid is sent to the pathological department for bacteriological examination, and in favourable cases it is found that the number of organisms per field steadily diminishes until the fluid is sterile; and very soon, with rapid re-expansion of the lung, no fluid is left in the pleura. On the other hand, should this ideal result not be attained, it is then a simple matter to take out a few stitches and insert a drainage tube

No harm is done—the general condition of the patient has not deteriorated and one simply relapses to the old-fashioned treatment of an open drainage tube.

The object of the ideal treatment of immediate closure and the abolition of a sucking wound is twofold. First, quick re-expansion of the lung, and, secondly, to prevent secondary infection. It is obvious that with an open drainage tube, no matter how carefully the sterile dressing is carried out, there must be a secondary infection of the pleural cavity.

The modern surgical treatment of empyema is not easy and has made but little progress. The ideal is very difficult to attain, but I have been distinctly gratified in many cases in which healing by first intention and immediate re-expansion of the lung have occurred. This has markedly shortened convalescence and has also done away with any resulting scoliosis.

It may be said, on the contrary, that these successful cases are those which do so well with rib resection and drainage. I quite agree—but why not aim at an ideal method of treatment? If the perfect result is obtained so much the better. On the other hand, if any case does not do well, it is a simple matter to carry out some form of drainage afterwards and the patient is none the worse. The ideal has then been aimed at and not accomplished, but we can only endeavour. If we do not try to get an ideal result, then we are not progressing on the only lines in which the treatment of empyema can progress.

To recapitulate, the three important points in treatment of pneumococcal empyemas are the following:—

(1) An incision large enough to allow the whole hand to be inserted into the pleural cavity.

(2) Abolition of a sucking wound by immediate closure.

(3) Repeated daily aspiration.

(4) Progress, I consider, can also be made in the treatment of an allied condition of the lung, i.e., bronchiectasis. The present-day treatment is very unsatisfactory, and I believe the right line of treatment is ligation of the pulmonary artery and division of the phrenic nerve. The object of ligation of the pulmonary artery is to produce a venous congestion of the lung with its resultant fibrosis, and division of the phrenic nerve to stop the irritating cough. I have not myself had a case on which to carry out this operation, but I shall certainly do so when the opportunity arises. It has been successfully carried out by Professor Wilms.

As regards the treatment of those cases—no matter what may be the causal organism—where the lung has no possible chance of re-expanding and again filling the rigid chest cavity, what should be done? Fortunately, these cases are exceptional and are due to neglect and want of early treatment. First, the wound should thoroughly be opened up and proper drainage established. If this is found to be faulty it should be placed at the lowest level of the old lung cavity and Carrel-Dakin treatment carried out. If, in spite of this treatment, the sinus does not close, it is obvious that, as the lung will not fill the thoracic cavity, the only logical course is to operate and make the rigid thorax come down to the collapsed lung. The extent of the cavity should be determined by injection of lipiodol and an x-ray photograph.

Then following the teaching of Basil G. Beck, of Chicago, the open method of interthoracic surgery should be carried out. By this is meant a modified thoracoplasty dependent on the size of the resultant cavity and filling up this cavity by skin grafts or sliding skin-flaps. I have had several such difficult cases to deal with, and have had in every case an excellent result.

In conclusion, empyema presents great difficulty in treatment. The recognized and well-established treatment of this disease is given in any textbook on surgery, but until the last few years no progress has been made, and it is obvious that no progress can be made except on the lines of aiming at early restoration of function of the lung. This can only be attained by immediate closure, with its four main objects:—(1) Healing by first intention; (2) early convalescence; (3) abolition of

a sucking wound and secondary infection; (4) early restoration of lung function.

Investigation of Pulmonary Conditions With Lipiodol.

By MAJOR A. G. BIGGAM, O.B.E.

(*Journ. Royal Army Med. Corps*, Vol. LIII, No. 1, July, 1929, p. 1.)

THE technique of administration of lipiodol is simple, and the information obtained from its use has proved of the very greatest value in certain pulmonary conditions where the diagnosis has been in doubt.

Composition and Local Effects on the Tissues.

Lipiodol is a compound of iodine in poppy-seed oil and contains 40 per cent. iodine. It is a clear amber-coloured fluid when fresh, but tends to darken after being exposed to light for a long time and should then not be used.

The iodine contained in it renders the oil opaque to x-rays, and so after injection its position in the tissues can be demonstrated by the radiologist.

The iodine is actually in combination with the unsaturated oil, and so has none of the irritating action on the tissues that one associates with the presence of free iodine. It does not stain the skin, and can be injected anywhere in the body without producing local irritating effects. It has been used intramuscularly and intrathecally and, even in the latter situation, the oily compound is usually found to produce no local irritative symptoms. I have, however, observed on two separate occasions some pain complained of in the lumbo-sacral region, due to the collection of the lipiodol there in patients when the injection was made by cisternal puncture for the elucidation of obscure spinal conditions. The pain, however, was of short duration and after a couple of days or so entirely disappeared. In pulmonary cases after injection into the trachea this heavy oily compound spreads down and lines the trachea, bronchi, bronchioles, and eventually the alveoli. An x-ray will then be able to demonstrate the size and condition of the various parts of the air passages outlined by this radio-opaque substance.

The oil is removed from these situations chiefly by expectoration, but a little of it remains in the lung and is dissociated by the pulmonary tissue, the iodine then being got rid of chiefly by the kidneys. The rate at which the lung is rendered free from the lipiodol varies; in some cases very little opacity remains after a few hours, but one has occasionally observed its presence in considerable quantities even as long afterwards as a fortnight.

There is practically no danger attached to the injection, even when the operation is carried on very carelessly and the oil allowed to flow into the peritracheal tissues. I have observed a case where practically the whole of the injection had been made into these tissues and was demonstrated there by x-rays. The patient, however, complained of no discomfort, the oil gradually extending down the tissues into the mediastinum and eventually becoming absorbed with no ill-effects to the patient.

It has been stated that ill-effects may result from the administration in cases of pulmonary tuberculosis, but I have not observed any injurious results after its use in such cases. It appears to me, however, inadvisable to employ it in cases with a history of recent hæmoptysis, for in these cases the residual oil, after dissociation, may possibly cause sufficient disturbance to lead to a recurrence of the hæmorrhage. Such occurrences have been noted by me, but in cases like this it is always difficult to decide whether the hæmorrhage has recurred as a result of the injection, or merely in the ordinary course of events.

In cases of bronchiectasis the patient states, not infrequently, that he is much relieved by the injection, and I have had patients make repeated requests for further injections owing to their having experienced relief from the previous administration.

The sputum in many cases is definitely diminished for some days following, but I have occasionally observed

the quantity to increase, even up to as much as double the amount, for a few days after the injection.

It is well to warn the patient that after the injection the sputum coughed up should be spat out and not swallowed, so as to get rid of the iodine from the system. I have, however, not infrequently observed opacity caused by the oil lying in the stomach, this having been swallowed after being coughed up, but apart from an occasional slight iodine coryza no ill-effects have ever resulted from this in my series of cases.

Information obtained by Lipiodol Injection.

Very valuable information is obtained by x-ray examination after the injection. It will show the outlines of the trachea and bronchi, and any compression or obstruction there will be visualized, likewise any dilatation of the bronchi or cavity formation in the lung parenchyma communicating with the bronchi will be demonstrated.

Indications for its Use.

The common lung conditions in which most assistance may be expected are those associated with chronic cough and expectoration. The clinical signs in this type of case are often very indefinite, and ordinary x-ray examination may not help very much in elucidating the underlying condition, which may vary from an ordinary chronic bronchitis to pressure causing obstruction to the air-passages due to masses of glands or a tumour. In such cases lipiodol followed by x-ray examination will often clear up the problem at once.

The differentiation between chronic bronchitis and bronchiectasis is often impossible without lipiodol injection, for the latter condition may exist without any of the typical symptoms, such as paroxysmal cough and profuse expectoration.

There may be only a history of cough with slight expectoration, and physical examination may not reveal any signs of dilatation of the bronchi, which may be too far from the surface to produce recognizable physical signs. In such a case lipiodol may demonstrate even quite large cavities which had escaped detection even after repeated clinical examination.

Where the diagnosis of bronchiectasis is in no doubt whatever, and the question of operation is being considered, the injection is also essential to confirm one's findings that the condition is unilateral and the case therefore suitable for operative treatment by phrenic avulsion, thoracoplasty, lobectomy, etc.

In bronchiectasis it is essential that the patient should carry out postural coughing prior to the injection so as to empty the dilated bronchi of secretion. Obviously, if they are already full of thick contents, the lipiodol will float on top of this viscid substance and not enter the cavities in the same way as if care had been taken to have them emptied prior to the injection. The emptying is also important from the point of view of diminishing the tendency to cough after the injection has been made until the radiologist has had an opportunity of obtaining the necessary pictures of the lung with the oil *in situ*.

Methods of Carrying out the Injection.

No special skill is required to enable one to carry out the injection, and the assistance of the surgeon should not be necessary, the operation being carried out by the physician, either in the ward, or, if this is not conveniently situated to the x-ray room, it can be done actually in the x-ray department.

There are various methods of getting the oil into the air passages, but the one I have used most extensively has been injection by the crico-thyroid route. The patient, if nervous, should have a preliminary injection of morphia one-sixth grain half an hour beforehand. He should be propped up by pillows in the semi-sitting position with the head supported in the extended position by pillows and kept in the middle line. This ensures that the structures on the anterior aspect of the neck will be kept on the stretch and less liable to slip about during subsequent manipulation.

The surface having been prepared, the skin and subcutaneous tissues down to the cricothyroid membrane

are anaesthetized by half per cent. novocain, using only a very little anaesthetic so as not to obliterate the landmarks.

The next step is to inject some cocaine inside the larynx so as to anaesthetize the structures inside and thus render them less sensitive. This is done by using a two-cubic-centimetre syringe with a stoutish needle, containing 10 minims of a five per cent. solution of cocaine.

The cricoid cartilage is fixed between the thumb and index finger of the left hand, and the needle inserted above the cricoid cartilage at right angles to the surface and pushed through the tissues till it is felt to slip through the membrane into the underlying air passage. It is always easy to recognize when this has happened.

The piston of the syringe having been withdrawn to suck in some air and so ensure that the point is free in the air passage, the cocaine is quickly injected and the needle withdrawn at once. Coughing will be induced by the contact of the cocaine with the sensitive mucous membranes and this will assist in spreading the local anaesthetic over the required area. The next step is the actual injection of the lipiodol, and here there is one most important point to be considered, that is the consistency of the oil. It is a thick viscid substance and consequently difficult to get to run through an ordinary fine-bore needle.

The only difficulty I ever experienced in my early cases was that of forcing the oil through the available needle. This was a very real difficulty until we procured a suitable needle.

The needle must be one with a wide bore, and there is now available a suitable one devised by Chandler (a-trocar and cannula), the cannula fitting an ordinary ten-cubic-centimetre Record syringe.

We actually used, and still use one devised by my Registrar, Dr. Mohamed Ibrahim, consisting of a lumbar puncture needle cut down to about two centimetres long so as to be more easily controlled and not so liable to scratch the posterior wall of the air passage after having penetrated the anterior wall. This needle fits a ten-cubic-centimetre Record syringe and has a good wide bore which allows the oil to flow readily.

The oil will flow much more easily if it is kept warm by immersing the vessel in which it is contained in very hot water, and if the syringe used for the injection is also warmed immediately before sucking up the oil.

The needle is inserted through the cricothyroid membrane in the same way as for the injection of the cocaine, and here there may be slight difficulty in getting it to penetrate the skin. It has been recommended that a small incision be made in the skin to facilitate the passage of the needle, but this seems to me unnecessary and undesirable.

The needle having penetrated the cricothyroid membrane, the syringe containing the oil is attached and the piston withdrawn a little to allow bubbles of air to enter and so demonstrate that the point is in the correct position, free in the air passage. The piston is then pressed slowly home and the oil gradually injected; the syringe will have to be detached for refilling until the required amount (twenty to thirty cubic centimetres) has been injected. It is advisable to verify the position of the point of the needle occasionally during the injection by sucking up a few bubbles of air.

The patient should be asked to refrain from coughing or swallowing during the injection, and to breathe quietly through the nose.

Usually no interference with respiration is experienced, even when as much as thirty cubic centimetres of oil are used.

The position of the patient after the injection will vary according to the area of the lung requiring investigation. The position and size of the right bronchus is such that, if the position of the patient be not changed after the injection, most of the oil will find its way into the right base.

Where the left lung is to be filled, the patient should be tilted towards that side after the needle has been inserted and before the injection has been commenced.

If the apex is the suspicious area, about two minutes after the completion of the injection the patient should have his head and shoulders lowered so as to allow the oil, having passed the bifurcation of the trachea, to gravitate to the apex which has now become the most dependent part of the lung.

The patient should be kept in the required position for about ten minutes and then photographed in the supine and the erect position. He should, as already stated, be asked to refrain from coughing till the examination has been completed, and also when he does cough to spit out the material brought up and so avoid swallowing the iodine compound.

Valuable information is occasionally obtained by getting the patient to cough after the photographs have been taken and then taking another picture. By this means lipiodol may be forced into areas of the lung that previously had not been filled.

Close on 100 cases under my care have been investigated by the aid of lipiodol, and no difficulty has been experienced in carrying out the above technique, and in many of these cases very great assistance has been obtained in arriving at a correct diagnosis.

Other routes for the injection have occasionally been tried. At first I made the injections into the trachea below the cricoid cartilage instead of through the cricothyroid membrane, but this position did not seem to have any advantages over the higher situation, and the trachea was found to be less easily fixed and controlled than the structures above the cricoid.

I have also administered it by the mouth in quite a number of cases, and this route has the advantage, from the physician's point of view, of greater simplicity, and from the patient's point of view entire absence of all idea of anything in the way of a surgical operation.

In carrying out this method I have used an ordinary glass urethral syringe with about three inches of rubber tubing attached to the nozzle. The patient sits in a chair with the head forward and the tongue protruded and held out by hand. The warmed oil is slowly injected, the end of the tubing being kept near the base of the tongue, between that and the uvula, and not touching either so as to avoid inducing retching. The patient should breathe deeply during the time the oil is being injected, and must refrain from swallowing. The tongue should be kept protruded during the whole period the oil is flowing. If the co-operation of the patient is obtained during this simple injection, all the oil will run into the larynx, and any part of the bronchial tree can thus be visualized quite as well as by any of the previous mentioned methods in which needles have to be used. This method has proved highly satisfactory in quite a number of cases investigated by us.

Lipiodol can be obtained in two-cubic-centimetre ampoules or in bulk, the latter form being less expensive and quite satisfactory for carrying out long examinations.

A satisfactory English preparation is now on the market.

Commentary.

(1) Lipiodol injections have been found to be of the greatest value in the elucidation of many obscure lung conditions.

(2) Its use is essential in cases of bronchiectasis, where, from clinical examination, the condition is considered to be unilateral and operative procedure is being contemplated for collapse or for other surgical methods of treatment of the diseased lung.

These clinical findings should always be confirmed by lipiodol injection, followed by an x-ray examination to see the exact extent of the disease in the affected lung and to exclude the presence of any commencing trouble on the other side.

(3) There is practically no danger attached to the procedure even when it is carried out carelessly, and some of the oil is injected into the peritracheal tissues.

(4) No ill-effects have been observed by us after administration in cases of sub-acute and chronic pulmonary tuberculosis.

(5) The only type of case in which we still use lipiodol with caution is one with a history of recent

hæmoptysis, since the dissociation of the compound in the lung may possibly tend to produce local irritation and a recurrence of the hæmorrhage.

(6) The cricothyroid route has been found by us to be the most generally satisfactory, the procedure being very simple and easily carried out if the difficulty of the thick consistency of the oil is overcome by previous warming and using a large-bore needle.

The oral method has also proved satisfactory, and has the advantage of extreme simplicity.

Reviews.

LEPROSY IN EUROPE, THE MIDDLE AND NEAR EAST AFRICA.—By Robert G. Cochrane, M.D., M.R.C.P., D.T.M. & H. 1928. London: World Dominion Press. Pp. 76. Price 2s. net.

In order to arrive at an approximation of the incidence of leprosy, Dr. Cochrane, late medical adviser to the Mission to Lepers has been engaged for the past few years in a world survey of this disease, and the volume before us is his second contribution to the subject.

It is not claimed that the figures quoted for many of the areas are even approximately accurate; this is particularly true of Africa as a whole. Perusal of Dr. Cochrane's report, however, discloses two points of considerable interest and undoubted importance—firstly that something (however little) is being done for sufferers from leprosy in even the most inaccessible corners of the earth, and secondly that forcible segregation as a method of dealing adequately with the leprosy problem in any particular area is fast losing ground.

J. M. H.

THE SCIENCE OF NUTRITION SIMPLIFIED: A POPULAR INTRODUCTION TO DIETETICS.—By D. D. Rosewarne, M.R.C.S. (Eng.), L.R.C.P. (Lond.). London: Henry Kimpton, 1929. Pp. VIII plus 314. Illustrated. Price 6s. 6d. net.

THE object of the author is to explain to the lay reader the fundamental principles of nutrition in simple and suitable language. The author's object in this direction seems to have been well fulfilled, as the essential facts of nutrition as described in the book will be easily understood even by those who have had no scientific training at all.

The preliminary considerations of the science of nutrition, such as, the object of dietetics, the functions of food, the chemical processes of nutrition and the methods of dietetics have all been dealt with in Part I of the book as lucidly and completely as possible.

In Part II of the book, the author deals with the special questions with which the subject of dietetics is immediately concerned; viz., (1) the protein, the fuel, and the mineral requirements of the organism; (2) the vitamin requirements of the body, and (3) the physiological functions of oxygen. Part III deals with general considerations of food substances, animal and vegetable, and in Part IV the author deals with the very important subject of dieting. The arrangement and calculation of dietaries, special dietaries of childhood, middle life and old age, etc., have been dealt with in a clear and lucid manner. The chapter on preparation of food is well-written and will repay perusal.

There is a bibliography in the final chapter of the book and this is meant for the guidance of those who wish to amplify their knowledge of the subject.

A useful table is given at the end of the book showing the percentage composition of the main food-stuffs.

We have no hesitation in recommending this book to both medical and lay readers.

J. P. B.

THE ELEMENTS OF THE SCIENCE OF NUTRITION.—By Graham Lusk, Ph.D., Sc.D., LL.D., F.R.S. (Edn.), 4th Edition, re-set. Philadelphia and London: W. B. Saunders Company Ltd. Pp. 844. Illustrated. Price 32s. 6d. net.

THIS book has undergone four new editions and was also reprinted another three times within four years.

This fact alone proves the great merit of the book, and it needs no further testimony as a standard book on the subject. Professor Graham Lusk belongs to the Voit School (Munich), being an illustrious pupil of the well-known late Carl Von Voit (1831-1908), who was the leader of a large circle of investigators including the author, Rubner, Atwater, and many others "through whose activity his spirit still lives." We all know what Voit has done to help the advancement of the science of nutrition.

The book gives an *exhaustive* review of the scientific foundations on which our present knowledge of nutrition in health and disease has been built up. The author has taken great care and pains to explain his deductions and conclusions by fully discussing all the evidence on which they are based. The book is a rich store house of useful information, and contains a full account of carefully conducted experiments by experts all over the world.

The extensive and detailed index which the author has appended should prove very useful to those who want to make an intensive study of the subject. The author's index alone covers 32 pages printed in small type (in double lines), and that of the subject-index covers 45 similar pages.

The book consists of 31 chapters and an appendix.

We have no hesitation in saying that this book should form a *rade-mecum* to all who want to make a special study of the science of nutrition.

J. P. B.

PRINCIPLES AND PRACTICE OF MINOR SURGERY.

—By E. M. Foote, A.M., M.D., and E. M. Livingston, B.Sc., M.D. 1929. Sixth Edition. New York and London: D. Appleton and Co. Pp. XL plus 787 with 420 figures. Price 35s. net.

THE first edition of this book, the work of the senior author alone, appeared in 1907; since that date five other editions have been called for and in the latest the task of revision has been shared by Dr. Livingston. The result is eminently satisfactory and there is an almost complete absence of that dissimilarity in style which so frequently mars the book written by more than one hand.

The volume is divided into three main parts devoted respectively to minor surgical technique, principles of diagnosis and treatment, and localized surgical treatment. The inclusion of such widely different conditions as "black eye" and cancer of the rectum in a volume devoted to minor surgery suggests perhaps that the author's conception of the term is fairly elastic. This tendency to stray into fields which do not strictly belong to the realm of minor surgery adds slightly to the bulk of the book, but its essential merit is not appreciably impaired thereby.

Little more than a rapid general survey could be accomplished in the time at the reviewer's disposal. Chapter V entitled "Anæsthesia in minor surgery" is especially interesting; in the development of local anæsthesia in general and of regional and nerve block anæsthesia in particular American surgeons appear to be advancing more rapidly than their British colleagues. Errors are few and unimportant; at p. 208 "blush" should be "bluish" and at p. 225 "struma" ought to read "stroma"—and "*Lochardt* Mummery" has a distinctly unfamiliar look.

"Principles and Practice of Minor Surgery" is a handsome volume; it is clearly printed on excellent paper and the illustrations, chiefly from original drawings and photographs, are beautifully reproduced; it can be unreservedly recommended.

J. M. H.

A TEXT BOOK OF FRACTURES AND DISLOCATIONS.—By Kellogg Speed, S.B., M.D., F.A.C.S. 2nd Edition. London: Henry Kimpton. Pp. 952. Illustrated with 987 engravings. Price 50s. net.

THERE are many good things in this volume, but there is one maxim which we wish could be posted up in every hospital and dispensary. It is "Treat fractures at once with as much respect and rapidity as the acutely inflamed appendix." It would save much suffering and the not uncommon reproach of a malunited fracture.

The opening chapter deals with general principles in the treatment of fractures, and includes a very excellent description of dressings and splints. The following chapter deals with the operative treatment of fractures. The views expressed on this last subject will commend themselves to all surgeons who have had much experience of fracture treatment. They probably will not commend themselves to the strong opponents of operative treatment, nor to the equally extreme enthusiasts for it.

In describing operative technique, perhaps insufficient attention has been drawn to the necessity of using the correct drill for the machine screw used. Neglect of this is the common cause of loose plates.

Chapter III is devoted in the same way to general considerations relating to dislocations.

Having thus disposed of general principles, the remainder of the volume is divided into chapters on a regional basis. These chapters are profusely illustrated, many of the illustrations being outline tracings of x-ray plates. A number of other plates are photographs of actual cases as splinted and suspended in the author's practice. These are valuable features, particularly for surgeons who have only occasionally to treat fractures.

Recurrent dislocation of the shoulder is very fully dealt with and the numerous operations for this trying disability are described. The author has his own bone transplantation operation, and naturally prefers it. Clairmont's operation is, we think, condemned unjustly. It is certainly more successful than the author suggests.

Very complete descriptions are given of fractures and dislocations of the carpal bones. These are fractures frequently overlooked and certainly among the most difficult to treat satisfactorily.

The book is up to date and includes all tried and approved methods of treatment. It can be relied upon as a safe guide and as a book of reference.

The printing, illustrating and binding are all that can be desired, and a credit to the publishers.

A. H. P.

THE TREATMENT OF RHEUMATOID ARTHRITIS.

By A. H. Douthwaite, M.D., F.R.C.P. (Lond.), 1929. London: H. K. Lewis and Co., Ltd. Pp. X plus 80 with two illustrations. Price 6s. net.

ALTHOUGH rheumatoid arthritis has been the theme of innumerable discussions in medical and scientific circles, it is a disease about which remarkably little is known. In this small book of eighty pages Dr. Douthwaite reviews succinctly and critically the different ætiological factors and outlines rational methods of treatment.

While not denying the part played by focal sepsis in the causation of the disease in certain cases, the author is at one with Pemberton, Jewell, and not a few other equally rational although less well-known investigators in condemning the wholesale dental extractions, tonsillectomies and colon excisions that have frequently been performed in the belief that sepsis in one or other of these situations *must* be at the root of all cases of rheumatoid arthritis. A review is given of the respective parts played by endocrine disturbances, vitamin deficiency and diminished oxygen consumption; the author himself suggests that parathyroid dysfunction plus diminished oxygen consumption by the tissues play an important part.

Dr. Douthwaite is an enthusiastic advocate of balneotherapy in early cases and of manipulative treatment in the stage of chronic deformity, but he rightly emphasises the importance of treating each case on its merits and of securing the complete co-operation of the patient.

This valuable little book will do much to clear up the obscurity which at present surrounds the subject. On p. 29 "*ehrondroitin* sulphuric acid" should be "*chondroitin* sulphuric acid"; our Oxford Dictionary does not give the word "*seanance*" and we doubt whether even the most scientific agriculturist is capable of unmasking a soil.

J. M. H.

MOVABLE KIDNEY: ITS ETIOLOGY, PATHOLOGY, DIAGNOSIS, SYMPTOMS AND TREATMENT.—By William Billington, M.S. (Lond.), Ch.M. (Blrm.), F.R.C.S. (Eng.). 2nd Edition. London: Cassell and Company Ltd. 1929. Pp. IX plus 177 with 14 full-page plates and illustrations in the text. Price 12s. 6d. net.

THE first edition of this fascinating work on movable kidney was published in 1910 and now, after nineteen years, a second edition has been prepared by the author. We are told that close attention has been devoted to the subject for twenty-five years, and during that period over 1,500 cases have been operated on. There are few surgical conditions which may produce more varied and more distressing symptoms than movable kidney, and in the words of the author, it "does almost always diminish working efficiency. It interferes with the physical or mental powers, or with both, in greater or less degree."

The subject is discussed in 14 chapters, as follows: anatomical considerations; visceroptosis and nephroptosis; frequency and aetiology; pathology (3 chapters); diagnosis; symptoms (4 chapters); treatment; nephropexy; results. Two pages of references are given at the end of the book.

In Chapter I important details of the surface and internal anatomy of the kidneys are discussed, together with the relations of the kidneys to other organs, indicating how excessive mobility may affect them. The very important attachments of the perirenal fascia are outlined—this fascia does not in the first instance arrest a movable kidney, but in the later stages of prolapse is itself pulled upon and stretched. The real supports which keep the kidney in position are:—(i) intra-abdominal pressure; (ii) the vessels of the renal pedicle, and (iii) the fatty capsule; by far the most important is the first.

Chapter II deals with visceroptosis and nephroptosis. Prolapse of the kidney may be part of the general process of ptosis of the abdominal viscera, known as visceroptosis or Glenard's disease, or this event may occur alone or in excess of the general prolapse, when it is called nephroptosis. The normal movements of the kidneys, tests for abnormal movement, and the not sufficiently recognized form of prolapse termed "rotation of the kidney" are gone into. The author prefers the term "dislocated" to those of "movable," or "dropped," or "prolapsed," for pathologically displaced kidneys. The mechanism of displacement is fully described. As a result of the various movements the hilum comes to look upwards, inwards and forwards, and there is practically no limit to the descent, an iliac or pelvic position even being reached. The congenital type of "floating kidney" is a rare phenomenon. During the descent of the kidney the ascending colon and hepatic flexure are loosened and pushed downwards, and the adjacent peritoneum is also loosened.

The classification adopted for dislocated kidney is that suggested by Wilson and Howell—viz., (i) simple prolapse; (ii) prolapse with internal rotation of the lower pole; (iii) prolapse with rotation inwards and forwards of the lower pole, with lateral mobility and absence of any movement communicated by the diaphragm; (iv) rotation with little or no prolapse—the kidney may not even be palpable.

Chapter III discusses the frequency and aetiology of movable kidney. The figures given by various authorities as regards frequency are very dissimilar. This is said to be due to the particular class of patients considered. In neurasthenic women it is probably as high as 30 to 40 per cent., but in healthy women not much higher than 5 per cent. In men the incidence works out at $\frac{1}{2}$ to 1 per cent., and the proportion between the two sexes is given as about 1 to 8 $\frac{1}{2}$. When examined in an erect position, the author states that of 594 cases of movable kidney investigated the right kidney alone was movable in 186, the left kidney alone in 30, and both kidneys in 368.

Aetiology is discussed under the headings of predisposing and exciting causes. Among the predisposing causes taken into consideration are heredity, debility and spinal curvature; among the exciting causes trauma, errors of dress, carelessness after confinement, constipation, and pathological changes in and around the kidney.

Loss of muscular tone from any cause is of great importance; sudden strain may dislocate a kidney for the first time; pregnancy in itself is a negligible cause.

Pathological changes in the surrounding structures and in the kidney itself are discussed in Chapters IV and V. The former are grouped under the effects produced on the perinephric fascia, capsula adiposa, peritoneum, colon, suprarenal capsules, and other organs—including the spleen, and pelvic organs. The widespread, and sometime serious, effects are clearly indicated. In the kidney itself, the effects of undue mobility produce changes in the capsule, ureter and pelvis, the renal vessels, renal parenchyma and nerves, and the urine. The value of taking pyelograms in the erect position is laid stress on. Mobility itself does not produce hydronephrosis as a rule, but this may result from the pressure of an aberrant renal artery. Dietl's crises are evidence of threatened renal strangulation.

General pathology is dealt with in Chapter VI. It is claimed that the very varied symptomatology of movable kidney is explained by the effects of traction and pressure on the sympathetic nervous system, by a disturbance of the normal balance which exists between the two sides of the autonomic nervous system. Further, the author definitely ascribes some of the effects to toxæmia, though this is denied by some authorities. The mechanical and toxic theories are described as complementary, both factors playing a part in the chronic ill-health and lowered efficiency associated with nephroptosis.

Chapter VII deals with diagnosis. Examination is advised with the patient supine, then lateral, and finally erect. Differential diagnosis is discussed between movable kidney and each of the following conditions: Riedel's lobe of the liver, an enlarged gall-bladder, a mass in the colon, pyloric tumour, and an enlarged ovary. Acute attacks of kidney pain have also to be distinguished from renal calculus, gall-stone colic, and appendicitis.

The next four chapters deal with symptoms. It is asserted that a movable kidney always diminishes working efficiency. Local symptoms are discussed under: pain, sudden displacement, obstruction of ureters by an aberrant artery, rotated kidneys, lumbar ache, vesicle irritability, and condition of the urine. The general symptoms are described as a form of neurasthenia—there is fatigue, loss of weight, and depression. Disturbances of digestion and sexual function may occur; the former may be caused by duodenal stasis, chronic appendicitis, or colitis; the latter is due to pressure effects, chiefly on the female pelvic organs. Disorders of the nervous system are among the most important and are of widely differing types, such as—neurasthenia, headache, tachycardia, Raynaud's disease, and disorders of the mind.

Chapter XII deals with the indications for treatment and the methods of treatment and the following chapter with nephropexy. The author is not in favour of support by special belts and trusses, but this method of treatment may help diagnosis. The only effectual method of radically remedying the displacement is by open operation. The essential steps to ensure a successful nephropexy are given, and the author's technique is fully described: Edebohl's incision is used, the kidney exposed and freed, the peritoneum is opened in order to explore other abdominal viscera, the kidney is suspended to the last rib by means of a triangular flap of capsule and also by Brodel's suspensory sutures.

Finally, in Chapter XIV, the results of nephropexy are discussed under the headings of (1) surgical results, and (2) therapeutic results. The results of the author's own series of cases are also given.

Movable kidney is a subject which, in the opinion of the reviewer, is a good deal neglected in India. Appendicitis, and gastric and duodenal ulcer were in the same way neglected for many years, and are only now beginning to be recognized as common and important. As a possible cause of neurasthenia, it must always be borne in mind. The case of an Indian, a bank clerk, is recalled, who was neurasthenic to the extent of threatening suicide, because of the constant lumbar pain and dragging sensation. A very movable right kidney was fixed with complete success, and this created such an impression on the patient's mind that he writes yearly to

express his thanks on the anniversary of his operation—a very unusual exhibition of post-operative gratitude!

This book on "movable kidney" should be read by every practitioner. It is a very thorough exposition of the whole subject; the various important aspects are freely illustrated by cases; and, the photographs and drawings are quite clear and sufficiently numerous.

F. P. C.

AN INTRODUCTION TO THE STUDY OF THE NERVOUS SYSTEM.—By E. E. Hewer, D.Sc. (Lond.), and G. M. Sandes, M.B., B. S. (Lond.), M.R.C.S., L.R.C.P. 1929. London: William Heinemann (Medical Books), Ltd. Pp. XII plus 104, with 55 diagrams. Price, 21s. net.

THIS small book, written by two members of the staff at the Royal Free Hospital, London, gives the reader an excellent grasp of the essentials of the anatomy and physiology of the nervous system; the use of numerous well-executed diagrams (many of them in colour) still further enhances the prevailing clarity of the text. There is only one feature of the book at which we cavil and that is the price. Excluding the index (five pages), there are altogether ninety-eight pages of reading matter: to these should be added the majority of the diagrams, which are executed on separate sheets interleaved with the text. The price of the whole is twenty-one shillings—say rupees fourteen. We doubt whether the average medical man in India can afford the luxury of medical textbooks at rather more than two annas per page.

J. M. H.

PHYSICAL DIAGNOSIS.—By C. P. Emerson, A.B., M.D. Second Edition. Revised. 1929. London: J. B. Lippincott Company. Pp. 553 plus XV, with 324 illustrations. Price, 35s. net. Obtainable from Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 26-4 net.

THERE appears to have been in recent years a marked increase in the number of books devoted to the science of physical diagnosis. Dr. Emerson entered this field in 1928 and already a second edition of his book has been called for. The present reviewer did not have the pleasure of perusing the first edition and he cannot therefore state from personal experience to what extent the volume before him differs from its predecessor. We learn from the preface, however, that "material which recent research has shown to be important enough to deserve mention" has been added. The author deals most exhaustively with the whole range of kindred sciences comprised under the heading of physical diagnosis, and on closing his book one feels that there is little more to be said on the subject. In a field so large divergence of views is, on occasion, inevitable and there are one or two points—minor ones it is true—to which criticism may be directed.

Dr. Emerson does not mention malarial cachexia and severe hookworm infestation (both relatively common conditions in the subtropical regions of America) as possible causes of infantilism. On p. 48 reference is made to the anthrax bacillus as a gas-producing bacterium. It is probable that confusion has arisen between *malignant pustule* (a form of anthrax) and *malignant oedema* a condition with which a gas-forming anaerobe is intimately associated. Diabetes and jaundice might have been mentioned (at p. 72) as possible causes of pruritus. The idea that the earliest lesions of leprosy manifest themselves on the nasal or phalangeal (*sic.*) mucous membranes rather than on the skin is now abandoned by competent leprologists. This particular section needs revision, including the removal from its midst of fig. 21—blastomycosis of the hand. The author's hypothesis regarding the mode of production of the functional heart murmurs (p. 362) might, we think, have been a little more clearly expressed; and is not talipes equino-varus as common a variety of club-foot deformity as true talipes varus?

These are small points which should not detract from the essential merit of the book as a whole. Our most serious criticism, however, concerns the number of printing errors that have been allowed to creep in. A hasty

survey of the work revealed no fewer than thirty-seven of these; in the majority the context makes the meaning clear, but in some the situation is frankly confusing. At p. 375 we are given a reference to *pulsus paradoxus* at p. 323; this pulse irregularity is described however not on p. 323 but on p. 303—and the index adds fuel to the fire by referring the reader to p. 302. It is difficult to see what adequate justification there is for referring the reader from Paget's disease of bone (osteitis deformans) on p. 504 to Paget's disease of the female breast on p. 217. At the bottom of p. 518 we read 'spastic paralysis of the upper extremities.....is best illustrated in hemiplegia (fig. 105)' but on turning to the figure in question we find a photograph illustrating inflammatory mastitis of the left breast. We are distressed by our enforced rôle of captious critic but we feel that the errors we have mentioned are blemishes on an otherwise valuable production. Finally, we would ask Dr. Emerson, as a personal favour, to amend in his next edition the Americanised spelling of Scotland's capital which appears at the top of page 12.

J. M. H.

INDIGESTION: ITS DIFFERENTIAL DIAGNOSIS AND TREATMENT.*—By H. G. Paterson, C.B.E., M.C., M.D., M.A. (Cantab.), F.R.C.S., London: William Heinemann (Medical Books), Ltd. 1929. Pp. VIII plus 153. Price, 7s. 6d. net.

IN the preface to this book the author states, "I have endeavoured to present a practical guide to the differential diagnosis and treatment of indigestion." This is a worthy aim, for it is probable that the general practitioner finds more difficulty in diagnosing the cause and directing the treatment of indigestion than he does in any other common complaint.

In the popular textbooks the chapters on diseases of the stomach are perhaps the least satisfactory. They certainly do not help the student to obtain a clear idea of the many causes of dyspepsia and the relative importance of the history and symptoms as an indication for treatment. Mr. Paterson has written his book in a different style.

He gives us a classification which may not be perfect, but is certainly very useful as a basis for the argument of a differential diagnosis. First place is given to indigestion secondary to causes outside the stomach. This is admirable, for there can be no doubt that in the majority of cases the symptoms are not due to any lesion in the stomach itself. Perhaps chronic appendicitis as a frequent cause of indigestion is exaggerated, but Mr. Paterson is a surgeon and to every surgeon the appendix is the *fons et origo* of many disabilities. It may be for a similar reason that in the classification there is no mention of any gynaecological cause, and the reviewer wonders what the gynaecologists will say to this. The importance of obtaining a detailed and accurate history of each individual case is emphasised. In this history the occurrence of pain as opposed to discomfort and its time relation to the ingestion of food is most important of all.

The physical examination must be thorough and complete. Mr. Paterson is an ardent advocate of the value of the test meal and gastric analysis. He states "It is quite wrong to attempt to treat chronic indigestion without a knowledge of what is happening in the stomach."

This knowledge can only be obtained examining the contents of the stomach, their chemical composition and the rapidity of its evacuation.

The Ewald test meal, stomach tube and Senoran's evacuator are used by the author, and this method in most cases will give all the information required. But it is surprising to find that no mention is made in this book of Ryle's tube and fractional analysis.

*Two copies of this book were received for review, and were inadvertently sent to two different reviewers. As, however, our readers may like to read both reviews, we publish both.—Editor, I. M. G.

The chapter on radiology is very short. Mr. Paterson agrees that this method of investigation is invaluable, but not infallible. An operation should not be performed on radiological evidence alone, neither should it be postponed if the clinical facts point towards its necessity although unsupported by the radiologist.

The second part of the book deals in sequence with the different diseases of the stomach.

They are all very well described, and the differential diagnosis is unusually clear.

Detailed methods of treatment are not given, neither are there descriptions of operations, but the general outline and the indications for operative interference are very good.

Dr. Paterson is very sceptical of the claims made for the intensive alkaline method of cure. Medical treatment will cure many ulcers, and should always be tried, but he states "The healing of a gastric ulcer is to be measured not by weeks but by months. This truth is based on the evidence of surgical right, and not on that of radiological faith."

There is a useful chapter on general treatment and the use of the stomach tube.

An appendix gives the various tests employed in the analysis of the gastric contents. There is also a list of useful prescriptions and a description of the apparatus required for a simple gastric analysis, that can be used by the general practitioner. The reviewer has not met with any book which gives a more lucid description of the diagnosis and treatment of indigestion. It should prove of great value to both the student and the practitioner.

H. H.

DR. PATERSON'S succinct account of one of the commonest symptoms encountered in medical practice is adequate and timely. An exhaustive consideration of a condition so protean in manifestations and origin as indigestion would require a much larger volume than that under review, and in his attempt to keep the subject strictly within bounds Dr. Paterson has at times drifted dangerously near the reef of dogmatism—this does not however seriously detract from the essential merit of the book.

The author insists that gastric disorder frequently arises from causes outside the stomach; in this connection the vermiform appendix is particularly blameworthy. We should have liked to see a little more detailed reference to the part played by chronic infective conditions of the accessory nasal sinuses and of the teeth in the causation of indigestion. Rosenow in America has recently produced both acute and chronic ulceration of the stomach by intravenous injection of streptococci obtained from lesions of the throat and mouth.

The distension of the stomach by means of an inflating air-pump in order to demarcate the contour of the viscus is not a procedure which meets with favour from all observers. Frequently there occurs a simultaneous distension of the entire intestinal tract with very little distension of the stomach. The technique of auscultatory percussion and of scratching percussion, both useful in outlining the stomach, is not mentioned.

Had this book not been written for practitioners (as opposed to specialists) Dr. Paterson would doubtless have mentioned the use of the œsophagoscope, rather than the less accurate œsophageal bougie, in the diagnosis of stricture of the œsophagus: it would be well, however, to remember the definite exclusion of aneurysm of the arch of the aorta before attempting to use either instrument.

That gastric lavage is the treatment of choice in the majority of cases of acute gastritis admits of little debate; but it appears doubtful whether the treatment in question should be applied in the small residuum of cases where the symptoms are the result of swallowing concentrated mineral acids or strong alkalis.

Dr. Paterson unequivocally condemns gastropexy, colopexy, and other "pexies" as among the most unsatisfactory operations in surgery. In this he is in agreement with another distinguished physician who cynically remarked that "since Waugh discovered the

'mobile ascending colon' the abdominal surgeon has made a fortune hitching up this unfortunate viscus—and a second fortune taking it down again."

The author is to be congratulated on the production of a compact and eminently readable little book which ought to find ready acceptance among practising physicians. Printing and binding are good and the price is reasonable.

J. M. H.

PEDIATRICS FOR THE GENERAL PRACTITIONER.
—By H. M. McClanahan, A.M., M.D. London: J. B. Lippincott Company. 1929. Pp. XI plus 606, with 230 illustrations. Price, 25s. net. Obtainable from Messrs. Butterworth and Company (India), Ltd. Price, Rs. 18-12 net.

THE author has written this book for the purpose of presenting a modern clinical picture of the diseases of infants and children under conditions encountered by the family physician.

It represents, to a great extent, his personal experience, first as a general practitioner and then as a child specialist.

The book does not differ in any way from the many textbooks on diseases of children, except that it is written in a more concise and practical style than the majority. The first chapter on the normal human infant is perhaps the best. It gives an excellent description of the normal growth and development, both mental and physical, of a child.

Birth injuries, congenital malformations, and the diseases of the new-born are then described.

The following chapter on "Breast and Artificial Feeding" does not occupy so much space as is usual in books of this kind, but all that is required is there, and the various methods of preparing and modifying artificial foods are clearly explained. The author prefers three hourly feeds to four hourly and advises one bottle feed a day at three months.

The diseases of the digestive and respiratory tracts are the most important in children. The author's description of these is conservative and the methods of treatment advised are practical.

The specific and contagious diseases receive their due share of attention. Miscellaneous diseases include those important conditions due to vitamin deficiency, rheumatism and diabetes. Heart disease and the various diseases of the nervous system occupy a prominent position in the book. Skin diseases, mental defects and tropical diseases are also described.

The last chapter on "Curative Agents" is most practical. All the methods of administering treatment to children are there.

It will be noticed that the whole range of children's diseases is included in one comparatively small volume. This is unusual and makes the book more useful to the general practitioner.

The book is very well illustrated. There is a bibliography after each chapter and a full index.

H. H.

BACTERIOLOGY: GENERAL, PATHOLOGICAL AND INTESTINAL.—By A. I. Kendall, B.S., Ph.D., Dr.P.H. Third Edition. Thoroughly Revised. London: Baillière, Tindall and Cox. 1929. Pp. XVI plus 733. Illustrated with 103 engravings. Price, 31s. 6d. net.

THE reviewer was not previously familiar with this book, of which the volume under review is the third edition, and there appears to be nothing to indicate when the first two editions appeared. However, from the preface one gathers that the more important additions include details of the Kahn test, and the Dick test, and recent work on filterable viruses, especially the bacteriophage.

In view of the fact that bacteriology is a very wide subject, of which medical bacteriology is only a comparatively small specialisation, it is surprising that more writers on the special subject do not give their books a more specific title. The author in this case has qualified his title "Bacteriology" by a somewhat unusual

subtitle "General, Pathological and Intestinal." Of the 700 odd pages only about 60 are on general bacteriology: these form an essential—and in this case a very excellent—introduction to the subject of medical bacteriology. The bulk of the volume is devoted to bacteriology in its relationship to human body, and where the diseases of animals are mentioned, it is only on account of their transmissibility to man. (There may be a few minor exceptions to this statement, as we notice that contagious pleuropneumonia of cattle—a disease not communicable to man—is mentioned.) The final section, which presumably justifies the "Intestinal" of the subtitle, is devoted to the subject of intestinal flora, and the bacteriology of sewage, water, milk, etc.; this section is a very short one consisting of only about 40 pages. The book is thus essentially one on medical bacteriology and is for the general medical student who proposes to sit for the higher examinations.

The usual arrangement is adopted; first the morphology, chemistry, and metabolism of bacteria are dealt with, then their relationship to man as saprophytes and parasites; this is followed by a section on the reaction of the body towards these organisms, that is immunity and antibody formation; in this last chapter are included all the serum diagnostic tests. Special attention has been paid to the Kahn test; Dr. Kahn himself wrote this chapter for the author. There are a few chapters on cultural methods and laboratory technique. The various pathogenic bacteria are then described in detail; the spirochaetal group of organisms are included here. There is a chapter on the higher bacteria, the Trichomycetes, moulds, etc. Only a few pages are devoted to filterable viruses; poliomyelitis and encephalitis lethargica receive most attention, whereas the bacteriophage is dismissed in a couple of pages; this is disappointing in view of the reference to this subject in the preface. Rabies is included under diseases of unknown aetiology and is not dealt with at any length; no attempt has been made to describe the different methods of giving anti-rabic treatment, and the statement that the neuro-paralytic symptoms, which have followed when big doses are given, are a modified form of the disease is not in accordance with the generally accepted opinion.

The book is of very convenient size, the type is clear and the page illustrations are excellent and not too profuse. The coloured plates are, however, disappointing and might well be omitted from future editions. It is difficult to justify plate III, for example; coloured plates add considerably to the cost of a book and this one could not possibly be of any assistance to the reader. This is, however, the only criticism we have to make and we think that the publishers, as well as the author, should be congratulated on the production of the book, which we can thoroughly recommend as a textbook for the student for higher degrees and for the laboratory worker.

L. E. N.

PHYSICAL THERAPEUTIC TECHNIC.—By F. B. Granger, A.B., M.D. With a foreword by W. D. McFee, M.D. Philadelphia and London: W. B. Saunders Company, Ltd. 1929. Pp. 417. Illustrated. Price, 30s. net.

It has been a great pleasure to the reviewer to read this book, which deals with a subject which has few really authoritative textbooks. The present volume is therefore welcome.

The author has successfully covered the ground of physical therapeutics from the electrical standpoint, and deals with all forms of therapeutics, such as diathermy, ultra-violet rays, infra-red rays, galvanism, faradism, the Morton wave, static electricity, and the sinusoidal current. He also touches on X-ray therapy.

It is interesting to notice that the author favours the metal to skin contact for diathermy in opposition to the general practice in his own country. This method is universal, practically, in England. The type is clearly printed, the book is well illustrated, and indexed. Altogether, this work can be recommended not only to

specialists, but also to general practitioners, who desire to know something of electro-therapy.

C. G. R. M.

AIDS TO ZOOLOGY.—By H. Lister, M.Sc., F.Z.S. London: Ballière, Tindall and Cox. 1929. Pp. VIII plus 214, with 29 figures in the text. Price, 3s. 6d. net.

This little book on zoology for young students covers a large field in a very short compass. The author should be heartily congratulated on having been able to deal with so much matter in a concise manner and in such simple language. The author's method of reproducing diagrams by the use of words only seems to be very simple and instructive; but we feel that a few more diagrams would have been helpful. The book, however, will not be suitable for Indian students, whether intermediate or medical, owing to the fact that Indian syllabuses are quite different from European, and most of our types equally so.

E. K. G.

AN INTRODUCTION TO THE HISTORY OF MEDICINE.—By F. H. Garrison, A.B., M.D. Fourth Edition. Revised and Enlarged. London and Philadelphia: W. B. Saunders Company, Ltd. 1929. Pp. 998. Illustrated. Price, 55s. net.

THIS book is one of the largest and best-known books on the history of medicine. No very remarkable additions have been made in this new edition, but the subject-matter has been brought up to date.

The first chapter is by way of being an introduction; in it the relationships of the ancient medicines to modern medicine is discussed. In the succeeding chapters the subject is dealt with chronologically. The prehistoric period, of which our knowledge is necessarily very scanty and dependent largely on paleopathological remains, is given a short chapter. There are then chapters on Egyptian Medicine, Sumerian and Oriental Medicine, and Greek Medicine, and then on the various periods, the Greco-Roman, the Byzantine, the Mohammedan and Jewish, and the Medieval, through which the cult of medicine passed before arriving at the stage of modern scientific medicine, which may be said to have had its earliest beginnings during the Renaissance. The seventeenth and eighteenth centuries, during which little advance was made, are each given a chapter. The Modern Period which occupies about half the volume is divided into two chapters "The nineteenth century; the beginnings of organised advancement in science," and "The twentieth century; the beginnings of organised preventive medicine." Finally, the book proper concludes with a chapter on medicine in the world war and after.

The first three hundred pages, which take us up to the end of the seventeenth century, are written as a history and make most excellent reading, though the student of the ancient Indian systems may be disappointed to find that only two pages are devoted to this subject. The rest of the book has degenerated into a sort of dictionary of medical biography. The historical sequence has been observed as far as possible, and an attempt has been made to group and to make a consecutive story out of the various biographies. This is probably the only possible way of dealing with the subject in a book of this size, which aims at being a complete history and not merely an historical sketch. It certainly increases its value as a book of reference, though it makes it somewhat tedious to read.

There are a number of appendices. The first appendix is a chronology of medicine and public hygiene. Here the writer has observed the natural perspective; in the first page he gallops through about 7,000 years, whereas in the last few he crawls at the rate of about two years to the page. The crawling process is rather laboured in places. We quite see the author's difficulty; not only is he afraid to leave out any event in case at some future date it may be considered an important one, but he has to please his contemporaries by bringing in as many of them as possible. Nevertheless, we feel that posterity will be able to view quite dispassionately the fact that between 1898 and 1915 W. T. Porter financed the *American Journal of Physiology*, that in 1917 mental tests were

employed in recruiting soldiers, and that Ruth Tunnicliff discovered a diplococcus in measles, that in 1920 an institute for albumen research was founded in Hamburg, and that in the following year the New York Health Department operated 68 infant milk depôts. Also, it is rather difficult to see how the fact that St. Petersburg became Petrograd in 1914 and then in 1922 became Leningrad can be considered an important medical event.

The book is an important one; it is essential to the serious student of medical history and it should find a place in every medical library of any standing. The format of the book is excellent.

L. E. N.

PRINCIPLES OF PATHOLOGY FOR PRACTITIONERS AND STUDENTS.—By H. D'Arcy Power, M.D., F.R.P.S. and William W. Hala, M.D. New York and London: D. Appleton and Company. 1929. Pp. XLIX plus 787, with 298 illustrations. Many of them in colour. Price, 42s. net.

THIS is a new book on pathology. In the preface the authors explain their reason for adding to the long list of books on this subject. They feel that the writers of most books on pathology do not sufficiently stick to the point and are liable to be diverted into the realms of parasitology. This, they think, is as much outside the province of pure pathology as a discussion on predatory mammals in a book on surgery. The reviewer has never noted this as a serious defect in the books that have come his way. They also feel that "pathology.... is greatly hampered by a superabundant, overlapping and often misleading nomenclature," and that "there is very little that cannot be said in plain English, and that is how we prefer to say it." They may have, done so, but they have spelt it in plain American. They have given few bibliographical references because "any real bibliography would consume more pages than those given to the text." This is quite true, nevertheless we cannot help feeling that at least 40 of the 42 pages which have been wasted—in our opinion—in printing a detailed list of contents and illustrations might have been with great advantage devoted to a selected list of references. A short contents list of a page or so is very useful, but one of this length is superfluous; its functions are performed far more efficiently by an index.

The subject is divided into two parts, general pathology and systematic pathology. In the first part there are successive chapters on the various forms of cell found in the body and on the degenerative and regenerative processes they undergo, on inflammation, causes of disease, defence processes, developmental errors, and cysts and neoplasms. In the second part each system is dealt with separately. Finally, there is an appendix, part of which is devoted to technique and the rest to a various assortment of subjects, from the theory of cell heredity to the sedimentation of erythrocytes.

The book is written in a clear and simple style. There are numerous very useful illustrations. It should make a useful textbook for the M.B. student in this country. The print is clear, the paper of good quality, and most of the illustrations are excellently reproduced.

L. E. N.

TOXÆMIAS OF PREGNANCY.—By H. J. Stander (Medicine Monographs). Volume XV. London: Baillière, Tindall and Cox. 1920. Pp. XI plus 161 Price, 13s. 6d. net.

THIS monograph is a monumental piece of work, reviewing as it does every considered opinion on the above subject in 140 pages. Some idea of the work done by the author can be given when it is stated that there is a bibliography of 735 names, most of whom are continental, but one wonders if the author has ever visited the clinics of some of the authorities he quotes, for the findings of horn-spectacled professors in laboratories cannot be compared with those who base their deductions on the pathology of the living.

Dr. Stander however writes without bias, and having stated multitudinous theories, always gives us the benefit of the experiences and deductions found at Johns

Hopkins Hospital. The toxæmias of pregnancy are classified by him as—

- (1) Vomiting of pregnancy.
- (2) Low reserve kidney.
- (3) Nephritis complicating pregnancy.
- (4) Pre-eclampsia.
- (5) Eclampsia.
- (6) Acute yellow atrophy of the liver.

This classification has been followed at his hospital and has proved satisfactory, for less than 5 per cent. of patients suffering from toxæmia of pregnancy have been placed in an unclassified group.

It is necessary to understand what is meant by the low reserve kidney, for this is a title which so far has not been used by British obstetricians, although it is a clinical entity that has been acknowledged by James Young, Gibberd and others in Great Britain, namely, (a) a clinical status of somewhat elevated blood pressure, (b) the amount of albumen is not excessive, and disappears after childbirth, (c) in subsequent pregnancies the patient's condition does not become aggravated, and the kidney is not permanently injured, (d) there is a reserve of capacity in the glomeruli of the kidney which enables them to maintain function up to about the eighth months of pregnancy without symptoms, and which is completely restored after the birth of the child.

This group of cases forms about 40 per cent. of the albuminurias of pregnancy, and is a very important one from the point of view of prognosis and treatment, for the state of pregnancy itself is the most delicate test of renal function that we possess. Therefore, before subjecting any such patient with albuminuria to emergency treatment, such as Caesarean section, or induction of labour, it is imperative that the blood-urea concentration and the urine-urea concentration should be assessed in ratio.

Eclampsia has been called the disease of theories, and Dr. Stander certainly gives us evidence thereof, for he tabulates *serialim* and criticises twenty-one present-day theories of causation, but clinically we are no nearer the light than we were ten years ago from the point of view of treatment, for the combined methods of Stronganoff, Tittus, and Hastings Tweedy still hold the field.

The biochemical findings indicate that eclampsia is seldom associated with nitrogenous retention in the blood, or that the blood-urea nitrogen is raised. Dr. Stander is of opinion that elevation of the non-protein nitrogen is the result of kidney injury caused by the eclamptic outbreak, and that the blood sugar is either normal or slightly increased.

He states that an increased uric acid and decreased carbon dioxide combining power are the outstanding findings in the blood chemistry. One interesting point is brought out, and that is that during the World War owing to a hunger blockade of the Central Powers with resulting deprivation of proteins and fat, the incidence of eclampsia fell from 1 in 70 to 1 in 118, which would indicate that semi-starvation or a carbo-hydrate diet were beneficial in Europe; but against this theory we have the immense incidence of eclampsia amongst Hindus in India, whose diet is mainly carbohydrate. It is possible that the incidence in India then, is due to the excess of ghee and vegetable fats used in the preparation of their food, such fats inhibiting the proper function of the liver and hence determining the accumulation of some unfilterable toxins which precipitates eclampsia.

Herein lies a line for research which it is hoped the Rockefeller Foundation in Calcutta will hasten to take up in the near future for, barring Russia, the incidence of eclampsia in India is greater than in any other country of the world.

This monograph of Dr. Stander is one that every professor of obstetrics and practising obstetrician should possess.

V. B. G-A.

HERMAN'S DIFFICULT LABOUR: A GUIDE FOR STUDENTS AND PRACTITIONERS.—By Carlton Oldfield, M.D. (Lond.), F.R.C.S. (Eng.), F.R.C.P. (Lond.). Seventh Edition. Revised. London: Cassell and Company, Ltd. 1929. Pp. XII plus 560, with 8 radiographic plates and 197 illustrations in the text. Price, 16s. net.

THIS book takes one back to student days when no candidate dared sit for examination without a thorough knowledge of Dr. Herman's work, and although during thirty years' popularity much has been added to the science and technique of obstetrics, the clinical fundamental facts of midwifery remain the same. Mr. Oldfield must be congratulated for maintaining and emulating the concise and picturesque literary manner of the original author, and for bringing the book up to date, whilst maintaining many of its dear old classical illustrations which find a place in the heart of all English obstetricians.

Far be it from us to criticise conservative and non-middlesome midwifery, but we would suggest that in the next edition a section should be devoted to the position of Cæsarean section in regard to occipito-posterior presentations, for no incision is made of this. We admit that trial labour has its advocates, but the recent statistics of "failed forceps," collected by Miller, Hendry and Fletcher Shaw which comprise 54 maternal and 332 foetal deaths, make us pause for breath, for the detailed summary of their findings illustrates the fact that 16 of the maternal and 100 of the foetal deaths were due to occipito-posterior positions.

We are of opinion that both in private and in hospital practice these presentations are a source of far more tragedies than is generally recognised. Therefore it is up to professors of obstetrics to teach that Cæsarean section, preferably by the low method of De Lee, is at times indicated, provided the foetal heart sounds are healthy. In these days of limited families if the first baby is in the right occipito-posterior position and born dead, it is not uncommon for the practitioner to cover himself by suggesting that further pregnancy should be avoided, and the psychological effects of birth tend to accentuate the doctor's advice, greatly to the prejudice of humanity.

Every professor in touch with general practitioners will bear out the fact that private patients frequently make these statements, therefore it should be generally known that the lower uterine segment Cæsarean section can be done with safety, even late in labour, and that such a Cæsarean does not mean the necessity of section at the next confinement, for if the pelvis is normal efficient ante-natal care and intra-natal skill will mean easy delivery *per vias naturales*.

We note with regret that Mr. Oldfield gives no detailed description of the low Cæsarean operation of De Lee, although there is hardly a hospital obstetrician throughout the world, who does not perform this operation in preference to the old eversion method described by him on p. 476 in detail. The reviewer up to 1924 having done scores of these eversion Cæsarean sections at the Eden Hospital, Calcutta, in septic or potentially septic cases, with a lamentable maternal mortality, has entirely given it up since seeing Dr. De Lee's operation in Chicago. Eighteen septic cases have been operated upon with 1 maternal death, the wound being drained suprapubically in all cases where the membranes have ruptured, and more than three examinations been made. The experience at the Rotunda Hospital has been the same. We trust therefore that in the next edition due prominence will be given to the virtues of the cervical Cæsarean section, together with an illustrated description.

Another smaller criticism we would make is that the description and illustration of that terrible instrument the Bossi dilator be omitted, and that if for historical reasons the author decides to include the description and picture of Walcher's position, a headline note will be made that he trusts that this method for the use of high forceps will never be put into practice, for surely the most hardened opponents of Cæsarean section are all

agreed that high forceps delivery is to-day almost akin to malpraxis, seeing that the infantile mortality, and maternal morbidity thereafter are outrageous, as compared with Cæsarean section. We are sure that Mr. Oldfield does not use it himself and that he teaches that the high forceps application and Walcher's position are as dead as the Dodo.

These minor criticisms of a clinician should not in the least detract from the general excellence of the book, for which the reviewer has had constant affection for twenty-five years. It is a book that every professor and consultant reveres.

V. B. G-A.

Annual Reports.

SIXTY-FIRST ANNUAL REPORT OF THE DIRECTOR OF PUBLIC HEALTH OF THE UNITED PROVINCES OF AGRA AND OUDH; FOR THE YEAR 1928. BY LIEUT.-COL. C. L. DUNN, C.I.E., D.P.H., I.M.S. ALLAHABAD, SUPDT. GOVT. PRINTING. PRICE, RS. 4.

THIS voluminous report contains a mass of vital statistics, but also much epidemiological information and interesting writing. According to the 1921 census the population concerned is 45,375,787 and the provinces cover an area of 107,167 square miles. Registration of vital statistics is still far from good, though every attempt is made to reform it, even including lectures to mortuary clerks of all *thanas* at *tahsil* headquarters. The birth rate for the year was 38.24 and the death rate 24.15; in other words, there is a steady increase of population in this, the most densely populated part of India, despite diseases and epidemics. The provincial infant mortality was 159.90 for the year. The municipal infantile mortality was 255.81; that in urban areas 252.67 as against a rate of 151.34 in rural areas. This difference seems surprising, but may be due to more careful registration in urban areas, to some extent. One of the greatest difficulties which the Public Health Departments all over India have to contend with is that the fines inflicted for neglect to comply with the registration rules are ludicrously inadequate; thus during the year a total sum of Rs. 1,109 only was realised from 2,294 persons so fined.

Turning to the principal diseases, *cholera* was more prevalent than in 1927; a death rate of 0.99 per mille as against one of 0.62 in the previous year. Anti-cholera inoculations totalled 60,880. The disease was prevalent in 16 districts out of 48. An interesting chart is given showing the periodicity of cholera in the United Provinces; whilst this periodicity is not quite regular, yet marked waves of increased incidence can be noted on it every third or fourth year. Infection appears to be imported in connection with every outbreak recorded. The relative failure of the monsoon was the chief contributory cause for the increased prevalence of cholera during the year; and the department had a very heavy year's work in connection with this disease.

Smallpox, on the other hand, was less prevalent, a death rate of 0.07 as against one of 0.17 for the previous year. *Plague* accounted for a death rate of 1.78 as against the quinquennial average of 1.11. Muzaffarnagar and Ghazipur districts were chiefly concerned. The death rate from *fevers* was 16.88, as against the quinquennial rate of 18.77. The Anti-tuberculosis League at Lucknow is doing good work, whilst Dr. Sousa carried out an investigation into the prevalence of tuberculosis in the schools in Lucknow. He also found Almora, a most popular hill station, to be badly infected. *Dysentery* and *diarrhoea* gave a provincial death rate of 0.29, the maximum being in May; *respiratory diseases* were responsible for a death rate of 0.75 as against a quinquennial average of 0.61. It is probable that the reported returns for dysentery, kala-azar and pneumonia are much below the

actuals, and those for malaria, smallpox, plague and relapsing fever are in excess. A table for nine years' verification of mortality returns shows that only cholera, smallpox, and plague are reported by the village chaukidars with any degree of certainty.

Section VII of the report gives a triennial review of vaccination in the provinces from 1926 to 1929. There were 3 officers in charge of ranges and 50 assistant superintendents of vaccination on duty. The average annual number of vaccinations works out at 1,484,111. Success is attained in 94 per cent. of primary vaccinations, and 52 per cent. of re-vaccinations. A most interesting diagram shows the relative proportion per 10,000 persons in each district of the deaths from smallpox to the number of persons protected by vaccination. This shows wide variations in different districts. It is proposed to make vaccination compulsory in the rural areas, and a Bill to this effect is before the Legislative Council.

Section IX shows that regular bacteriological and chemical examination of water supplies is carried on throughout the provinces. The new Provincial Hygiene Institute was officially opened by H. E. the Governor on December 8th, 1928.

Dr. A. N. Goyle continued to carry out research work on plague under the Indian Research Fund Association. The conditions under which plague "carries over" from one epidemic season to another appear to be diverse. In very humid localities, such as Ballia and Azimgarh, fleas on rats will remain more numerous, and the chances of successful carrying over be greater. A much larger number of villages carry over in the western districts where the climate is more humid, than in the drier eastern districts. Villages infected late in the season are much more apt to carry over than those infected earlier. A carry over in a very small number of villages is sufficient to establish widespread epidemic conditions in the next epidemic season by importation of the infection.

The cholera research enquiry under the Indian Research Fund Association was brought to a conclusion during the year. Colonel Dunn is no believer in the hypothesis of the conversion of the non-agglutinating into the agglutinating vibrio; the whole of the evidence in the United Provinces is that every outbreak begins with a fresh importation of infection. Hardwar is often blamed as being an epidemic focus of cholera; this is not true; the infection is always imported, whilst under favourable conditions the true cholera vibrio may live for a week or even longer in Ganges water.

A special activity of the department during the year was the preparation of cinema films on health matters for propaganda purposes, and copies of these were sent to the League of Nations' Health Section by request. A public health exhibition was also held at King George's Medical College, Lucknow, in January 1928, in connection with the visit of the League of Nations' interchange of health officers.

Three post-graduate courses of instruction in malariology were given during the year, and 30 officers trained for this work. Anti-malarial investigation was continued in the Terai, and recommendations carried out. (This most important work in so notorious a malaria area was first begun some years ago by Lieut.-Col. J. A. S. Phillips, I.M.S.; nothing with regard to it has been published in the journals; but the results are beginning to tell.) The Sarda Canal is also another important area where full malaria control is in force. Experimental schemes are being tested out in rural areas, such as the use of larvæ-eating fish, free distribution of cinchona febrifuge, and even utilizing the services of the Seva Samiti boy scouts to help in anti-malaria campaigns. Clover and cactus are both under trial; also the issue of cinchona febrifuge to febrile children in schools, and the treatment of village tanks. Malaria surveys were carried out in ten rural areas and five urban areas. Quinine pills were tested. It is true that much of this big and successful organisation's results are not published; but on the other hand, financial grants can sometimes be

obtained for schemes for "general sanitary improvement," whereas grants for specific anti-malarial measures might be refused.

Plague.—Plague was responsible for 80,943 deaths during the year, a very marked increase on the four previous years; though almost insignificant when compared with the 1905, 1907, and 1911 epidemic years. Evacuation is the most popular measure; but the lesson needs to be driven in that evacuation should begin at the first sign of rat mortality, and not be delayed until the super-imposed human epidemic has set in. Anti-rat campaigns were on trial in twelve municipalities and five towns; the Hindu opposition to this measure has entirely ceased. Travelling dispensaries, readily mobilised, are reported to be very valuable in the campaign against plague.

Hygiene propaganda is the subject of a special department; and has been very vigorously carried on during the year. The district health service was extended to the Naini Tal area; it has now acquired the status of popularity and requests for its installation in further areas are noted. Pp. 60 to 65 of the report record the unanimous approval of deputy commissioners and others on this organisation, and the value of its work. A village aid scheme for rural villages was instituted in August, 1928. Model villages are being constructed in Gonda district. In all 751 applications were made for sanitary schemes in notified areas, estimated to cost Rs. 9,00,000; in reply water-supply schemes received priority, and a total sum of Rs. 71,743 was allotted. The Provincial Village Sanitation Act was extended to 85 villages during the year, and is now in force in 768 villages in all.

A detailed report of the work in different districts follows. The work of the Public Analyst has increased from 77 specimens in the year 1915 to 1,938 in 1928; this department is now housed in the chemistry department of the Lucknow University, but further accommodation will certainly be wanted. Maternity and child-welfare work was active throughout the year in all parts of the provinces. Pp. 116 to 118 deal with the result of medical inspection of schools.

The report also includes the Thirty-Fourth Annual Report of the Superintending Engineer, Public Health Department, United Provinces for the year 1928-29.

There is a wealth of statistical and epidemiological information in this report which will be of importance to public health workers in India. Its chief feature, however, is to emphasize—unconsciously—how widespread and energetic is public health work in the United Provinces.

ANNUAL REPORT ON THE ADMINISTRATION OF JAILS OF THE BENGAL PRESIDENCY, 1928. BY LIEUT.-COL. W. G. HAMILTON, I.M.S., CALCUTTA, BENGAL SECRETARIAT BOOK DEPOT. PRICE, RS. 13-2-0.

We regret that this is Colonel Hamilton's last annual report, as he has recently gone on leave prior to retirement. His interest in jail problems has always been intense; he has introduced many much-needed reforms in Bengal; whilst his whole attitude towards the prisoner population has always been that of a physician and a student of penology. Above and beyond all, his constant efforts towards getting short-term sentences done away with, towards the organisation of After-care Associations, and towards a Children's Act and a Borstal scheme, are notable.

This report is in itself so much by way of a summary, that we may abstract from it, rather than attempt to review it.

"The principal event affecting the Jail Department in 1928, was the improvement of pay of the warder staff. This was long overdue and I am very grateful for the liberal increase sanctioned by Government and voted by the Legislative Council in August. Warders now receive the same pay as the Armed Police, the substantial rise of Rs. 6 per mensem should now attract a better type

of recruit. I regret to say that the housing conditions of the warders are deplorable, the barracks are ill-ventilated and there is overcrowding in all warders' barracks. New quarters are essential, but I fear that funds will not be available as long as the present financial condition of the Presidency continues. The number of family quarters for warders is quite inadequate, a minimum of 33 per cent. should eventually be provided for.

The Borstal Act came into force on January 1st, 1928, but magistrates have not availed themselves of this valuable alternative to imprisonment as much as had been hoped for. They still apparently prefer to send lads to prison with short terms of imprisonment, rather than give them the benefit of a long training in the Borstal School; it is mistaken kindness to give short sentences of imprisonment, as it usually means that a lad becomes a criminal for life if he once has the misfortune to undergo a term of imprisonment, and mix with confirmed malefactors. The Borstal Institution at Bankura has made some progress during the year, the results of the educational classes have been very hopeful, the District Inspector of Schools gave a satisfactory report at his first inspection. Technical training in carpentry, book-binding, smithy works, weaving and tailoring is carried out and the inmates have turned out some useful work. They now make their own clothing and the institution will supply all jails in Bengal with galvanised iron buckets. Government recently sanctioned rules for the management and control of the institution and a Visiting Committee has been appointed. The grade system has been started, and it is hoped that it will prove a success. Well behaved lads now play football and hockey outside the institution walls. Government have sanctioned the construction of a new playground for the institution; the work will be carried out by the inmates. Route marches have been started in the neighbourhood of the school. The newly conceded privileges have so far not been abused.

The success of the Borstal system largely depends on an effective After-care Association which will look after the interests of the discharged inmates. The Bengal After-care Association for Juveniles and Adolescents has done good work since it was founded in March, 1928; the Association is fortunate in having the Chief Justice of Bengal, the Hon'ble Sir George Rankin, as its President; he is supported by an energetic executive committee of leading Indian and European ladies and gentlemen. After-care work deserves generous support from the public. In this connection it is interesting to read the remarks of Sir Ernest Wild, K.C., Recorder of London, at the Central Criminal Court on March 1st, 1929: "I know the difficulty of discharged prisoners getting work, but we cannot blame the After-care Societies. The whole blame rests on the community. If they would only recognise that the money is well spent and is a good insurance against crime, and would subscribe more, better chances would be given to discharged prisoners and less crime would be committed." A successful district After-care Association has been started in the district of Tippera; it has been able to get the co-operation of the Union Boards as recommended by the Pearson Committee. Dacca and Mymensingh districts have also started after-care work. I hope in time every district in Bengal will follow suit. I am convinced that the surest way to reduce the population of our prisons is to treat juvenile delinquency on rational lines and provide efficient after-care during the critical period after discharge from reformatories, Borstal institutions or prisons.

It is very unfortunate that the Bengal Children Act, 1922, is still not in force outside Calcutta; young children are sent to jail for trivial offences in every district; it is to be hoped that it will be possible to provide funds to extend the Act over the whole Presidency. Remand homes and certified schools under the Act will have to be provided, but the ultimate benefits should more than justify the extra expense.

Lunatics.—The question of providing accommodation for lunatics in Bengal has been a serious problem during

the past year. The Indian Mental Hospital, Kanke, near Ranchi, which takes in lunatics from Bengal, is grossly over-crowded and it has been impossible to find accommodation for certified lunatics in that institution. The result is that many dangerous and troublesome lunatics have had to be kept in various jails. The number of separate cells is notoriously inadequate in the jails of Bengal for disciplinary purposes; at the present time they are mostly occupied by certified lunatics, both non-criminal and criminal, and by confessing under-trial prisoners; the Superintendents are, therefore, deprived from using them for their intended purpose. Jails are obviously unsuitable places for treating mental diseases; there is no skilled attendance or nursing available, and the results on the unfortunate patients must be very detrimental to their chance of recovery. The practice of sending non-criminal lunatics to jail for observation or treatment is quite indefensible; this system was severely criticised by the Indian Jails Committee, 1920, in their report; unfortunately the position is worse now than previously, owing to lack of sufficient accommodation at the Indian Mental Hospital.

An expert alienist is needed in the Jail Department who could give advice on the many questions which occur in connection with weak-minded and insane inmates of our jails.

Weak-minded prisoners.—There is a considerable number of prisoners in jails who are a trouble to the authorities and to themselves; they are not insane enough to be certified as lunatics, but are mentally defective and not wholly responsible for their actions. They are constantly getting into trouble for short work or for frequent breaches of jail discipline; they are exploited by bad character prisoners for their own ends. They were scattered in small numbers in most jails. I have concentrated them all in one place where they can be observed and treated on suitable lines. They are now confined in Berhampore Jail; cases suitable for transfer must be personally certified by the medical officer of the jail before they can be admitted to Berhampore.

Leper prisoners.—I am glad to report that funds have been allotted for the extension of the Leper Jail at Midnapore. Of late years the number of leper prisoners has increased and the accommodation at Midnapore Central Jail was quite inadequate. I hope the work will be completed within a few months' time and all lepers awaiting accommodation in other jails will be transferred to Midnapore.

Short-term prisoners.—The problem of the short-term prisoner still remains unsolved; the remarks I made in my last report still hold good. The Presidency Jail is the principal sufferer; a very large number of people arrested on "suspicion" under section 54, Criminal Procedure Code, are sent to this jail. Long detentions in hajat for trivial offences are too many, especially in the mufassal. I recently had reported to me the case of a youth who was charged with travelling without a railway ticket; his case was not to be taken up until after he had been in jail for eight days; he had never been in jail before and was thus brought into contact with bad characters with the possibility of becoming a confirmed criminal.

In this connection I would mention that Union Boards committed 11 persons to jail in 1928 with sentences ranging from 3 days' simple imprisonment to 7 days' rigorous imprisonment. This number will probably go up in time. I need hardly stress the undesirability of such short sentences and their most injurious effect on the persons concerned. Such sentences are contrary to the recommendation of the Indian Jails Committee, made in paragraph 444 of their report to the effect that sentences of imprisonment under 28 days should be prohibited. The possibility of introducing a system of labour in lieu of imprisonment similar to that in force in Egypt, as described in paragraph 444A of the above report, might be considered for such cases.

Classification and separation of prisoners.—Owing to the obsolete construction of most jails in Bengal, it is impossible to properly segregate various classes of prisoners from each other. Advanced schemes of reformation have been possible in the prisons of the

United Kingdom and other countries by completely segregating first offenders and "star" class prisoners from habitual criminals. As long as the convict officer system on its present lines is in force, I do not see how a strictly class system can be introduced in most jails in Bengal, but a proposal has been put up to Government for converting one central jail into an habitual jail, where all well known bad characters and recidivists could be concentrated. I hope it will be possible to find money for this important reform as soon as possible.

Difficulty of securing orders from Government departments.—I wish to bring to the notice of Government the difficulty of securing orders from Government departments for the Jail Department. It is only with the greatest difficulty that we can secure work to keep the prisoners suitably employed throughout the year. The Jail Department is in a position to supply textile goods, blankets, furniture, durries, etc., to the various consuming departments of Government, but in many cases orders are given to outside contractors for articles at higher prices than those quoted by the Jail Department. If the quality of articles tendered by the Jail Department is as good as that of private contractors, and the price is not higher, I think the Jail Department should be given the preference.

The Jail Department has in some cases got contracts from the East Indian Railway, Eastern Bengal Railway and Bengal-Nagpur Railway, but in several instances large orders have been given to contractors for articles at a greater cost than those quoted by the Jail Department. I know that railways are under no obligation to obtain goods from jails, but provided that the price is not higher and the quality not inferior, and that the Jail Department is in a position to fulfil the contract in due time, I think Government railways should support the Jail Department if possible.

As recommended in paragraph 59 of the Indian Jails Committee's Report, 1919-20, a recreation room for the jail staff should be provided in each jail, and Government should sanction a grant for the purpose annually. Arrangements for recreation should also be made for prisoners as recommended by the Indian Jails Committee in paragraph 275 of their Report. Lectures and lantern demonstrations on instructional subjects should be provided for good-conduct prisoners. The Inspector-General should be empowered to incur an expenditure not exceeding Rs. 25 per jail per annum on the purchase of magic lantern slides, as in Madras. Besides being instructive, this should have some effect on the reformation of prisoners.

Another important need is a juvenile jail for the confinement of juvenile and adolescent prisoners who are not sent to Reformatory and Industrial Schools and the Borstal School, or who are not fit for these institutions. As recommended by the Bengal Jails Enquiry Committee, 1927, a permanent juvenile jail should be started in the site of the old Mental Hospital at Dacca as early as possible.

The experimental scheme of primary education for young prisoners in Alipore Central Jail has continued to be a success, and Government have sanctioned money to continue the classes for the coming financial year.

In my opinion these classes should be introduced into all central jails for prisoners under 25 years of age.

The young Indian prisoner has been found very anxious to learn the elements of reading, writing and arithmetic. I consider education to be the most reformative influence in a jail. It has been found that offences against discipline have greatly diminished amongst young prisoners attending educational classes.

Advisory Boards for the premature release of prisoners eligible under the rules were held half-yearly in each of the five Central Jails. One hundred and sixty-five prisoners were brought before the Boards; of this number 103 were recommended for release, cases of 62 prisoners were rejected or deferred. Government eventually released 93 of those recommended.

Judicial statistics.—The following table shows the number of prisoners of all classes who passed through the jails and subsidiary jails of this Presidency during the year as compared with the previous year:—

Class of prisoners.	REMAINED ON 1ST JANUARY—				RECEIVED DURING THE YEAR INCLUDING DIRECT ADMISSIONS AND TRANSFERS.			
	1927.		1928.		1927.		1928.	
	Male.	Female.	Male.	Female.	Male.	Female.	Male.	Female.

Total ..	13,247	133	13,733	144	13,398.42	137.71	13,863.72	141.18
GRAND TOTAL	13,380		135		13,536.13		14,004.90	

There has been a substantial increase in the daily average population during the year under report as compared with the previous year.

The number of convicts on the 1st January was 10,916, against 10,368 in 1927; 22,354 were imprisoned during the year 1928 against 23,970 in the previous year, and 531 were received by transfer from other provinces.

The average number of European prisoners was 32.97 against 30.03 during the previous year.

Religion.—Of the 22,354 convicts admitted during the year, 56.20 per cent. were Muhammadans, 39.95 per cent. Hindus, 0.89 per cent. Christians, 2.00 per cent. Buddhists and Jains; 0.96 per cent. belonging to all other classes.

Age.—The number of convicts of less than 16 years of age admitted was 75 (72 males and 3 females) or 0.34 per cent. of the total of all classes of convicts, against 335 or 1.40 per cent. in 1927. Of these 13 boys were received direct at the Juvenile Jail, while 30 were admitted from the various sub-jails and 32 from central and district jails.

It is satisfactory to note that there has been a considerable fall in the admission of juvenile prisoners during the year under report as compared with the figures of the preceding 3 years which stood at 335, 240 and 128 respectively. The operation of the Bengal Children Act is partly responsible for this decline. The committing courts are to be congratulated on this good result and it is hoped that there will be a rapid decline in the admission of juvenile prisoners to jails with the extension of the Bengal Children Act to all districts.

Education.—The number of convicts able to read and write was 9.78 per cent., able to read only 2.72 per cent., and illiterate 87.50 per cent.

Of the 22,354 convicts imprisoned during the year, 27.27 per cent. had sentences not exceeding one month, against 30.07 per cent. in the previous year, 25.70 per cent. over one month and not exceeding three months, 17.12 per cent. over three months and not exceeding six months, 16.01 per cent. over six months and not exceeding one year, and 13.38 per cent. over one year; 0.45 per cent. were sentenced to transportation for life and term and 0.07 per cent. were sentenced to death. Two thousand, four hundred and eighty-seven were sentenced to simple imprisonment, 19,850 to rigorous imprisonment, 14 to rigorous imprisonment with solitary confinement, and 3 to rigorous imprisonment with whipping.

The percentage of prisoners with sentences not exceeding one month shows a decrease as compared with the previous year, but it is still far too high.

State prisoners.—The number remaining at the beginning of the year was 1 and 8 were received during the year, either direct or by transfer from other jails, making a total of 9. Of these 7 were released or transferred, leaving a balance of 2 at the close of the year. There were no escapes or deaths among these prisoners. The daily average number for the year was 2.21. These prisoners are treated in accordance with the rules specially made by Government for their treatment.

Detenus.—This class of prisoners was detained under the provisions of the Bengal Criminal Law Amendment Act, 1925. Under the orders of Government they are excluded from jail statistics. There was no such prisoner at the end of the year confined in the jails of Bengal.

Subsidiary Jails.—The number of sub-jails in the Presidency was reduced from 63 to 62 during the year under report, due to the abolition of the Shazadpur sub-jail, with effect from 1st January, 1929.

Warder Guard.—The number of punishments inflicted on warders was 1,055 against 1,188 in the previous year. Of the punishments inflicted departmentally, the number of dismissals was 52, degradation or suspension 25, fines 469, extra drill 209, and censures or other punishments 300.

The number of punishments inflicted on warders during the part year shows an appreciable decrease as compared with the previous year.

The fall in the number of punishments may be due to the improvement of the morale of the warder force owing to improvement of their pay and prospects.

The long-standing grievance of the warder establishment has been removed by the grant of increased rates of pay on a liberal scale, with effect from 1st November, 1928, and this has been much appreciated by the warder guard in general. It is hoped that the revised pay will attract a better class of recruits for jail service.

The provision of an adequate number of family quarters for warders will make the service more attractive.

Escapes and recaptures.—During the year there were 11 escapes among convicts, 5 from inside and 6 from outside the jails; 4 of them were recaptured before the close of the year.

Out of the daily average population of 11,021.42 male and 105.62 female convicts, an average of 724.73 or 6.57 per cent. male and 4.19 or 3.96 per cent. female convict officers were employed during the year.

As in the previous year difficulty was experienced in finding suitable men for employment as convict officers. Most of the men promoted to convict officers' rank were not eligible under the rules and had to be promoted as special cases.

The number of convicts released under the remission rules was 5,637, against 5,703 in the previous year.

Forty-seven convicts were released during the year who came under the remission rules, but failed to gain any remission, against 27 in the previous year. The remission system worked well and is appreciated by the prisoners. It is an incentive to convicts for doing good work and to be of good behaviour.

Claude Martin Fund.—A sum of Rs. 3,000 was received from the Commissioner of Police, Calcutta, out of the fund during the year under report for distribution among released prisoners.

The number of prisoners who received benefit from the fund was 2,121 against 2,444 in the previous year. The maximum amount received by a prisoner was Rs. 10, the same as in the previous year.

Financial.—The cost of guarding and maintaining prisoners in jails and subsidiary jails of this Presidency, including the cost of general supervision, amounted to Rs. 25,55,477 against Rs. 25,09,958 in 1927.

Presidency Jail.—The jail has a large workshop and some minor industries such as durrie, oil-pressing, printing of forms and jail also carries out the distribution of quinine treatments and cinchona products.

Alipore Central Jail.—The principal industries of the jail during the year were mustard oil-pressing, cane and bamboo works, and carpentry. The net profit during the year amounted to Rs. 6,920.

Midnapore Central Jail.—The principal industry of the jail during 1928 was tailoring of police uniforms. The minor industries included weaving of prison cloth, durrries, ashmis, dosuti cloth, duster cloth, bandage cloth, garrahi cloth, gamchhas, towels, purdahs, etc., mostly required by the jail depot; also cane work and mustard oil-pressing. A daily average of 405 prisoners were employed on manufactures. Police uniforms to the value of Rs. 1,19,824 were supplied during the year. Large orders for police uniforms were received from different districts in the Presidency and most of them were complied with during the year.

Rajshahi Central Jail.—The principal industry of the jail during 1928 was weaving of prison cloth and tailoring. The minor industries were mustard oil-pressing, durrie and ashmi-weaving, cane and bamboo work, wheat-grinding, carpentry and smithy. The net profit during the year was Rs. 80,049.

Dacca Central Jail.—The principal industries of the jail during the year were blanket-weaving, tailoring of chaukidari, dafadari, excise and warders' uniforms, prison clothing and cloth-weaving (including durrie and carpet). The minor industries were mustard oil-pressing, cane and bamboo works, carpentry, wheat-grinding and smithy. The daily average number of convicts under sentence of labour was 1,220 and the number employed on manufactures was 702.

Sickness and mortality.—The following table shows the average number of prisoners, the ratio per mille of admissions to hospital, the daily average number of sick and the number of deaths among all classes during the past five years:—

Year.	Daily average number of prisoners of all classes.	Admissions into hospital.		Daily average number of sick of all classes.		Deaths from all causes of all classes of all prisoners.	
		Number of admissions.	Ratio per mille.	Daily average sick.	Ratio per mille.	Total number of deaths.	Ratio per mille.
1923...	13,734	15,751	1,146.8	577.31	42.0	207	15.0
1924...	13,477	14,993	1,112.5	521.43	38.6	226	16.7
1925..	12,653	12,091	955.5	430.77	34.0	165	13.0
1926..	12,772	11,737	918.9	402.17	31.4	175	13.7
1927..	13,536	12,952	56.8	439.73	32.4	197	14.5
1928..	14,005	12,332	880.5	416.04	29.7	190	13.5

The following table shows the deaths and admissions from the chief diseases among convicts in 1928.

	1927		1928	
	Admissions.	Deaths.	Admissions.	Deaths.

Correspondence.

GONORRHOEA AND ITS TREATMENT WITH "ACRIFLAVIN."

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The writer has for some time been seeking a cheap, yet efficacious, drug for the treatment of gonorrhœa. The patients who seek treatment for this disease are numerous and can ill afford treatment involving much expense. To meet the situation I have selected "Acriflavin" (Boots), Euflavin and Tryflavin. I have tried these preparations in a dozen of my patients; the results were roughly as under:—

All these preparations are administered intravenously under strict aseptic measures. A dose of gr. 1 dissolved in 5 c.c. of double distilled water is given as the initial dose; this is gradually increased up to 1.75 grains.

The maximum number of injections so given is 10 to 12, administered bi-weekly. Though it has been recommended by some that the total number of such injections be continued up to 15, it is my practice to abandon the treatment if the first four or five injections do not produce a response.

Eight persons, all males, having a gonorrhœal discharge were treated first. In 5 patients there was a decided improvement after 6 injections. In 3 patients improvement was noticed after 4 injections and continued up to 10 injections. In another 3 persons, with 6 to 7 injections, urethral discharge and other distressing symptoms totally subsided and they appeared to have been cured.

In some of the patients who resisted treatment as far as urethral discharge is concerned, the injections were supplemented by urethral injection or irrigation of "Acriflavin" 1 in 1,000. This brought about an apparent cure within a very short time. In the single case of a female having a copious discharge and burning pain, a marvellous result was provided after a course of four injections; both the discharge and the burning pain stopped.

In brief, the results obtained are undoubtedly encouraging.—Yours, etc.,

S. P., L.M.F. (Cal.),
Medical Officer,

PIPLI,
5th October, 1929.

NEW CONCEPTIONS OF SCIATIC PAIN AND ITS TREATMENT.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The paper by Major Hance, I.M.S., and his collaborators on "New Conceptions of Sciatic Pain and its Treatment" is of considerable interest to radiologists, as such cases are frequently passed on to them for treatment.

The bulk of the material included dealing with the admirable work of Professor Putti on the subject is already known to many of us, and calls for no comment. It is fairly generally recognized that the majority of cases of so-called "idiopathic" neuritis are of arthritic origin, the causative factor usually being focal sepsis. In the case of a sciatic neuritis, the appearances described by Professor Putti of an arthritis of the lumbar intervertebral joints, with effusion of inflammatory exudates, destruction of cartilage, and, in some cases, ankylosis, causing pressure on the funiculus at the intervertebral foramen, are constantly observed by radiologists.

It is at Major Hance's statement to the effect that he has not been able to find any but the scantiest reference to electrical treatment for this condition, that I am amazed! If Major Hance will refer to Dr. E. P. Cumberbatch's *Essentials of Medical Electricity*, and to the same author's *Diathermy*, he will find details of the treatment given.

It has been my routine treatment, both at the Medical College, Calcutta, and in private, for the last five years, to give diathermy to all acute cases of sciatica. At first I used to apply one electrode to the painful part, and another opposite, but since reading Professor Putti's paper, I have also heated up the lumbo-sacral region on the side involved.

In some cases I have used a single large electrode on the abdomen and overlapping the groin as one pole, and two smaller ones both connected to the opposite pole. One of these is placed on the lumbo-sacral region on the involved side, and the other on the painful sciatic nerve. The total area of these two electrodes is very much less than that of the large abdominal one.

As regards the galvanism given by Major Hance on alternate days with diathermy, I prefer to use this when the acute stage has passed. It may be given either in Schnée baths, or with pads soaked in saline. Major Hance has startled me by his statement that he uses the negative pole on the painful part. He will find his results will be very much improved if he uses the positive pole here, and the negative pole, in the form of an indifferent electrode, elsewhere, e.g., on the abdomen.

A routine investigation and treatment of such cases could be summarized as follows:—

1. Investigation of cause.—

(a) Examination generally.

(b) Examination of the spine and pelvis, the latter including a rectal examination.

(c) Radiography in both positions—(posterior and lateral) of the lumbo-sacral region.

Radiography of the pelvis; radiography of the teeth; radiography of the accessory nasal sinuses.

(d) Examination of the fauces.

(e) Examination of the stools, especially if there is any history of bowel irregularity.

(f) Examination of the urine.

(g) In doubtful cases a Wassermann reaction should be done.

2. *Treatment.*—

(a) *General.* Where possible the cause should be eliminated, e.g., by the removal of septic teeth or tonsils. Vaccines in the case of bowel infections, etc. Rest in bed is essential while the pain is at all severe, and all exercise should be, as far as possible, cut out while there is any pain at all.

(b) *Drugs.* Aspirin and Veramon are of value. In very severe cases morphia may be needed to control the pain.

(c) *Electrical.* Diathermy should be given every day as described. The treatment should last twenty minutes, excluding two minutes or so to get up to maximum; in diathermy there is no need to spend five minutes in doing this, and there even less need in spending five minutes in coming down to zero. It is in galvanism that this need arises. The amount of current shown on the milli-ampéremeter will vary with the size of the electrodes used; it may be anything between 500 and 3,000 milli-ampères, or more. The main thing is to heat to the maximum of the patient's tolerance, and to heat evenly.

When the acuteness of the attack has passed off, galvanic current is used, either in Schéne baths, or with pads soaked in 1 per cent. saline. The positive pole should be used on the painful part, and the current raised to maximum and lowered very slowly, taking five minutes each way. The total duration of the treatment should not exceed half an hour. In some cases salicylate ionization is of value, and in such cases the negative is the active pole.

Ultra-violet irradiation, both general and local, taken together with galvanism and diathermy, has a markedly beneficial effect, and shortens the time of convalescence.

When the pain subsides, exercise should be taken very gradually. The galvanism should be kept up three times, and later twice weekly, till the patient is quite well.

I am glad to say that I have not yet had a case that has failed to respond to treatment on the lines indicated.—Yours, etc.,

G. GALSTAUN, M.A., D.M.R.E., M.R.C.S., L.R.C.P.,
Hon. Radiologist, Medical College Hospitals.

CALCUTTA,

ALUMINIUM UTENSILS AND TUBERCULOSIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—There is a common belief in the rural area among laymen that the use of aluminium utensils gives rise to tuberculosis. I have not seen any literature, or any article in your esteemed journal regarding the use of such utensils—therefore will you or any of your learned readers throw light on this subject.—Yours, etc.,

IKRAWD DUJABBASI (IKRAM-UD-DIN).

Medical Officer,

In-charge Dispensary,

MAHATPUR,
DIST. JULLUNDUR,
PUNJAB,
8th October, 1929.

(Note.—We know of no ground for such a belief, except that possibly aluminium utensils are not scoured as bright as brass ones and might therefore harbour tubercle bacilli. This would of course only apply to utensils that are used for eating out of—not to those that are used for cooking.—EDITOR, I. M. G.)

A CASE FOR DIAGNOSIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the case which appeared in the September issue of your paper for diagnosis, I suggest that the case is one of arterio-venous aneurysm between the internal carotid artery, and the internal jugular vein of the right side, just below the superior bulb of the vein. The loud bruit is conducted through the mastoid. (or petrous) part of the temporal bone to the internal ear

to be heard as the "chirping of the birds." The same bruit is heard by the patient's guardians when they apply their ear and also by the doctor through his stethoscope. The sound is conducted to the occiput and the temporal region of the other side through the lateral sinuses. As regards the cause of this aneurysm, only this much can be suggested, that (in the absence of any history of trauma or of any previous aneurysm of the internal carotid artery) there may have been some inflammation about the region of the superior bulb of the vein leading to the formation of adhesion between the artery and the vein. I think other signs and symptoms are only superimposed.—Yours, etc.,

UMA PADA MUKHERJEE,
Carmichael Medical College, Calcutta.

24th October, 1929.

BOGUS "M.D.s."

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Cannot anything be done to check one of the gravest abuses in the lay press of to-day? I refer to articles—advertisements would be better term—published in lay newspapers over the bogus signature "M.D." I have seen a considerable number of cases where laymen have read such articles, recommending some non-ethical line of treatment, and have transferred their treatment from that given by registered medical practitioners to bogus "M.D.s." The results are frequently disastrous.

A personal friend of mine had a son who developed tuberculous arthritis of the knee joint. He read such an article in the lay press advocating some special "nature cure." He finally came to me with the patient in a hopeless condition, which ended in a fatal issue. I could quote further examples.

It is the title "M.D." in such articles that misleads the public. Cannot the Medical Councils of India do something to check this evil?—Yours, etc.,

C. H. KARNIK, L.C.P.S.

CIVIL HOSPITAL,
SAWANTWADI, via BELGAUM,
BOMBAY PRESIDENCY,
10th October, 1929.

(Note.—Our correspondent raises what is undoubtedly a serious issue. As long as the Indian public remains as uneducated in medical matters as is now the case, so long will it remain credulous; the same indeed may be said even of the educated public of Great Britain.

The Medical Councils are in a difficult position. They can only take action upon specific information lodged and definite evidence produced. Such proceedings would probably lead to litigation; whilst the vague use of the 'qualification' "M.D.," without any indication of the university at which the advertiser obtained this diploma, whilst a legal offence, presumably, would be one which it would be difficult to run to earth. The best solution of all, of course, would be to so educate the general public that they would realize that the vague term "M.D.," without any indication of the university from which the degree was granted means nothing. A second solution would be action by Government; but the evils of quackery in India are so widespread that very extensive legislation would be called for to check them effectively—something on the lines prevalent in the United States, where, if fraudulent medical advertisements are being sent through the post, they are opened, marked "Fraudulent," and returned to the sender.

A third solution would be for the lay newspapers concerned to look up the official medical directories concerned, and ascertain whether the "M.D." is or is not an M.D. of a recognized university and belongs to a registered medical practitioner, before publishing the letters or articles concerned. We are afraid however that journalism would hesitate before adopting such an altruistic attitude.—EDITOR, I. M. G.)

THE STERILIZATION OF HYPODERMIC SYRINGES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the correspondence in your columns with regard to the sterilization of hypodermic syringes, we beg to state that in our experience 90 per cent. Spiritus Rectificatus is the best, most rapid, and easiest method for sterilizing all types of syringes. We have given some few thousands of subcutaneous, intramuscular, and even intravenous injections with syringes sterilized in this manner, and have never seen abscess formation or any other trouble follow. The method is as follows:—

Spiritus Rectificatus, 90 per cent., is carried in a small stoppered phial. After fitting the needle to the syringe a sufficient quantity of spirit is drawn into the syringe, and then ejected back into the phial. This is repeated five or six times. Finally, the whole needle and the adjoining part of the barrel of the syringe is dipped into the spirit, and the piston once. The spirit is then allowed to dry before the syringe is filled with the solution to be injected. After the injection the syringe is cleaned with water, and its parts replaced in its case.

We have frequently used the same syringe to give a series of injections to a number of patients, one after another, at the same time, using only this simple mode of sterilization, without seeing any subsequent harmful results.—Yours, etc.,

K. P. SARKAR,
P. B. SIRCAR,
Medical Officers.

THE TREATMENT OF VAGINISMUS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the recent correspondence in your columns on this subject, it should be pointed out that complete investigation of the conditions underlying it is only possible when the patient is fully anaesthetised. Under such conditions local lesions are not infrequently discovered, the most common being red spots and patches at the urethral meatus and in the vulva just outside the hymen or its remains. Sometimes one or more of the carunculae myrtiliformes show similar red patches, with increased vascularity and round celled infiltration of the corium. In other cases small fissures or excoriations may be present at the entrance to the vagina. Occasionally, a more remote cause may be present, such as vaginitis, a prolapsed ovary, or a fissure of the anus.

Opinions differ widely as to the essential cause of the spasm. Its treatment calls for much patience and tact. The best method is probably forcible digital dilatation of the vulva under an anaesthetic, followed by the daily passage of vaginal dilators. A 10 per cent. solution of cocaine is first applied to the vulva, and a 1¼" bougie is passed, fixed in position with a T bandage, and retained for two hours. By the fourth or fifth day a 5½" bougie can be passed, and by gradual steps a 1" bougie can be used daily for two or three days. The series can then be repeated without the use of a local anaesthetic. If there is any slight spasm or discomfort, a weak solution of glycerine and carbolic acid may be applied.

The essential point in treatment is not to cause the slightest pain during the insertion of bougies, to gain the patient's confidence, and not to hasten matters. From eight to twelve weeks may be needed. When a 1" bougie can be passed without any local anaesthetic, or glycerine-carbolic acid, the condition is usually completely cured.—Yours, etc.,

SHAILENDRA MUKHERJI,
Medical Practitioner.

BOALIA, KALUPOT P. O.,
NADIA DISTRICT,

Service Notes.

APPOINTMENTS AND TRANSFERS.

LIEUTENANT-COLONEL H. W. ILLIUS, F.R.C.S.E., C.I.E., I.M.S., Officiating Inspector-General of Civil Hospitals, United Provinces, to be President of the United Provinces Medical Council, *vice* Colonel C. A. Sprawson, M.D., F.R.C.P., C.I.E., I.M.S., resigned from 16th July, 1929.

Lieutenant-Colonel J. R. J. Tyrrell, I.M.S., an Agency Surgeon, on return from leave, is posted as Chief Medical Officer in Central India and Residency Surgeon, Indore, with effect from the 22nd September, 1929.

Lieutenant-Colonel R. F. D. MacGregor, M.C., I.M.S., an Agency Surgeon, on return from leave, is posted as Residency Surgeon and Chief Medical Officer, Baluchistan, *vice* Lieutenant-Colonel J. Husband, I.M.S., reverted from the cadre of Agency Surgeons under the Government of India in the Foreign and Political Department, with effect from the 16th September, 1929.

Lieutenant-Colonel W. J. Simpson, I.M.S., an Agency Surgeon, is posted as Agency Surgeon in Bhopal, with effect from the 22nd September, 1929.

On return from leave, the services of Lieutenant-Colonel H. G. Stiles-Webb, I.M.S., are replaced at the disposal of the Army Department.

Lieutenant-Colonel H. R. Nutt, I.M.S., Civil Surgeon, on return from leave, to Allahabad.

Lieutenant-Colonel J. F. Boyd, I.M.S., Civil Surgeon, on return from leave, to Aligarh.

Major H. Williamson, O.B.E., I.M.S., is appointed to officiate as an Agency Surgeon and is posted as Civil Surgeon, Sibi, with effect from the 28th August, 1929.

Major E. S. Goss, M.C., I.M.S., Officer-in-charge, Medical Store Depot, Lahore, is appointed to officiate as Assistant Director-General, Indian Medical Service (Stores), *vice* Lieutenant-Colonel Lapsley, with effect from the date on which he assumes charge of his duties. He will be appointed permanently to that post with effect from the 3rd November, 1929.

Major R. L. Vance, I.M.S., an Officiating Agency Surgeon, resumed charge of his appointment as Civil Surgeon, Quetta, with effect from the 15th September, 1929.

Captain H. W. Mulligan, I.M.S., a temporary officer of the Medical Research Department, is posted as supernumerary officer at the Central Research Institute, Kasauli, with effect from the 9th September, 1929, or subsequent date on which he assumes charge of the duties of the appointment.

Major G. Covell, I.M.S., an Officer of the Medical Research Department, is placed on foreign service under the Indian Research Fund Association for employment as Assistant Director, Malaria Survey of India, with effect from the 9th September, 1929, or subsequent date on which he assumes charge of the duties of the appointment.

The services of Major M. A. Singh, I.M.S., are placed at the disposal of the Government of Bengal for employment in the Bengal Jail Department, with effect from the 6th August, 1929.

PROMOTIONS.

Brevet-Colonel to be Colonel.

W. H. Leonard, F.R.C.S., K.H.P., I.M.S., dated 10th June, 1929, *vice* Colonel A. Spitteler, O.B.E., M.B., I.M.S., retired.

The promotion to his present rank of Major A. N. Palit, F.R.C.S.E., I.M.S., as published in Army Department Notification No. 225, dated the 10th February, 1922, is antedated from "29th January, 1922" to "29th July, 1921."

The promotion to his present rank of Major Monindra-nath Das, M.C., M.B., I.M.S., as notified in Army Department Notification No. 236, dated the 5th March, 1926, is antedated from "31st January, 1926" to "31st July, 1925."

The promotion to his present rank of Major J. H. Smith, M.B., I.M.S., as published in Army Department Notification No. 1065, dated the 20th August, 1926, is

antedated from the 1st August, 1926 to the 1st February, 1926.

The promotion to his present rank of Major A. C. Craighead, M.B., I.M.S., as published in Army Department Notification No. 1194, dated the 1st September, 1928, is antedated from the 9th August, 1928 to the 9th February, 1928.

The promotion to his present rank of Major J. Findlay, I.M.S., as published in Army Department Notification No. 1085, dated the 7th August, 1925, is antedated from the 26th July, 1925 to the 26th January, 1925.

Captain to be Major.

Ajab Singh Garewal. Dated 1st October, 1929.

Lieutenants to be Captains.

P. H. Cummins. Dated 26th August, 1929.

I. J. Beausang. Dated 26th August, 1929.

T. C. Ramechandani, M.B., F.R.C.S.E. Dated 12th May, 1929.

LEAVE.

Lieutenant-Colonel J. B. Lapsley, M.C., I.M.S., Assistant Director-General, Indian Medical Service (Stores), is granted leave on average pay for 3 months under Fundamental Rules, combined with leave for 9 months under Military Furlough Rules, with effect from the 1st October, 1929, or date of relief.

Lieutenant-Colonel N. M. Wilson, O.B.E., I.M.S., Civil Surgeon, Simla West, is granted leave on average pay for 3 months and 22 days, with effect from the 7th November, 1929, and his services are replaced at the disposal of the Government of the Punjab from the 1st March, 1930.

Lieutenant-Colonel W. D. Wright, I.M.S., Civil Surgeon, Allahabad, leave for 2 years and 2 months, preparatory to retirement, with effect from the 18th October, 1929, or date of availing.

Lieutenant-Colonel B. E. M. Newland, I.M.S., Civil Surgeon (on leave), leave for 1 month in extension of the leave already sanctioned.

Major F. R. Thornton, I.M.S., Civil Surgeon, Coorg, is granted leave on average pay for 20 days, with effect from the 4th December, 1929.

RETIREMENTS.

The undermentioned officers are permitted to retire from the service, subject to His Majesty's approval:—

Major-General Sir Walter H. Ogilvie, K.B.E., C.B., C.M.G., M.B., K.H.P., I.M.S., dated 2nd September, 1929.

Lieutenant-Colonel H. M. H. Melhuish, D.S.O., I.M.S., with effect from the 3rd September, 1929.

Lieutenant-Colonel John Norman Walker. Dated 29th August, 1929.

MISCELLANEOUS.

The following extract from the *London Gazette*, dated the 6th September, 1929, is published for general information.

India Office,

6th September, 1929.

GEORGE R. I.

WHEREAS we deem it expedient to consolidate and amend the rules for the promotion and precedence of Our Indian Medical Service contained in Our Warrant of 28th May, 1913, and in such other Warrants granted since that date as are still in force.

Our Will and Pleasure is that from and after this date the following rules shall be established:

It is also Our Will and Pleasure that this Our Warrant shall be administered and interpreted by Our Secretary of State for India in Council, who shall be the sole and standing authority upon the matters herein contained.

1. The substantive ranks of Medical Officers in Our Indian Military Forces shall be as follows:—

Major-General.

Colonel.

Lieutenant-Colonel.

Major.

Captain.

Lieutenant.

The Director-General of Our Indian Medical Service shall hold the substantive rank of Major-General, or, when approved by Our Secretary of State for India in Council, the substantive rank of Lieutenant-General.

2. An Officer will not be permitted to remain in the Service if at any time during the first three years from the date of his first commission his retention therein is, in the opinion of Our Secretary of State for India in Council, undesirable.

3. Except as otherwise herein provided, a Lieutenant shall be eligible for promotion to the rank of Captain on completing three years' full pay service, if he has previously passed such examinations as may be prescribed by Our Secretary of State for India in Council, and is in all other respects qualified and recommended. An Officer who has not passed the prescribed examinations may be provisionally promoted, if, in the opinion of Our Governor-General of India in Council, he has not had a reasonable opportunity of passing. Such provisional promotion may be cancelled as soon as he has had such opportunity and has not passed.

4. Except as otherwise herein provided, a Captain shall be eligible, if in all respects qualified and recommended, for promotion to the rank of Major on completing nine years' full pay service in the rank of Captain. This period may be reduced by six months in the case of an officer who produces satisfactory evidence of progress in any branch of knowledge which is likely to increase his efficiency. A Captain who may be prevented by exigencies of the Service from obtaining an opportunity of qualifying for such accelerated promotion shall have the concession open to him for a period of four years after his promotion to the rank of Major in ordinary course, but any antedate of promotion which may be granted shall be without adjustment of pay.

5. Except as otherwise herein provided, a Major shall be eligible, if in all respects qualified and recommended, for promotion to the rank of Lieutenant-Colonel on completing eight years' full pay service in the rank of Major, including any period covered by antedated promotion without adjustment of pay.

6. Time on half-pay, not exceeding one year, shall be allowed to reckon as service for promotion under Articles 3, 4 and 5 if removal to half-pay has been in consequence of medical unfitness caused by duty, military or civil. An officer shall not by reason of any promotion during the late war be eligible for promotion to the rank of Major/Lieutenant-Colonel under 12/20 years' service from the date of first commission (or 11½/19½ years from the date of first commission if he is entitled to the reduction of six months specified in Article 4), except that an officer appointed as the result of the competitive examination of July 1915 may be promoted to the rank of Major/Lieutenant-Colonel at such date before he has completed 12/20 years' service as may be required to avoid his supersession (otherwise than through the reduction of six months in the circumstances specified in Article 4) by an officer entering the service by nomination during the war.

7. A Captain after at least six years' service, a Major or Lieutenant-Colonel may be promoted to the next higher rank by brevet for distinguished service in the field or for meritorious or distinguished service of an exceptional nature other than in the field.

8. A certain number of Lieutenant-Colonels may be specially selected for increased pay for ability and merit.

9. Promotion from the rank of Lieutenant-Colonel to that of Colonel and promotion to the rank of Major-General, shall be given by selection for ability and merit, and the grounds of such selection shall be stated to Us in writing, and recorded in the Office of Our Secretary of State for India.

10. A Lieutenant-Colonel may also be promoted to the rank of Colonel, and a Colonel to the rank of Major-General, for distinguished service in the field. In any such case the Officer shall remain supernumerary in the higher rank until the vacancy to which, in the ordinary course, he would have been promoted, or, in the case of an officer promoted to the rank of Colonel, until selection for the rank of Major-General.

11. Exchange between officers of Our Indian Medical Service and officers of Our Royal Army Medical Corps,

being of the same rank and below the rank of Major, and transfers of officers below the rank of Major from either of the abovementioned Service to the other, shall be permitted with the approval of Our Army Council and of Our Secretary of State for India in Council, and on the following conditions:—

(1) That the officers have less than seven years' service.

(2) That in the case of Captains, their seniority for the purpose of exchange shall be determined as if they had been promoted after the period of service required for promotion to that rank in the Service into which they exchange, but that any alteration of date of rank made in pursuance of this provision shall be without adjustment of pay.

(3) Subject to (2) that the senior officer exchanging takes the place of the junior on the list to which he exchanges, and shall not be promoted until the officer next above him has been promoted, or has been refused promotion in consequence of failure to qualify for it.

(4) Subject to (2) that the junior officer exchanging is placed for seniority next below all officers on the list to which he exchanges whose commissions have the same date as his own.

(5) That the officer transferred is placed for seniority below all officers holding the same rank at the time of his transfer, and shall not be promoted until the officer next above him has been promoted or has been refused promotion in consequence of failure to qualify for it.

12. With a view to maintaining the efficiency of the Service, Medical Officers shall be placed on the Retired List when they attain the following ages:—

Director-General, 60.

Director of Medical Services in India if an Officer of Our Indian Medical Service, 60.

Major-General, 60.

Colonel, 57.

Brevet-Colonel, 57.

Lieutenant-Colonel, 55.

Major, 55.

But a Lieutenant-Colonel who entered the Service before the 1st April, 1911, and who has been specially selected for increased pay under Article 8 may, if he attains the age of 55 years before he completes 27 years' service for pension be retained until completion of such service.

13. An officer appointed after the 11th September, 1890, who may retire on pension before completing 30 years' service, shall be liable, till he completes 55 years of age, to be recalled to duty in case of emergency.

14. Six of the most meritorious officers of Our Indian Medical Service on the Active List shall be named Our Honorary Physicians and six Our Honorary Surgeons, and they shall relinquish such appointment on retirement. On appointment as one of Our Honorary Physicians or Honorary Surgeons an officer under the rank of Colonel in Our Indian Medical Service may be promoted to the brevet rank of Colonel.

Given at Our Court at *St. James'* this 7th day of August, 1929, in the Twentieth Year of Our Reign.

By His Majesty's Command,
WEDGWOOD BENN.

NOTES.

INGRAM'S RUBBER PRODUCTS.

RUBBER GOODS are especially liable to deteriorate in the climate of India, and it is therefore essential that supplies of such materials should be purchased from unimpeachable sources. One of the best known and reliable British firms in this connection is J. G. Ingram & Son, Ltd., the London India Rubber Works, Hackney Wick, London, E. 9, established in 1847. We have recently received from them a series of small brochures which they publish, and which will be of interest to our readers.

One deals with the "Agrippa" teat for feeding bottles; this has a reinforced band of rubber at its base which effectually prevents the teat from slipping off the bottle; it is also claimed that it will withstand sterilizing by boiling indefinitely. The "Eclipse" hot water bottle is designed on a new principle, so as to make leakage from the neck impossible. Special lines of air cushions and seamless household red rubber gloves are also described in the same booklet.

A second booklet gives an illustrated list of the products manufactured by the firm, including seamless enema syringes; ear, nose and urethral syringes, etc. The firm also issues from time to time a small journal entitled *Rubber Notes*, which contains much interesting information.

The Indian agents are Messrs. N. Powell & Co., Lamington Road, Bombay.

HEWLETT'S SODIO-CALCII LACTAS TABLETS.

THE firm of Messrs. C. J. Hewlett & Son have so world-wide and established a reputation that any new preparation placed upon the market by them is of interest. One of their recent and most interesting preparations is a tablet containing $7\frac{1}{2}$ grains of sodium-calcium lactate, flavoured and sweetened, so as to be readily taken by children and invalids. This preparation should be of special value for weakly children and as an aid to infants during dentition. For infants the tablets may be crushed and administered in milk.

A modification of this tablet is Hewlett's Tablet Sodio-Calcii Lactas cum Parathyroid. Each tablet contains $2\frac{1}{2}$ grains of sodium-calcium lactate with $1/20$ th grain of parathyroid. These tablets have been found of value in the treatment of hæmorrhage in pulmonary tuberculosis, in surgical tuberculosis, and in backward, weakly and ricketty children. Although the manufacturers do not mention the point, it is also obvious that such a prescription is eminently suitable for the calcium-parathyroid treatment which is so often extremely successful in the treatment of sprue. The preparation is one which will certainly be of interest to our readers.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers, relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India, Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

“THE INDIAN MEDICAL GAZETTE”

ORIGINAL ARTICLES:—

	<i>Page</i>
A Preliminary Note on the Action and Uses of Pseudo-ephedrine. By R. N. Chopra, M.A., M.D. (Cantab.), Lieutenant-Colonel, I.M.S., B. B. Dikshit, M.B., B.S., D.P.H., and K. Venkatachalam Pillai, L.M. & S. (Mad.)	1
The Continuous Administration of Saline per Rectum. By A. H. Proctor, M.D., M.S., F.R.C.S.E., Lieutenant-Colonel, I.M.S.	4
Cæsarean Section. Some Types and Their Uses. By S. A. McSwincy, B.A., M.B., B.Ch., F.R.C.S.I., Major, I.M.S.	5
Seven Cases of Diaphysial Aclasis (Multiple Exostosis) in Indians, Including Four Cases from One Family. By H. Stott, M.D., M.R.C.P., D.P.H., Lieutenant-Colonel, I.M.S., and Raghunandan Lall, M.B., B.S.	9
A New Test for Albumin in Urine. By Chunilal Bose, C.I.E., I.S.O., M.B., F.C.S.	17
Report on the Investigation of an Outbreak of Epidemic Dropsy in Rangoon in the Year 1924. By K. R. Dalal, L.M. & S. (Bom.), D.T.M., D.P.H. (Liverpool)	19
Homogentisuria (Alkaptonuria) with Glycosuria. With Notes on a Detailed Clinical and Chemical Investigation of a Case. By J. P. Bose, M.B., F.C.S. (Lond.), and Sudhamoy Ghosh, D.Sc., F.R.S.E.	61
The Spread of Dysentery in a Khasi Village and its Treatment with Bacteriophage. By B. K. Pal Choudhury, B.Sc., M.B., and Lieutenant-Colonel J. Morison, I.M.S.	66
Berberine in the Treatment of Oriental Sore. By B. M. Das Gupta, and B. B. Dikshit, M.B., B.S., D.P.H.	67
Terminalia Arjuna: Its Chemistry, Pharmacology and Therapeutic Action. By Lieutenant-Colonel R. N. Chopra, M.A., M.D. (Cantab.), and Sudhamoy Ghosh, D.Sc., F.R.S.E.	70
A Preliminary Note on the Action of Vasopressin and Oxytocin. By J. Christodoss David, M.B., B.S., and C. Vareed, M.B., B.S.	73
The History of Tick-Bites in Cases of Tick-Typhus in India. By S. Sundar Rao	76
Intravenous Calcium Therapy. By S. Rama Iyer, L.M. & S. (Mad.), V.H.A.S.	77

ORIGINAL ARTICLES—(Continued).

	Page
Some Sources of Vitamin C in India. By Captain R. C. Wats, M.D. (L'pool), D.P.H., D.T.M., I.M.S.	79
Blood Tests in Relation to Blood Transfusion. By R. B. Lloyd, M.A., M.B., B.Ch., Lieutenant-Colonel, I.M.S.	121
Gastric Syphilis. By E. W. C. Bradfield, C.I.E., M.S., F.R.C.S., Lieutenant-Colonel, I.M.S., and A. Vasudevan, M.B., B.S.	125
On the Determination of Age in Indians, from a Study of the Ossification of the Epiphyses of the Long Bones. By S. M. Hepworth, M.B., D.M.R.E., Major, I.M.S.	128
Radiology in the Diagnosis of Chronic Appendicitis. By J. H. Barrett, Captain, I.M.S.	129
Studies in the Treatment of Filariasis. By R. N. Chopra, M.A., M.D. (Cantab.), Lieutenant-Colonel, I.M.S., and S. Sundar Rao	130
Berberine Sulphate in Oriental Sore. By A. Lakshmi Devi, M.B., B.S. (Punjab)	139
On the Anopheline Mosquitoes of Hazaribagh (Bihar and Orissa). By Bhudeb Chandra Basu, M.Sc.	141
The Fate of the Merozoites seen in the Cultures of Malarial Parasites. By R. Row, M.D. (Lond.), D.Sc. (Lond.), O.B.E.	142
The Response of a Group of Indian Infants and Children to the Schick Test. A Preliminary Report of 186 Tests. By V. C. Rambo, M.D.	145
On a Recent Outbreak of Epidemic Dropsy in the District of Birbhum. By Kali Gati Banerjee, M.B.	181
Epidemic Dropsy in Birbhum. By U. Ghosh, M.B. (Cal.), D.P.H., D.T.M. (Bengal)	182
Indian Dietaries in the United Provinces. By Niant Dhan Banerjee	183
Detachment of the Retina. By M. D. Anklesaria, D.O.M.S. (Eng.), F.C.P.S. (Bom.), M.R.C.S. (Eng.), L.R.C.P. (Lond.)	186
A Note on <i>Spirillum minus</i> (Carter), the Causative Organism of Rat-bite Fever. By M. J. Parmanand, M.D. (Bom.)	190
An Improvised Drop Regulator. By R. L. Spittel, F.R.C.S.	192
Analysis of a Hundred Cases of Cataract Extraction at the Raipur Main Hospital by Smith's Method with a Flap of Conjunctiva. By H. B. D. Nanhorya, M.B., B.S.	193
Causes of Blindness. By G. Joseph Guanadikam	194
A Modified Sippy's Line of Treatment in Duodenal Ulcer. By B. G. Vad, M.D., and N. W. Kulkarni, M.B., B.S.	196
A Note on the Anophelines Found in Baroda Camp. By W. J. Webster, M.C., Major, I.M.S.	197
Plasmoquin in Pregnancy. By K. V. Thakkar, L.M. & S. (Bom.)	198
A Vaccine for the Treatment of Phthisical Patients Who Expectorate Tubercle Bacilli in the Sputum. By S. Mallannah, M.D., D.P.H.	198
A Suggestion for Improvement in the Dietary of the Indian Community to Secure a Higher Degree of Health and Efficiency. By A. Mallannah, M.D., D.P.H.	199
Tattooing of the Cornea with Platinum Chloride Solution for Leucoma. By B. P. Banerji, F.R.C.S.I.	201
Breath Sucker Snakes. By Kidar Nath Dutt, L.S.M.F.	201
"Cooly Itch." A purulent folliculitis due to the <i>Trichophyton violaceum</i> variety <i>Indicum</i> . By Hugh W. Acton, Lieutenant-Colonel, I.M.S., and C. McGuire, D.T.M.	241
A Note on the Value of Medicinal Treatment in Cholera. By Dr. J. Walker Tomb, M.A., M.D., D.P.H., O.B.E.	246
Notes on the Value of the Sedimentation Test in the Treatment of Leprosy. By Mrs. Isabel Kerr, M.B., Ch.B.	247

ORIGINAL ARTICLES—(Continued).

Page

Notes for Staff Engaged on Anti-Malarial Work. By W. D. Speedy, M.B., B.Ch. (T.C.D.)	249
A Note on the Anopheline Fauna of a Small Tank Throughout the Year. By E. S. Feegrade, I.M.D.	251
Experiments with Isotex as a Larvicide. By E. S. Feegrade, I.M.D.	252
A Simple Method for the Estimation of Blood Urea Applicable at the Bedside. By Harendra Nath Mukherjee, B.Sc., M.B., D.I.C. (Lond.)	252
Results of Experiments with Crude Oil Products of the Burma Oil Co., Ltd., Rangoon. By E. S. Feegrade, I.M.D.	255
The Use of Pneumococcus Immunogen Combined in the Treatment of Pneumonia. By G. B. Bhaduri, M.B.	301
The Treatment of Vesico-Vaginal Fistula by Rectal Transplantation of the Ureters. By J. C. Fraser, Lieutenant-Colonel, I.M.S.	301
Malignant Anæmia of the Tropics. By F. P. Mackie, K.H.S., Brevet-Colonel, I.M.S.	305
A Review of Malaria during 1928 in a Minor Hill Station in the Punjab. By G. M. Irvine, Captain, I.M.S.	307
Observations on the Potency of Indian Digitalis. By R. N. Chopra, M.A., M.D. (Cantab.), Lieutenant-Colonel, I.M.S., and Premankur De, B.Sc., M.B. (Cal.), M.R.C.P. (Edin.)	312
The Intensive Treatment of Kala-azar by Neostibosan; Part II. By L. Everard Napier, M.R.C.S., L.R.C.P. and M. N. Mullick, M.B. (Cal.)	314
Leprosy in Manipur State. By G. G. Crozier	315
On the Rationale of Treatment of Carcinoma of the Cervix Uteri. By Subodh Mitra, M.D. (Berlin), M.B. (Cal.), F.R.C.S. (Edin.)	316
A Year's Record of Kata-Thermometer Readings at Rangoon. By G. G. Jolly, C.I.E., Lieutenant-Colonel, I.M.S., and V. W. Fenn, L.M.F. (Bengal)	319
Kala-azar in Bijpur. By M. Umar, P.M.S.	322
The Carnivorous Habits of Indian "Blood-Worms." By S. Mukerji, M.Sc.	323
Dangerous Blood Donors. By R. B. Lloyd, M.A., M.B., B.Ch. (Camb.), Lieutenant-Colonel, I.M.S., and S. N. Chandra, M.B.	361
Encephalitis Lethargica—A Brief Description of the Disease, with Short Notes on the Post-Encephalitic Lethargic Cases Treated at the Ranchi Indian Mental Hospital. By J. E. Dhunjibhoy, Major, I.M.S.	362
The Species Distribution of Hookworms in India. By P. A. Maplestone, D.S.O., M.B., Ch.B., D.T.M.	371
The Valuation of Charas. By D. N. Chatterji, B.A., B.Sc., A.I.C., and M. B. Roy, B.Sc.	373
Radiological Examination of the Liver in Cases of Suspected Amoebic Abscess. By J. H. Barrett, D.R.M.E., Captain, I.M.S.	375
Paris Green as an Anopheline Larvicide. By S. N. Sur, M.B., D.P.H. (Lond.), D.T.M. (Liverpool), and Haripada Sarkar, L.M.S., D.P.H. (Cal.)	376
Simple Tests for Stock Solutions of Quinine and Potassium Iodide. By J. W. D. Megaw, Colonel, I.M.S. and Herbert Hawley, M.Sc., F.I.C.	378
Myiasis in Lepers. By G. R. Rao, D.M.C. (Madras), D.T.M. (Bengal)	380
A Preliminary Note on a Colour Reaction for "693" and its Application in the Estimation of that Compound in the Urine. By T. C. Boyd, F.R.C.S.I., D.P.H., F.I.C., Lieutenant-Colonel, I.M.S. and A. C. Roy, M.Sc.	382
The Importance of Secondary Infections in the Causation of Filarial Lymphangitis. By H. W. Acton, Lieutenant-Colonel, I.M.S., and S. Sundar Rao, L.M.P.	421
Tetrachlorethylene in the Treatment of Hookworm Disease. By P. A. Maplestone, D.S.O., M.B., Ch.B., D.T.M., and A. K. Mukerji, M.B.	424
The Use of Fibrolysin in Leprosy. By Norbert Figueredo, M.B., B.S.	426
The Superimposed Blood Agar Slope. By S. N. Goré, L.M. & S. (Bom. Univ.)	429

ORIGINAL ARTICLES—(*Continued*).

Page

Avertin Rectal Narcosis. By A. R. Poduval, B.A., M.D., C.M.	432
An Analysis of 675 Cases of Puerperal Morbidity Treated in the Rotunda Hospital, Dublin. By P. C. Dutta, M.B. (Cal.), F.R.C.S. (Edin.), D.G.O., (Dub.), Lieutenant, I.M.S.	435
Leprous Reaction. By John Lowe, M.B., Ch.B.	438
Perthe's Disease. By Nisanath Ghosh, M.B.	441
Isolation of the Antineuritic Vitamin. By Ashutosh Mukherji	443
Unusual Displacements of the Epiphysis of the Patella. By J. H. Barrett, D.M.R.E., Captain, I.M.S.	445
Kurchi Bismuthous Iodide, its Value in the Treatment of Chronic Amœbic Infections of the Bowel. By Hugh W. Acton, and R. N. Chopra	481
The Erythrocyte Sedimentation Test in Leprosy. By E. Muir	488
A Note on Cholera in Infants. By J. Das Gupta	489
The Effect of Tetronal on the Production of Hamatoporphyrin in the Urine. By Frederick G. Germuth	491
Goitre in Multan District. By J. R. Chaudhuri	492
A List of the Species of Mosquitoes Collected in the French Settlements in India. By the late Dr. E. Borel and Major V. G. F. Labernadie	495
Records of Anophelines from the Bengal Dooars. By Bhupendra Mohan Khan	496
A Comparative Study of the Effect of Climate and of the Seasons on Body Weight in Pulmonary Tuberculosis in Different Countries. By M. Kesava Pai	496
The Treatment of Seasickness. By A. Saha	498
Observations on the Excretion of Alcohol in the Cerebro-Spinal Fluid and Urine after Oral Administration. By B. G. Vadl. and N. W. Kulkarni	500
Local Anæsthesia by Apothermine in General Surgery. By A. B. Banerjee	501
Some Cases of Bacillus Coli Bacilluria. By C. H. Reinhold, F.R.C.S. (Edin.), Lieutenant-Colonel, I.M.S. and L. A. N. Greenway, M.R.C.S., L.R.C.P.	503
Notes on the New Conceptions of Sciatic Pain and on its Treatment. By J. B. Hance, O.B.E., M.A., M.D. (Cantab.), F.R.C.S.E., Major, I.M.S., N. C. Mody, M.B., B.S., and Shiva Datta Ujwal, L.M.P. (C. P.)	541
Webster's Operation for Entropion of the Upper Lid. By R. E. Wright, C.I.E., M.D., Lieutenant-Colonel, I.M.S.	549
Maternal Mortality in India: A Preliminary Study. By Captain N. R. Ubhaya, L.R.C.P. & S., D.P.H., and R. Adiseshan, B.Sc., Dip. Hyg. (Camb.)	550
Microscopic Diagnosis of Malaria on a Group of Tea Estates. By R. A. Murphy, L.R.C.P. & S.I.	557
A Malaria Survey of Madarihat and its Environs. By S. N. Sur, M.B. (Cal.), D.P.H. (Lond.), D.T.M. (Liverpool), and Banamali Ghosh, M.B. (Cal.), D.P.H. (Cal.)	558
Pathological Laughing and Crying. By J. Norman Pacheco, M.R.C.S., L.R.C.P.	561
Chaulmoogra Oil in the Treatment of Trachoma. By R. Gubbay	563
Chemotherapeutic Investigations with Antimony Preparations in the Experimental Kala-azar of the Hamster. By the late Wilhelm Roehl, M.D.	563
A Coat Effect Observed in Mice when Fed with Fats under Certain Conditions. (A Preliminary Note). By T. C. Boyd, F.R.C.S.I., D.P.H., F.I.C., Lieutenant-Colonel, I.M.S., and A. C. Roy, M.Sc.	564
Nervous Manifestations in Tuberculous Infections. By P. V. Gharpure, M.D. (Bom.)	565
X-Ray Work in Baluchistan. The New X-Ray and Electrotherapy Department of the C. M. S. Hospital, Quetta. By J. H. Barrett, D.M.R.E., Captain, I.M.S.	566

ORIGINAL ARTICLES—(Continued).

Page

"Kataphylaxia," a Phenomenon seen Clinically in Filariasis. By H. W. Acton, Lieutenant-Colonel, I.M.S., and S. Sundar Rao, L.M.P.	601
A Case of Human Infection with a Gnathostome in India. By P. A. Maplestone, D.S.O., M.B., Ch.B., D.T.M.	610
Notes on the Detection in the Urine of Some Drugs Used for the Treatment of Malaria. By Richard Green, M.B., B.S.	614
The Value of Preventive Inoculation against Cholera. By G. Jolly, C.I.E., Lieutenant-Colonel, I.M.S., J. J. G. Da Costa, L.M.S., and Ah. Shoung, M.M.F.	618
Epidemic Jaundice (Weil's Disease) or Malaria in Kandi Subdivision of Marshidabad District in 1928. By S. N. Sur, M.B., D.P.H., D.T.M., and Haripada Sarkar, L.M.S., D.P.H.	619
The Infectiousness of Leprosy. By E. Muir, M.D., F.R.C.S. (Edin.)	620
Observations on a Series of Bacteriological Examinations of Tube Well Water in Rangoon. By Military Assistant Surgeon G. Mackey, D.T.M., I.M.D., and G. G. Jolly, C.I.E., M.B., Ch.B., D.P.H., D.T.M. & H., Lieutenant-Colonel, I.M.S.	624
Plasmochin Compositum in the Treatment of Malaria. By P. V. Karamchandani, Captain, I.M.S.	626
A Record of Malarial Cases in the Bengal-Nagpur Railway Construction Hospital, Titlagarh, from July 1928 to August 1929, with some Observations on Mosquito Findings and Conditions of Transmission. By W. D. Speedy, M.B., B.Ch. (Dnb. Univ.), and A. K. Adhikari, M.B.	629
The Significance of the Antimony Test in the Diagnosis of Kala-azar. By R. N. Chopra, M.A., M.D. (Cantab.), Lieutenant-Colonel, I.M.S., and N. N. De, M.B. (Cal.)	661
Notes on "The Significance of the Antimony Test in the Diagnosis of Kala-azar." By L. Everard Napier, M.R.C.S., L.R.C.P.	669
T. A. B. Vaccine in Relation to an Outbreak of Enteric Fevers. By M. K. Afridi, M.B., Ch.B. (St. And.), D.T.M. & H. (Lond.), Captain, I.M.S.	670
A Simple Method of Standardizing the Red Cell Suspension in Connection with the Wassermann Reaction. By S. D. S. Greval, B.Sc., M.D., D.P.H., Captain, I.M.S.	673
An Inquiry into the Physical Conditions of Indian Labour. By Dr. P. V. Gharpuré, M.D. (Bom.), and S. G. Latey, B.Com. (Bom.)	673
A Further Note on the Treatment of Vesico-Vaginal Fistula by Rectal Transplantation of the Ureters. By F. C. Fraser, Lieutenant-Colonel, I.M.S.	677
A Note on Museum Making. By Dr. P. V. Gharpuré, M.D. (Bom.)	678
Dysentery in the Central Jail, Rajamandry, Madras Presidency. By Sub-Assistant Surgeon Ch. Krishnamurthy, L.M.P.	679
Notes on Malaria in the Sibsagar District, Assam. By Assistant Surgeon J. M. Sen Gupta, M.B., D.T.M. (Bengal)	681
Notes on the Use of Carbon Tetrachloride. By S. C. Nag	683
Malaria Therapy in Tabes Dorsalis. By B. G. Vad, M.D., and N. W. Kulkarni, M.D.	684
The Indications for Suprapubic Cystotomy. By A. N. Ghose	687
A Note on the Action of Synthetic Adrenaline. By A. S. Paranjpe, M.B., Ch.B. (Edin.), M.D. (Heidelberg), D.T.M. (Lond.)	688
Wertheim Schanta's Interposition Operation for Complete Prolapse of the Uterus. By Captain D. H. Variava	689
The Successful Use of a Tuberculous Methylic Antigen in External Tuberculosis. By Major V. Labernadie, M.D., M.S.P.E. (Paris), and Medical Officer Andre Zeganadin, M.S.M.H.T. (Paris)	691

An Interesting Case. By T. S. Dakshinamurthi, L.M.S.	21
Post Encephalitic Parkinsonism. By F. Noronha, M.B., C.M., D.P.M. (Eng.)	21
A Case of Amyotrophic Lateral Sclerosis in an East Indian. By V. C. Rambo, M.D.	22
Nerve Abscess in Leprosy. By John Lowe, M.B., Ch.B.	24
An Interesting Case of Melæna and Hæmatemesis in a Newly-born Baby. By S. C. Sen Gupta, L.M.F.	25
A Case of Acholuric Jaundice. By M. L. Kamath and P. Kutumbiah	26
A Case of Foreign Body in the Vagina. By Binode Krishna Banerji, M.B.	26
Two Cases of Surgical Interest. By Captain Mohd. Ajmal Husain, M.B., B.S., P.C.M.S.	85
Musculo-Spiral Nerve Paralysis Following an Intramuscular Injection of Quinine. By T. Seshachalam, M.R.C.S., L.R.C.P.	86
A Case of Hysteria (Narcolepsy?). By M. L. Kamath, B.A., M.D., and P. Kutumbiah, B.A., M.B., B.S.	87
An Undescended Testicle in an Unusual Position. By Francis Christian, M.R.C.S., L.R.C.P., L.M.	87
Occurrence of Chyluria after Confinement. By S. Sundar Rao	87
A Case of Syphilitic Basal Meningitis. By Lieutenant M. N. Pai, I.M.S. (T. C.)	89
A Case of Cephalic Tetanus. By Harendra Nath Bagchi, M.B. (Cal.)	89
Alastrim or Small-Pox? By S. C. Nag	90
A Case of Post-Kala-azar Dermal Leishmaniasis. By Nepal Chandra Dey	147
A Heart Case—for Diagnosis. By Provat Chandra Bagchi, L.M.F.	148
A Case of Bleeding from the Breast. By D. N. Sinha, M.B., and R. K. Mukherjee, S.A.S.	149
A Case of Unusually Large Cystic Goitre. By G. M. Irvine, Captain, I.M.S.	149
Congenital Deficiency of Two Fingers and their Metacarpal Bones. By Jamal-ud-din, Major, I.M.S.	150
An Interesting Case of Recurrent Pregnancy Toxæmia. By Sudhir Chandra Bose, B.Sc., M.B.	202
An Unusual Complication of Kala-azar. By Nishanath Ghosh, M.B.	205
A Case of Ivory-Grafting. By S. C. Das Gupta, L.M.S.	205
Notes on a Case of <i>Bacillus coli</i> Septicæmia. By A Bayley De Castro, Lieutenant, I.M.D.	206
An Interesting Early Right-Sided Goitre. By A. Bayley De Castro, Lieutenant, I.M.D.	207
Apyrexial Pneumonia. By U. A. Krishna Iyer	207
An Interesting Case of "Chorea." By S. B. Imam	208
A Case of Inguinal Hernia with a Fæcal Tumour in the Scrotum. By D. N. Ghose, M.B., B.S., and A. K. Mitter, M.B., B.S.	208
A Case of Exfoliative Dermatitis after Neosalvarsan Injections. By Indulal S. Dave, M.B., B.S.	209
A Case of a Rubber Catheter inside the Bladder. By A. K. Dutt Gupta, M.B., D.T.M.	210
A Case of Medico-Legal Interest. By M. Umar	255
A Case of Valvulus of the Large Intestine at the Splenic Flexure. By T. S. Dakshinamurthi, L.M.F.	256
Tiger Bites and their Treatment. By K. G. Khandekar, M.B., B.S.	256
A Further Note on the Action of Hæmoplastin. By Kamakhya Prosad Lahiri, L.M.S.	256
A Huge Ovarian Cyst. By Assistant Surgeon Rai Sahib Dr. Chhagan Nath	257

MIRROR OF HOSPITAL PRACTICE—(Continued).

A Further Case of Diaphysal Aclasis (Multiple Exostosis) with a Marked Family History. By H. Stott, M.D., M.R.C.P., D.P.H., Lieutenant-Colonel, I.M.S., and P. A. Shunandan Lall, M.B., B.S.	258
A Case of Typhoid Fever, Relapse, Toxæmic Collapse and Recovery. By Ch. Krishnamurthy, L.M.P.	259
A Case of Hyperpyrexia for Diagnosis. By C. R. Pereira, M.B., B.S., and J. M. D'Cruz, M.B., B.S.	260
Roundworm Infection Simulating Appendicitis. By B. Sukhavanam, L.M.P.	261
A Case of Suppression of Urine. By B. Sukhavanam, L.M.P.	261
A Case of Acute Ascending (Landry's) Paralysis. By R. Viswanathan, B.A., M.B., B.S.	328
A Case of "Glandular Fever." By F. H. B. Norrie, M.D., Ch.M., F.R.C.S. (Edin.)	328
A Benign Spinal Tumour. By P. McRitchie, M.C., M.D., M.R.C.S., L.R.C.P.	328
Quinine Abscesses. By Captain Mohd. Ajmal Husain, M.B., B.S., P.C.M.S.	330
A Case of Pseudo-Pregnancy. By P. Sharma, M.B., B.S.	330
A Case of Induced Poly-Leucocythæmia. By L. Everard Napier, M.R.C.S. L.R.C.P., and K. C. Haldar, L.M.P.	382
A Case of Free Bile in the Peritoneal Cavity. By A. Hameed Siddiqi, B.Sc., M.B., B.S.	385
A Case of Ectopic Gestation. By Aghore Nath Ghose	385
A Case of Myiasis of a Carious Tooth. By C. Strickland, M.A., M.D.	386
An Obscure Neurological Case Simulating Early Leprosy. By E. Muir, M.D., F.R.C.S. (Edin.), and John M. Henderson, M.B., Ch.B. (Glas.)	386
Acute Amœbic Dysentery Treated by <i>Hedyotes Auriculares</i> , N. O. Rubiaceæ. By Captain P. R. Bhandarkar, L.M. & S.	387
Electro-Coagulation (Surgical Diathermy) in Multiple Angiomata of the Head. By P. P. Lalvani, L.C.P.S. (Bom.)	387
Three Cases of Combined Leprosy and Dermal Leishmaniasis. By L. E. Napier, M.R.C.S. (Lond.), L.R.C.P. (Eng.), and J. M. Henderson, M.B., Ch.B. (Glas.)	446
Tabes Dorsalis in an Indian. By Mohammad Yusuf	448
Unusual Intra-Uterine Tumours. By D. L. Hari, M.B., B.S. (Bom.)	449
A Distended Bladder Simulating a Full-Term Uterus. By Captain C. C. Das Gupta, M.B.	450
A Case of Elephantiasis Cured by Arrhenol. By Md. Abdul Quiyum, L.M.P.	450
Retention of Urine in Blackwater Fever. By S. C. Nag	505
A Case of Accidental Poisoning with Barium Sulphide. By Bhupal Singh	506
Cerebral Symptoms Caused by <i>Plasmodium vivax</i> . By C. R. Das Gupta	507
Temporary Insanity Following an Attack of Malaria. By S. C. Sen Gupta	507
A Case of Staphylococcal Septicæmia. By Harendra Nath Bagchi	508
A Case for Diagnosis. By Prafulla Kumar Bachaspati	508
Notes on a Case of Human Hermaphrodite. By M. C. Albuquerque and T. Seshachalam	509
A Case of Abscess of the Iris. By Jadavji Hansraj	510
A Case of Diverticulum of the Oesophagus. By C. D. Torpy	511
A Case of Variola Treated by Vaccination. By C. D. Chatterji, B.Sc., M.B., B.S.	569
A Case of Abscess of the Brain. By Suresh Chandra Das Gupta, L.M.S.	569
A Case of Accidental Suffocation in a Well. By J. F. Henriques, L.M. & S. F.C.P.S., B.M.S.	570
A Case of Rat-bite Fever. By M. A. Krishna Iyer	571
Ascariasis Simulating Abdominal Tumours. By J. F. Henriques, L.M. & S., F.C.P.S., B.M.S.	571

MIRROR OF HOSPITAL PRACTICE—(Continued).
